1. — *Importing countries.* — *United States.* This country is the world's greatest consumer of bananas. During the fiscal year ending June 30, 1913, $ 28 657 084 worth of fruit were imported, more than half of which consisted of bananas. The latter were imported chiefly from the regions bordering the Caribbean Sea, as shown in the following table :

Imports of Bananas to the United States, 1912-13.

	No. of bunches	Value
		$
Jamaica	11 163 269	3 488 498
Honduras	7 983 591	2 435 006
Costa Rica	6 973 684	2 744 813
Panama	4 438 300	2 082 502
Guatemala	2 359 250	600 041
Columbia	2 684 749	1 107 429
Cuba	2 213 733	834 206
Nicaragua	1 681 944	348 064
Mexico	1 541 504	412 315
British Honduras	651 054	163 249
S. Domingo	475 500	222 626
Guiana	184 498	39 932
Grenada	4 398	4 111
Other regions of the West Indies	1 625	466
Total	42 357 109	14 484 258

Half of the bananas imported to the United States enter through the port of New Orleans, which receives more bananas than any other port in the world and possesses special facilities for landing the fruits.

The value of the bananas imported to *Europe* is almost equal to that of the United States, but the quantity is only about one-third. England, France and Germany are the most important consumers in Europe.

England is second to the United States in imports of bananas, which are increasing rapidly.

	No. of bunches	Value $
1900	1 287 000	2 740 000
1912	6 978 876	9 587 000

Germany imports 35 226 000 kg., valued at $2 525 000, while *France* received 21 749 000 kg., valued at $1 219 000.

II. *Exporting Countries.*— *Jamaica* comes first in the exportation of bananas:

1911	16 947 385 bunches
1912	13 382 072 »

The decrease in 1912 is attributed to accidental causes.

Costa Rica comes second, with an export of 10 647 000 bunches, and shows an increasing production.

Honduras is rapidly increasing her exports to the United States, and *Panama* has doubled her exports during the last ten years.

The *Canary Is.*, which were formerly the chief exporters to Europe, maintain their exports at about 2 723 000 bunches.

533 – ***Citropsis*, a New Tropical African Genus allied to *Citrus*.** — SWINGLE, WALTER and KELLERMAN, MAUDE in *Journal of Agricultural Research*, Vol. I, No. 5, pp. 420-436 + 7 figs. + 1 plate. Washington, February 1914.

The fruits of *Citropsis* are known as "African cherry oranges"; they are produced in clusters from the axils of the leaves. The writers consider it necessary to establish a new genus to include these African species, and they do this by raising the section *Citropsis* of Engler to generic rank. The following species are described: *C. Preussii* (Engler), *C. Schweinfurthii* (Engler), *C. gabunensis* (Engler) and *C. mirabilis* (Chev.), as well as *C. articulata* (Willd.) which is not well known.

The members of this genus are worthy of the attention of agriculturists, since several of them produce an abundance of delicious fruits. *C. Schweinfurthii* has given good results on poor sandy soils in Florida. It is hoped that the numerous small fruits may be increased in size by hybridization with *Citrus*; successful crosses have already been obtained.

LIVE STOCK AND BREEDING.

HYGIENE

534 – **Research on the Life History of the Large Warble Fly** (1) **and Means of Controlling it.** — LUCET, ADRIEN in *Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences*, Vol. 158, No. 13, pp. 968-970. Paris, March 30, 1914.

The writer communicates further investigations into the life history of the large warble fly. The adult fly lives only until it has mated and deposited its eggs.

In eleven flies, observed by the writer, the average duration of life was from four to five days. During this time the fly does not seem to take food. It does not appear either to travel any distance from the place where it was hatched, flying only in fine, warm weather, and not moving is the mornings, evenings or cool wet weather. The number of eggs which were found in the bodies of four females were : 372, 386, 357 and 343, which is less than the number found by GLÄSER. Recently-laid eggs contained the larvae already clearly formed.

Neither placing adult flies on the neck and back of an ox nor enclosing the ox with some flies in a cage for several days appeared to alarm the animal, from which the writer is led to believe that the gadding of cattle is not caused by warble flies.

The writer also undertook experiments for the control of warbles and obtained very satisfactory results with tincture of iodine prepared according to the pharmacopoea. An injection of 0.5 and 1 cc. of pure or diluted tincture of iodine (Gram solution) practised on the swellings of two oxen had the result of killing all of the 81 larvae they contained. These experiments were to be continued in May in the Département of Ariège.

535 – **Practical Observations on Contagion in Anthrax of Cattle, on the Diminution of Cases by Vaccination and on Uniform Immunization.** — VIASZ, J. in *Allatorvosi Lapok*, XXXVI, No. 30, pp. 355-358. Budapest, 1913.

The writer reports on his results obtained from the dissection of 1200 cattle and from the clinical observation of about 250 diseased ones. Contrary to the generally accepted opinion, according to which the food is credited with being the chief source of contagion, the writer believes that at least 80 per cent. of the cases are due to the drinking water. In support of his opinion he mentions instances of large estates and communes in which only the animals that drank the water from certain sources fell ill and the disease disappeared as soon as these sources were closed. Infection by wounds in the skin is possible, but it is so rare that it can be practically neglected. Where, on the contrary, infected water exists, the disease may attack stall-fed animals also, and exceptionally even buffaloes.

As for the age, it has been observed that in such localities not only steers contract the disease, but also calves immediately after weaning, and this so frequently that they must be regularly vaccinated at that time. In order

(1) See No. 144, *B.* Feb. 1913; No. 251, *B.* March 1914; No. 445, *B.* May 1914.

to avoid cases of sickness due to the inoculation, it is recommended to grind very fine the powdered matter used for vaccinating, as by this means it can be more exactly dosed. Only the matter obtained from the liquid contained in the swellings is suitable for this purpose, as that obtained from the muscles cannot be reduced to a uniform powder.

Observing this method, 5000 head of cattle have been inoculated in the course of eight years without any losses, and only in the ninth year did two deaths occur shortly after inoculation.

For the treatment of diseased animals intravenous injection of hydrogen peroxide, followed by the incision and washing out of the swellings, is recommended. As a prophylactic measure immediately on the outbreak of the disease, a search should be made for infected wells or other sources of water.

536 – **Swine-pox in Young Pigs.** — BÁN, E. in *Állatorvosi Lapok*, Year XXXVI, No. 52, pp. 620-621. Budapest, December 27, 1913.

The existence of swine-pox was until recently considered doubtful. Chauveau, Gerlach and R. Koch had, however, demonstrated that cow-pox can be artificially communicated to pigs, but under natural conditions the disease had hardly ever been observed. In 1906 Száutó proved that pigs, especially sucking ones, sometimes contract the disease and that they communicate it to healthy animals by merely living with them. Since then, from year to year the number of observations has increased and it appears that in many districts of Hungary the disease is fairly frequent, that it attacks some herds every year and that sometimes it causes considerable losses. This is especially true of districts on the right bank of the Danube, where, according to the writer's observations, it is one of the most frequent diseases of sucking pigs. Generally it develops so insidiously that the owner is only aware of its presence when a proportion of the weaned pigs are arrested in their development or some of them die. When the herds are once infected it is very difficut, as with cow-pox, to free them again, even making use of repeated disinfections.

The disease is accompanied by severe itching, which leads to the production of an eczema. The course of the attack is generally mild, but sometimes serious losses occur, mostly through complication with intestinal catarrh or chronic catarrhal pneumonia. In one herd the necrosis of the teats was observed, but it is not certain that this complication was caused directly by the disease. Protective inoculations with cow-pox lymph gave good results in several localities on about 400 young pigs. Small nodosities were formed at the place of inoculation, but otherwise the animals' health was in no wise impaired. In one case, a few pigs developed small pustules on the inner side of the thigh, where they had been inoculated, and after 6 or 8 weeks all the other animals fell ill, but not seriously. It is not impossible that these inoculations, which of late have been more frequently practised, may have contributed to the spread of the disease.

537 – **Causes and Effects of Cryptorchism.** — ZSÁMÁR, GEORGE in *Állatorvosi Lapok*, Year XXXVII, No. 6, pp. 61-64, No. 7, pp. 74-78, No. 8, pp. 90-95. Budapest, February 7, 14, 21, 1914.

With the object of throwing more light on the question of the procreative power or the sterility of cryptorchids, the writer subjected eight testicles which had been retained by monorchid horses to a rigorous histological investigation as to their sperm-producing capacity.

The result of his investfgations can be summarized as follows: Independently of whether the testicles had been retained in the abdomen or in the inguinal canal, and of the age of the animal within the limits of 2 to 3 years, the germinative cells in the tubuli are represented only by earlier stages of development, as spermogones or at most spermocytes. Such testicles therefore resemble normal testicles in young animals, with the essential differences that in the former degenerative processes point to the cessation of development, while in the latter the conditions for further development exist. The degeneration concerns more the germinative cells than Sartoli's cells, while the so-called plasm cells on the contrary seem more numerous.

The formation of sperm in the retained testicles does not reach the degree of being vital and fertilizing; consequently stallions that are completely cryptorchid must be considered as sterile and monorchid stallions as owing their generative power only to the testicle which has descended normally into the scrotum.

If the male sexual characters are well marked in completely cryptorchid horses, this is explained by the fact that the so-called plasm cells which produce the inner secretion have not suffered any degeneration.

538 – **Sugar in Blood Plasma.** — BIERRY, H. and FANDARD, L. in *Comptes rendus hebdomadaires des séances de l'Académie des Sciences*, Vol. 158, No. 1, pp. 61-64. Paris, January 5, 1914.

The blood of horses, chickens and dogs was examined for sugar, and it was found that venous plasma was always richer in sugar than the corresponding arterial plasma.

ANATOMY AND PHYSIOLOGY

539 – **Influence of Fluorine on the Animal Organism.** — SCHWYZER, F. in *Biochemische Zeitschrift*, Vol. 60, Part I, pp. 32-42. Berlin, February 14,1914.

Experiments with rabbits led the writer to conclude that fluorine introduced into the body caused a loss of lime, chlorine and fat from the bones; even in daily doses inferior to one millionth of the live weight it acts as a poison, and consequently is strictly to be avoided for preserving mashes for live stock and similar uses.

FEEDS AND FEEDING

540 – **The Food Value of Certain Grasses.** — GRÉGOIRE, A. and CARPIAUX, E. in *Rapports et Communications du Ministère Belge de l'Agriculture et des Travaux Publics*, No. 8, pp. 5-48. Brussels, 1914.

The following grasses, Italian ryegrass (*Lolium italicum*), English ryegrass (*Lolium perenne*), tall fescue (*Festuca elatior*), tall oat grass (*Arrhenatherum elatius*) and timothy (*Phleum pratense*), were investigated from two points of view: 1) their food value, and 2) the assimilation by the animal of lime

and phosphoric acid contained in the grasses. The first three were sown on an old experimental field at Gembloux in May 1908; no manure was applied, a good set was obtained and the first crop cut in September 1908 under good weather conditions. In April 1909 the plots received 180 lbs. of nitrate per ace, and half of each plot was cut on June 15, the hay being got up in good condition, while the other half was not cut till later and made in bad weather. The other two grasses were also sown on an old experimental field at Gembloux, but on land in good heart. Seed was sown in 1909 and came up normally; 180 lbs. of nitrate were applied in April. A good crop of tall oat grass was obtained, but only a moderate one of timothy.

Food value of hay. — Feeding trials were carried out on sheep in KÜHN feeding boxes similar to those in use at the Möckern Experimental Station; the faeces and urine were also collected by the same system as employed at Möckern. The trials lasted a fortnight after a preliminary preparatory period of a week. The hay was chaffed and carefully mixed with other foods, samples being analysed by Belgian official methods with slight modifications. The results are tabulated in Table I and compared with those obtained by POTT for similar plants.

The two sets of figures are somewhat different: the two kinds of ryegrasses and timothy contain less albuminoids and the two former more nitrogen-free extract than POTT's samples and the percentage of fibre in English ryegrass in also lower; tall oat grass is poorer in nitrogen-free extract

TABLE III. — *Average amount of total organic matter and digestible matter (and their starch value) provided per day and per* 1000 *kilog. live weight in the different kinds of hay (in kilog.).*

Kind of hay	Total organic matter	Digestible material				Starch Value
		Crude protein	Crude fat	Nitrogen free extract	Crude fibre	
Italian ryegrass:						
Cut young	15.984	1.043	0.231	7.456	3.037	8.3

but richer in cellulose. These differences show how the composition of hay may vary from year to year and the very approximate value of figures in recognised tables.

Results of digestibility trials are given in Table II, and in Table III the average amount of total organic matter and digestible material (together with their starch values) provided in the rations per day and per 1000 kilog. live weight.

KELLNER's maintenance ration for an adult sheep is as follows :

Dry matter	18.23	kilog.
Crude digestible protein	1.20	»
» » fat	0.20	»
Nitrogen-free extract + fibre . .	10.50	»
Starch value	8.30	»

Of the experimental rations the two ryegrasses and the tall fescue were the only ones which supplied amounts of food elements up to KELLNER's standard, and Table IV gives the gain or loss of nitrogen undergone by the animals calculated from the difference between the nitrogen digested from the food and that excreted in the urine, and stated as loss or gain of protein per day and per 1000 kilog. live weight.

TABLE IV. — *Loss* (—) *or gain* (+) *of protein to the animal body in gms. per day and per* 1000 *kilog. of live weight.*

Italian ryegrass:	
Cut young	+ 256
Cut in flower	— 34
English ryegrass:	
Cut young	+ 322
Cut in flower	+ 25

Tall oat grass:	
Cut young	— 43
Cut in flower	+ 44
Timothy:	
Cut after flowering	+ 8

The present results would seem contradictory to those obtained by KELLNER, but the discrepancy may be explained by the fact that KELLNER's maintenance rations are not minimum but maximum maintenance rations, *i. e.* that any increase will cause the animal to put on weight, and, consequently, the rations can be reduced within certain limits without causing the animal to actually lose weight.

The digestibility coefficients obtained in the present trials are tabulated in Table V and also stated as percentages of the hay made from young grasses. KELLNER's digestibility coefficients for hay made from grass in flower (Table VI) differ considerably from these results. He places English rye grass below Italian with regard to digestibility, while the order is reversed in the present results. The variation in digestibility makes it difficult to judge of the relative value of the plants on this basis, but the remarkable digestibility of tall fescue may be pointed out. As the time of cutting advances the digestibility decreases, but even in this decrease there is considerable variation with the different species ; with tall oat grass the decrease is small, while with the ryegrasses and the fescue the decrease amounts to 25 per cent., and of the nutrient elements protein suffers the largest proportional loss. Considering both digestibility results and the production per acre, the value of the above grasses as fodder plants may be classed in the following order: 1) tall fescue, 2) English rye grass, 3) Italian rye grass, 4) tall oat grass, and 5) timothy.

Mineral matter. — It is impossible to determine digestibility coefficients for the various mineral elements on account of the large experimental error which would occur due to the interchange of salts in the animal organism ; a balance can only be struck between amounts fed and amounts excreted. This balance showed a considerable loss of lime to the animal body when the ration consisted entirely of grass hay, fescue and timothy causing least loss. The writers analysed the urine for silicic acid and were

led to believe that the two following causes might account for the observed loss of phosphoric acid and lime :

1. The acidity of the ash of grasses, due more especially to silicic acid, produces an eminently toxic effect ; silicic acid goes into the circulation, where, notwithstanding its weak acid properties, it plays an important part, causing a loss of mineral bases and eventually even of phosphoric acid.

2. The movement of phosphoric acid is regulated by that of the lime with which it is intimately connected. It would therefore appear that the insolubility of the phosphoric acid in the ash of grass is an important factor, making it difficult for the animal to make good the losses which follow as a consequence of the lime drainage caused by the silicic acid.

The mineral matter of a ration composed solely of grass hay should therefore be supplemented. In practice this is usually done by adding to the ration fodders with alkaline ash, such as leguminous fodders or roots, but failing these means, calcium carbonate should be added. The writers carried out some trials in which calcium carbonate was introduced into the ration, and observed that the latter substance in no way diminished the digestibility of the grasses, while it prevented the losses of lime and phosphoric acid to the animal body, so that a small gain was actually recorded.

CONCLUSIONS.

1. The figures given in tables of food values cannot be more than approximately accurate in so far as they deal with hay made from certain grasses.

2. The digestibility of hay decreases with the increase in age of the grasses from which it was made, but the amount of decrease varies considerably with the different species, which may be placed in the following ascending order : tall oat grass, tall fescue, English ryegrass, Italian ryegrass.

3. The food value of various hays differs considerably from that given by KELLNER. Tall fescue heads the list and is followed by the two ryegrasses and tall oat grass.

4. A ration composed solely of hay made from grasses causes losses of phosphoric acid and lime to the animal organism, more especially when

the hay is cut very young. The chief cause for this would appear to be the silicic acid present in the grasses, and possibly also the low solubility of the phosphoric acid.

5. The addition of calcium carbonate to the ration has no effect on its solubility, but reduces the losses of phosphoric acid and lime.

541 – **Bacteriological Research on Ensilaged Forage** (1). — GORINI, C. in *Annuario della Istituzione Agraria Dott. Andrea Ponti*, Vol. II, pp. 165-179. Milan, 1911.

As a result of ten years', investigation on the subject, the writer distinguishes four types of silage :

1. Silage in which butyric acid bacteria predominate.
2. Silage in which lactic acid bacteria predominate.
3. Silage in which putrefying bacteria predominate.
4. Silage comparatively free from bacteria.

The first two may be considered normal types, the remaining two abnormal types of silage. Abnormal silage may be produced either when the temperature of fermentation is too low, which favours the development of putrefying bacteria, or when the temperature is too high, which destroys all bacterial life; consequently the making of successful silage depends chiefly upon the amount of heat produced in the silo, which may be controlled by the packing, and only to a lesser extent upon the moisture content and quality of the forage. The optimum temperature for the silo is 50° C. (122° F.), at which temperature lactic acid bacteria predominate; if the temperature rises to 60° C. (140° F.) the butyric acid flora is especially favoured.

With regard to the question as to whether it is advisable to classify silage as "sweet" and "sour", the writer observes that strictly speaking all silage is more or less acid and that consequently it should all be classified according to the degree and nature of its acidity, though it does not follow that the quality of the silage can always be determined from its degree of acidity : the rule holds good only within certain limits.

Opinions are still divided with regard to the relative value of the two types of silage for food in general, but when fed to dairy cows the writer gives preference to the lactic acid type, as the butyric acid type is liable to taint the milk and butter.

The writer has also carried out some experiments on seeding pure cultures of lactic bacteria into the silos. The experiments are not yet completely finished, but the results obtained up to the present lead to the following conclusions:

1. That the addition of lactic acid bacteria to the silo improves the keeping qualities of the silage.
2. That different lactic acid bacteria act differently upon the silage.
3. That even at a relatively low temperature it is possible to make so-called sweet silage.

(1) Cf. *Ricerche Batteriologiehe sui Foraggi conservati nei Silos*, by the same writer, for the years 1906, 1908, 1909, 1910, 1912. Premiata Tipografia agraria, Milan. (*Ed*).

542 – **Toxic Bran.** — MARCHADIER and GOUJON in *Annales des Falsifications*, Year 7, No. 64, pp. 77-81. Paris, February 1914.

Bran undergoes degenerative changes on storage which may be the cause of serious disturbances when it is fed to animals. In order to find a method of determining whether any given sample of bran be fit for food, the writers carried out the following experiments: 100 tons of fresh bran were put into a heap in November 1912; in the following February the formation of lumps was observed, while in March the temperature had risen considerably and the centre of the heap was carbonized. Samples were drawn 1) from the outside of the heap which was in friable lumps but not discoloured, 2) from a little further in where the lumps were less friable and dun coloured, and 3) from the centre where the bran had become a compact black mass yielding a fracture rather like that of linseed cake made under high pressure, and looking and smelling of roasted chicory. A sample of the same bran kept apart from the heap was also taken, as well as a fresh commercial sample. They were all analysed and yielded the following results.:

	Commercial sample	Bran not put in heap	Bran from the outside of the heap	Bran from lower layers of the heap	Bran from centre of the heap
Moisture	12.7	14.8	13.6	11.6	11.5
Acidity as H_2SO_4 total	0.074	0.172	0.211	0.776	2.062
Acidity as H_2SO_4 fixed	0.074	0.172	0.211	0.578	1.445
Acidity as H_2SO_4 volatile	0.000	0.000	0.000	0.198	0.617
Fat	1.32	1.70	1.10	2.64	4.98
Ash	5.5	5.8	5.9	6.0	6.2
Anaeroxidase	present	present	present	absent	absent
Soluble in cold water	10.65	12.35	4.35	9.80	18.30

The acidity increases as fermentation proceeds, so that at the end of the process the acid content is fifteen times as high as it was originally, and the oxidising enzymes disappear in the later stages of fermentation. The writers suggest that these two factors be taken as a base for determining whether bran be fit for food, classing the bran as follows:

	Acidity
Normal bran	below 0.150
Bran undergoing decomposition, not yet unfit for food but liable to become so very rapidly	0.150 to 0.300
Bran unfit for food	above 0.300

543 – **The Rate of Liberation of Hydrocyanic Acid from Linseed** (1). — COLLINS, S. H. and BLAIR, H. in *The Analyst*, Vol. XXXIX, No. 455, pp. 70-72. London, February 1914.

Linseed was digested with water to which other substances were added experimentally and the resulting hydrocyanic acid, when formed, was removed, by a stream of hydrogen gas, absorbed in weak caustic soda solution and estimated colorimetrically by the prussian blue test. One particular sample of linseed yielded 0.38 mgm. of hydrocyanic acid per gm. of linseed. The velocity of reaction was such that one half of the total amount was yielded in 46 minutes, whereas solutions of hydrocyanic acid in water yielded one half the total amount in 26 minutes, reaching in 3 hours' time from 98 to 99 per cent. of the total amount present. When the linseed was acidified to represent digestive conditions, no hydrocyanic acid was liberated, and similar negative results followed the use of pepsin and rennet in acid solutions. Even hydrochloric acid of $\frac{N}{100}$ strength prevented the enzyme from working, and $\frac{N}{1000}$ strength produced a marked slowing in the rate of liberation of hydrocyanic acid from linseed.

With non-ruminant animals the acidity of the stomach would render the enzyme inactive. In the case of cattle where 2 to 3 lbs of linseed may be fed daily, the writer attributes the usually innocuous effects partly to the influence of other foods in slowing down the action, and partly to the fact that the hydrocyanic acid formed must be largely evaporated into the air during rumination with its attendant continual regurgitation of the food into the mouth. The linseed " mash " fed to calves is a more likely source of danger. Linseed treated with a large volume of boiling water and kept at 100° C. for half an hour produced no hydrocyanic acid gas, but at 60° the evolution of acid was only slightly checked, though almost completely checked at 90° C.; linseed heated dry to 100° C. or ground finely produced an increased amount of hydrocyanic acid. Linseed mash prepared in a lumpy condition generated hydrocyanic acid from these lumps, slowly at first, but rapidly when the lumps were broken up, showing that the enzyme had not been destroyed in the comparatively dry material inside the lumps.

The extractives, such as petrol, ether, chloroform, etc., had no marked effect on the enzyme, so that the removal of oil from the seed in the manufacture of linseed cake by the solvent method, far from producing a safer material, only tends to concentrate both enzyme and glucoside.

544 – **Live Stock in Morocco.** – MONOD, T. in *Revue générale des Sciences pures et appliquées*, Year 25, No. 7, pp. 341-346. Paris, April 15, 1914.

Though Morocco is a country eminently adapted to agriculture and live stock, its production has remained at a low level owing to the defective methods practised by the natives, who make no attempts to save their stock in years of drought. Conditions could be considerably improved by 1) creating food reserves to fall back upon in periods of drought, such as hay, forage crops, irrigated meadows or maize and sorghum silage; and

(1) See No. 1352, *B.* Dec. 1913. (*Ed.*).

2) tapping springs and building stone drinking troughs to improve the hygienic condition of the present water holes, which are a constant source of disease to stock.

Horses.— The type varies with the soil in the different localities but all are preeminently saddle horses and belong to the Berber type. They are quiet, hardy, mettlesome, but are lacking in breed and shapeliness. Usually they are less well cared for than in Algeria, brood mares being ill fed and generally undersized. Where they receive rather better treatment, such as in the Marrakech district, the superiority of the animals is evident. The introduction of Arab thoroughbreds should prove very beneficial and the work undertaken in this direction by the State studs should give excellent results.

Mules are very popular in Morocco both for agricultur al purposes and as carriage or saddle beasts; they fetch a good price (£24 to £64) and their improvement by means of selection and the use of imported asses should prove remunerative.

Cattle.— A large demand and a low production due to droughts and diseases have combined to raise prices abnormally, *i. e.* to twice their value of two years ago. Numerous breeds exist, all hardy and fattening readily when well fed. Cattle receive no kind of care; they are allowed to breed promiscuously and are kept out without any kind of shelter. Yet it should be possible to obtain both a good milking breed and a good working breed from the native animals.

Sheep. — Sheep number 1 500 000 in Western Morocco and 900 000 in Eastern Morocco in those districts under French influence, and would be liable to vast improvement under a judicious system of br eding and selection.

Pigs belong to the Iberian race and are spreading all over the country as the natives have not the same antipathy for that species of animals as have the Algerians. A good export trade to Europe, where the products find a ready market, may be predicted.

545 – **Live Stock in New Caledonia.** — LAFFORGUE, G. in *La Vie agricole et rurale*, Year 8, No. 7, pp. 175-177. Paris, January 17, 1914.

New Caledonia is situated on the southern limit of the tropical zone and has a remarkably constant climate, with a mean temperature of 68° to 77° F. (minimum 57° F. and maximum 97° F.), rather long droughts and occasionally very wet periods. The soil is only moderately fertile and may be put under coffee, but live stock rearing is the chief resource of the country.

Colonists embarked on cattle rearing from the outset, using as basis animals of the Shorthorn, Hereford, Devon and Aberdeen-Angus breeds. Crosses of Shorthorn-Devons or Shorthorn-Herefords are now commonest, and of these two, the former seems the better adapted to the country. Large herds, up to 1000 head, range freely on the open stations, which may cover an area of 15 000 acres each, in charge of mounted stockmen who are ably seconded by their dogs. Males and females are never separated and breed promiscuously.

In 1908 New Caledonian cattle underwent a serious crisis due to two principal causes: 1) the deterioration of pastures owing to frequent overstocking, which destroys the grasses and gives the weeds a chance of getting a hold; and 2) running males and females together, which results in numbers of the females being called upon to perform maternal duties before maturity, the annual castration of males not required for breeding purposes being an insufficient preventive measure. Better times are dawning, colonists are beginning to co-operate in order to improve the management of live stock, and stations are being reduced in size in order to lead to a more intensive form of agriculture. Such measures should be completed by the erection of a cold, storage factory, which would make the export of meat remunerative, for New Caledonia is too remote from centres of consumption to make the transport of meat in the form of live cattle an economic possibility.

HORSES, ASSES AND MULES

546 – **Short-faced Abyssinian Mules.** — DECHAMBRE, P. in *Bulletin de la Société Nationale d'Acclimatation*, Year 61, No. 5, pp. 129-132. Paris, March 1, 1914.

The writer mentions an abnormal head conformation frequently met with in Abyssinian mules and interesting from its analogy to special conformations in other types of animals. It consists in a considerable depression of the base of the subnasal bones together with an underhung jaw giving the animal a bulldog expression.

Mules possessing this characteristic are in no way inferior to normal animals; they are small, strong and well ribbed up; but, of course, should the abnormality be developed beyond a certain point, both the breathing and the articulation of the jaws are interfered with and the animal suffers. From an enquiry made by Dr. GROSLAMBERT, it would appear that the short-faced mules, or "fongga", are the result of purely accidental variations which are not inherited. Analogous conformations in other types of animals are represented by the bulldog, the "nãtos" or short-faced Chilian cattle, and tumbler pigeons.

CATTLE

547 – **Present State of Milk Record Associations in Austria.** — ROSSMANIT, RITTER VON in *Mitteilungen des Zuchtvereins für das alpine Grauvieh in Steiermark*, Year 2, No. 1, 9 pages, 1914.

Milk recording has only comparatively recently gained a footing in Austria (1), but it has rapidly become important, as may be gathered from the following data.

In East Galicia milk records are registered by the Lemberg Agricultural Society in 140 herds containing 4344 cows. For this object a special office exists, employing thirteen persons besides the director.

In West Galicia two associations were founded in 1904, followed by two more in 1906. At present the number of animals under record is 450, of which 160 belong to small farmers.

In Bohemia regular test milkings have been carried out since 1905

(1) See article: « The Present State of Dairy-Cow Testing », *B.* Oct. and Nov. 1912. (*Ed*).

exclusively by cooperative breeding and economic associations. Up the present 3500 cows on 692 farms have been tested.

Moravia has, at present, two testing associations with 50 membe and 320 cows.

In Upper Austria the Simmentaler Cattle-breeders' Federation Schärding has kept milk records since 1904. Since 1912, 96 breeders wi 888 cows have submitted to the control. From 1904 to 1912 the avera milk yield rose by about 44 gallons per head per annum. In 1910 t Federation of Simmental Breeders at Ried began the work of milk recor ing, and the next year the Montavon breeders followed suit. In t latter federation, 191 members with 2879 cows submit to the control.

In Salzburg, for the last two or three years six cooperative breedi associations with 1675 cows have been keeping milk records.

Extensive test milking is practised in the Tyrol also, but on accou of the communes and farms being so widely scattered in the high mou tains, a good deal is left to the private recording of the farmers.

In Styria, the "First Styrian Milk Control Association" has carrie out regular milking tests since 1904. In that year it numbered 11 me bers with 365 cows, while in 1914 there were 30 members and 1050 cow The contributions for large landowners are 16*s* 8*d* per year and 2*s* 6*d* p cow per year, while peasant owners pay only 10*d* per year per cow. T association has a yearly State subvention, which has grown gradually fro £33 4*s* to £125. The tests are made three times a week, three perso being employed for the purpose.

Besides the above, milking tests have been practised in Styria b the Federation of Murbodner Cattle-breeding Cooperative Associatio since 1910. At present 1632 cows are under control.

548 – **Red Flemish Cattle.** — RAQUET, H. in *Annales de Gembloux*, Year XXIV, No. pp. 81-102. Brussels, February 1, 1914.

The total number of Flemish cattle is estimated at 700 000 head France and 500 000 head in Belgium. In Flanders in 1912, their density w about 1 to 2 ½ acres. As milkers they are almost equal to the Dutch bre when under a favourable system of management: 14 cows on the fa of Mr. Talpe of Hooghlede, West Flanders produced during the sev years 1902-1908 an average annual yield varying from 780 to 1080 gallo with the nature of the season, being highest in the wetter seasons.

At agricultural shows in Belgian Flanders, points are awarded a cording to the following scale:

Cows.

General appearance, frame	20	general conformation 50 points
Dorsal line	10	
Head, horns, breed characteristics, coat colour	10	
Skin	10	
Udder and teats	20	milking qualities 50 points
Milk veins	20	
Escutcheon	10	
	100	

Bulls.

Dorsal line	20
Frame	20
Fore quarters	20
Skin, horns	10
Pedigree, milking characteristics, escutcheon	10
	100

The breed is very adaptable and has been substituted for Swiss and Dutch cattle in the province of Santander (Spain). It has successfully established itself in Argentine, but the Argentine strain, which is the result of crossing the old red-and-white Flemish cattle with Shorthorns, is more like the old Zeeland cattle than the modern Flemish breed. The breed, represented by 52 bulls and 11 heifers from the best Flemish herds, has also been imported into Saô Paulo, Brazil.

The French herd-book was started in 1886 at Bergues, while the Flemish one is of more recent origin and has its headquarters at Roulers in West Flanders. The writer considers that for registration purposes, the breed should be divided into three sections: 1) milking type, red with a black nose, the original type; 2) beef type produced by crossing with the Shorthorns, red with a pink nose; and 3) general purpose type with predominant milking qualities, red and white with a pink nose. He further suggests that the fee for entering should be abolished as an encouragement to breeders.

549 – **Determination of Growth in Grazing Cattle.** — Bruchholz, K. G. in *Deutsche Landwirtschaftliche Tierzucht*, Year 18, No. 16, pp. 185-187. Hanover, April 17, 1914.

The writer divides young cattle into three groups according to the nature of the growth they make while at grass: 1) Those which form chiefly bone and flesh: these eventually grow to big beasts, and when still young give promise of becoming good breeding, milking or fattening stock. 2) Those in which the increase of weight is almost entirely due to fat: they always remain small, and are less valuable than those of the first group. 3) Those which make little increase in fat, bones or flesh: they will always be poor animals.

To find out to which category the young stock at grass belong, it is essential to take body measurements as well as noting the increase in weight. The writer recommends taking only the girth measurement, at the beginning and end of the grazing time, as taking detailed measurements of a large number of animals is very laborious. The value of this method is shown by the accompanying table, in which data are given for eight heifers; these were turned out to grass in May, at eighteen months old, and taken off again in October. Four months after dropping the second calf they were weighed again for comparison wirh the data obtained earlier.

It may be noted that the chief increase of live-weight took place in May and June; four of the heifers showed much less increase in July and August, and three of them a decrease in September. The girth increased much more evenly.

Increase in weight and girth of heifers.

Number of heifer	1	2	3	4	5	6	7	8
Increase in live-weight during grazing period. . lbs.	216	249	129	64	115	164	293	140
Increase in girth during grazing period . . . . . in.	12	10	9 ½	8	7 ¼	3 ½	2 ½	1 ¼
Live-weight 4 months after second calving. . . . lbs.	1 456	1 318	1 397	1 273	1 278	1 154	1 067	1 005

The table shows clearly that the heifers which increased most in girth were the ones which eventually made the heaviest cows, while the increase of live-weight at this period shows no correlation with the live-weight of the mature animals.

550 – **Heredity of Twin Births in Cattle.** — UHLMANN, E. in *Deutsche Landwirtschaftliche Tierzucht*, Year 18, No. 14, pp. 163-164. Hanover, April 3, 1914.

The writer has investigated a herd in which the birth of twin calves has been very frequent. He found two sisters which had borne twins 2 out of 7 and 4 out of 9 times ; the dam of these cows (as well as the two other sisters) never had twins, but the maternal grand-dam once gave birth to twins. Two daughters of the first cow have also given twins (each 1 out of 3 times), while two daughters of the second cow have calved two and four times respectively without producing twins.

The bulls used have been of various strains not known to have a tendency to twin-production.

The evidence seems to point to a twin-producing character being inherited from the grand-dam mentioned.

SHEEP

551 – **Marocco Sheep and their Products.** — *Bulletin économique du Maroc*, Year 1, No. 6, pp. 5-7. Rabat, August 15, 1913.

There are two chief breeds of sheep in Morocco.

1. The *Muluya Basin* breed, found in the high plateaux of Eastern Morocco, has a close fleece very similar to the Merino ; it is hardy and resistant to drought.

2. The *Atlantic* or *Western* breed which is a kind of degenerate merino.

These types vary to a certain extent; in the neighbourhood of Tangiers, some imported Spanish Merinos have improved the local sheep, while in the neighbourhood of Fez two modifications are met with: the *Beni-Hassen* with a long silky fleece. and the *Berber* which is smaller with a heavier, coarser fleece.

The principal sheep-breeding centres are the High Plateaux of Eastern Morocco and the fertile plains of the Atlantic coast, the Rharb district, the district of Beni Hassen, parts of Shawia, and above all the Marakesh district, the annual production being approximately as follows:

Rabat district	100 000
Fez and Sifru district	50 000 to 60 000
Meknes district	20 000 » 25 000
Shawia	50 000 » 60 000
Mazagan and Saffi districts . .	300 000

In the Rabat district, prices range from 12*s* to 17*s* per head. Exports by sea are prohibited; sheep may leave the country by way of Algeria (approximately 200 000 per annum are exported), and are taxed 3*d* per head on passing out at the frontier. Shearing is carried out in spring and the natives take the fleeces to Jewish or European dealers the following winter and receive 1*s* 4*d* to 2*s* per fleece. The wool is graded into three qualities:

1. *Ourdigha* — short and fine, comes from Shawia and Tadla and fetches the highest price.
2. *Aboudia* — medium quality and unwashed, comes from the Rharb district and the Sebu Valley.
3. *Beldia* — low quality, comes from Rabat, Saffi, and Mazagan districts.

Exports are taxed 4*d* a lb. on washed wool and 6 ½*d* a lb. on unwashed wool, the washing having caused the wool to loose 50 to 60 per cent. by weight. Formerly France was the only importing country, but now Germany takes a large part of the wool produced, as is shown by the following table:

Importing country	Value of imported Moroccan waol			
	1909	1910	1911	1912
	£	£	£	£
France	74 250	91 600	106 800	32 740
England	6 000	13 060	5 250	4 290
Germany	26 990	69 630	90 240	32 580

Large quantities of skins are exported. Sheep skins are also largely turned into slippers, which are then exported to Algeria and Egypt.

552 – **Development and Prospects of Sheep Breeding for Wool in German South-West Africa.** (Lecture given by Prof. GOLF at the meeting of the Kolonial Wirtschaftliches Komitee) in *Zeitschrift für Schafzucht*, Part 4, pp. 81-86. Hanover, April 1914.

The breeding of sheep for their wool is destined to become the most important branch of farming for at least one half of the total area of German South-west Africa. The most important area is the whole south of the colony, that is all the country south of a line running eastward from Windhuk. Then in the northern half of the colony there is a western dry part which is bounded on the west by the Namib desert and on the east by a line drawn from Windhuk to the Kunene passing through Waldaw, Omaruru and Franzfontein. To the north and east of this district cattle are more suitable than sheep, as the thorny pastures injure the fleeces.

On April 1, 1912, the number of wool sheep in German South-west Africa was 46 901. The yield of wool is inferior to that of South Africa, which

is 8.8 lbs. of unwashed wool per head; in 1910 the export from German South-west Africa was 186 180 lbs. worth £37 401. If this industry is to develop satisfactorily, the breeding and management must be improved with the introduction of special wool-producing breeds, the aim being the production of wool of the best quality.

As the most suitable sheep the writer recommends Cape Merinos, which might be improved by the introduction of pedigree rams. In the North of the colony the German Tuchwollschaf would probably be suitable for crossing; in the south, however, the German, Australian or African Kammwollschaf would be more advisable for the present.

GOATS

553 – **Present State of Milk Recording for Goats in the German Empire.** — Report made in the autumn of 1913 to the German Agricultural Society, subcommission for milk records for goats, by Dr. MÜLLER of Dortmund; in *Mitteilungen der Deutschen Landwirtschafts-Gesellschaft*, Year 29, Part 9, pp. 138-140. Berlin, February 28, 1914.

The German Agricultural Association (D.L.G), in the summer of 1912, addressed an enquiry to all the central agricultural offces (landwirtschaftliche Zentralstellen) on the present situation and development of milk recording for goats, and received the following information.

Milk records are kept at present in the Grand Duchy of Hesse, in Hesse-Nassau (district of Wiesbaden), in the province of Saxony, in the Rhine province, in Westphalia, Hanover, Brunswick, Coburg and Sachsen-Altenburg, and in the Kingdoms of Württemberg and Saxony. In several localities, as in Silesia, Oldenburg, Baden, Bavaria and Lippe, the record of performances has been begun, but up to the present there are no complete yearly records available. The milking tests, which yield more or less useful figures, are about 500, and refer to the most different breeds of goats. The first tests appear to have been made in the Grand Duchy of Hesse and in the Kingdom of Saxony about the end of the last century. Recently, thanks to the increasing recognition of the importance of milk recording work, it has been receiving considerable financial aid from the numerous agricultural central offices. Special instructions on the method of carrying out these milking tests are at present published only in Württemberg and Hanover, though short directions are to be found almost everywhere.

The best results have been obtained in those localities in which a special control assistant was available (Westphalia), or in those in which some organization took an interest in milk control.

Most of the observations, especially of late years, are no longer made by measure, but by weight, and if possible every fortnight. In only a few localities are records kept of the weight, age and mating of the animals and of the number and weight of the kids dropped. Data on the height and girth, and on the feeding and utilization of the food, are nowhere to be found. On the other hand in some places the net returns have been calculated. The results vary between — 5*s* 9*d* and + £ 7 10 *s* per animal per year.

The results hitherto obtained are insufficient for the clearing up of several questions connected with the keeping of goats, to a great extent

ecause they have been obtained by different methods. It is therefore ghly desirable that in future uniform methods be adopted.

4 – **The Olfactory Sense of the Honey Bee.** — Mc Indoo, N. E. (Bureau of Entomology, U. S. Dep. of Agriculture, Washington, D. C.) in *The Journal of Experimental Zoology*, Vol. XVI, No. 3, pp. 265-345. Philadelphia, Pa., April 5, 1914.

Olfactory pores were found on the bases of the wings, and on the ochanter, legs, and sting. They numbered approximately 2600 in the rones, 2200 in the workers, and 1800 in the queen. They are described detail.

5 – **Silkworm Rearing in Madagascar** (1). – 1. Fauchère, A. in *L'Agriculture Pratique des Pays Chauds*, Year 14, Nos. 130-132, pp. 12-23, 92-102, 140-147. Paris, January to March, 1914. — 2. *Journal d'Agriculture Tropicale*, Year 14, No., 153, pp. 89-91. Paris, March 31, 1914. BEES

A full account is given of the treatment of silkworms in Madagascar; ie Centre is the most favourable part for *Bombyx mori*, called "landikely". The native worm is *Borocera madagascariensis*, known as "landibe"; iis is reared in the open, either in natural forests of "tapia" (*Uapaca usiacea*) in the Centre and "afiafy" on the coasts, or in plantations of tsitovina" (*Dodonea madagascariensis*) and *Cajanus indicus*. There are two roods in the season; the cocoons are grey and cannot be reeled: they are nerefore carded and spun. This silk gives rise to a considerable trade in ie island.

6 – **Silkworm Rearing in the Yalong Valley, China.** — Legendre, A. F., in *Annales de l'Ecole Nationale d'Agriculture de Montpellier*, Vol. XIII, Parts I-III. Montpellier, July and October 1913, and January 1914. SILKWORMS

The rearing of silkworms in China has been very little improved since arly times, and it would probably be possible to double the yield at very ttle expense. The writer has studied silkworm rearing at a village near ie Yalong river in Szechuan; it varies little throughout the Empire, unless ubject to European influence, as at Canton and Shanghai.

In spite of the height (6000 to 7000 ft.), the eggs begin to hatch at the nd of February or in early March; hatching is sometimes hastened by eeping the eggs in a warm room; it lasts three or four days.

Little attention is given to the worms; they are kept on heaps of aves of mulberry (*Morus alba*) or "ta tchou" (*Cudrania triloba*), in askets or on coarse bamboo mats; these are kept in the roof, and often oove the kitchen, as the smoke from the green firewood is supposed to eep away insects.

The worms of the Kienchang district (Szechuan) moult three times: ch stage lasts about 13 days, and spinning up takes another 10 days, that the whole rearing period is 49 days. For the first two stages only *udrania* leaves are used; they are fed cut up small in the first stage, in rge pieces or whole in the second. The leaves are picked once a day, as on as the dew is off, and the number of meals is increased from four to

(1) See No. 967, *B.* Aug. 1913.

eight as the worms grow; in rainy weather they are not fed. It is suppo that leaves covered by the fine sand occasionally brought by the wind fatal. The old leaves are not removed till there is a considerable accu lation of them, when the worms are picked off into baskets and then back onto the fresh leaves.

The chief errors in the Chinese method are crowding together of worms and not cleaning out often enough; for these reasons the worms liable to disease. The only remedy known is to pick out the diseased or which can be done only imperfectly owing to the size of the mats.

For spinning up, dry rape stalks or oak twigs with the dead leaves are used. Seven days after the cocoons are finished they are placed the sun to kill the larvae, or in dull weather they are put in an oven.

The moths emerge from the cocoons kept for egg production 12 to days after the beginning of spinning; a number of females are made to on each of the egg papers used: these measure about 17 by 11 inches.

Cocoons. — The cocoons are divided into six groups according to sha and quality. In a normal rearing there are 15 to 20 per cent. of the fi quality and 35 to 40 per cent. of the next two, some 35 per cent. bei inferior and 10 per cent. double.

About 33 fresh or 43 dry cocoons go to a Chinese ounce (37 gms.). T yield of raw silk does not exceed 9 per cent. of the weight of the fre cocoons and 7 ½ per cent. is a good average; in bad years it may be or 4 to 4 ½ per cent.

The cocoons are of four chief colours: pure white, canary yello golden and green. The raw silk is dull and dirty-looking.

The yield from 25 gms. of eggs may be 23 kg. in a good year, and 18 kg. in ordinary seasons, while in France 60 kg. is often obtained.

Breeds. — Four breeds are known, all being single-brooded and wi eggs in clusters:

1. *Pé-ts'an* (uncoloured); two varieties, one with white legs (giving white cocoo and the other with yellow legs.
2. *Houa ts'an* (speckled); each segment with a grey band posteriorly; legs yell
3. *Lao hou ts'an* (striped green); uniform dark brown, with pale yellow velv legs; head striped with black; cocoon very full, but often green and theref not liked.
4. *Ou ts'an;* less dark than the preceding, with the same striped head; prol yellow.

There is also a wild silkworm ("ié ts'an"), much like the "lao hou ts'an living on mulberry.

Diseases.—"Pébrine" occurs occasionally in a mild form, and is su posed never to occur with "flacherie"; the latter breaks out every thr or four years and carries off 90 per cent. of the worms. "Muscardine takes about 1 per cent. of the worms, and "grasserie" (which preven their spinning) about 10 per cent. A good many of the worms pupa without spinning.

Bajac's three-furrow Flemish plough with counterweight.

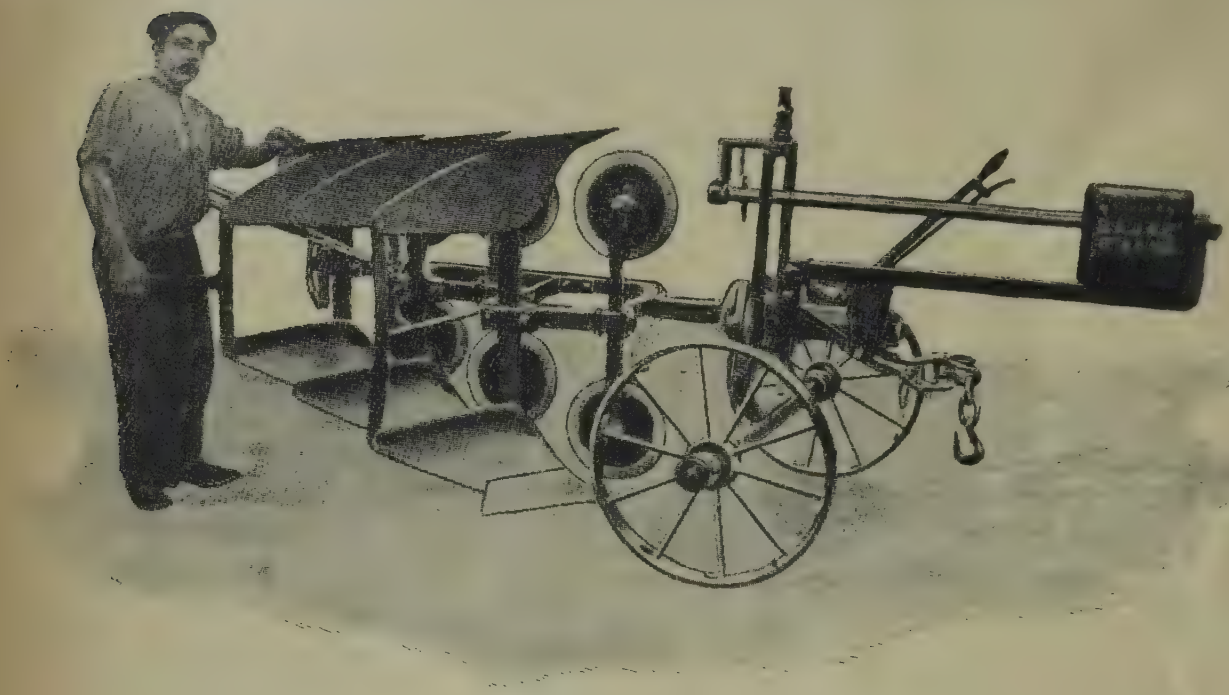

Fig. 1.
Position for turning.

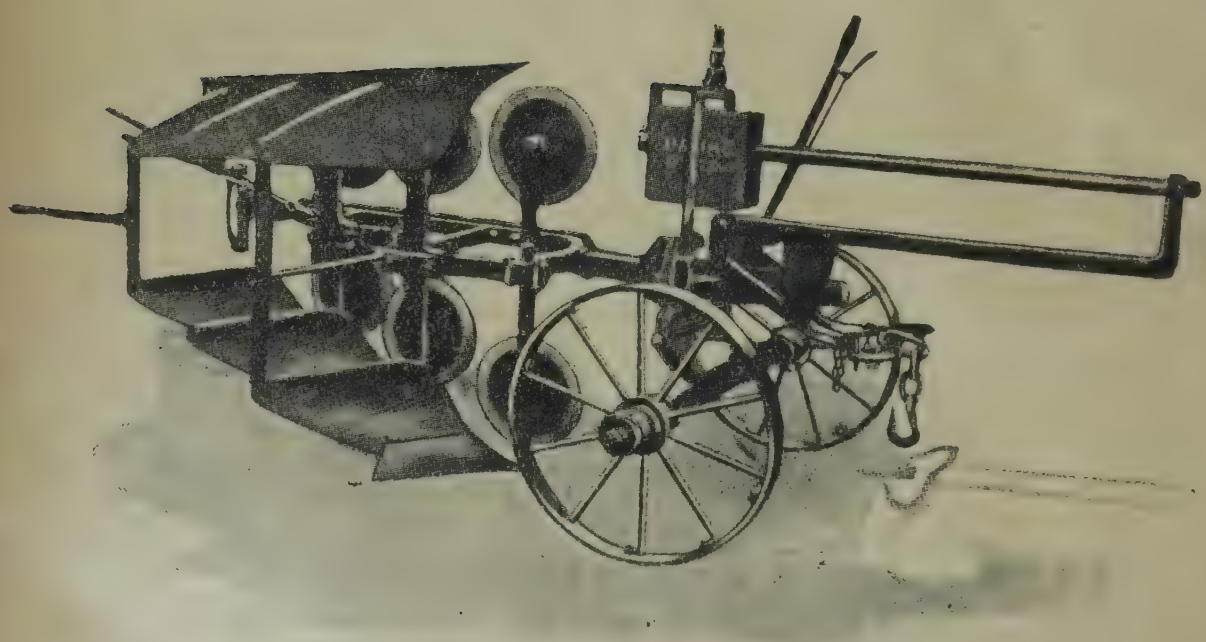

Fig. 2.
Position for working.

One of the worst enemies is a fly, which oviposits in the larvae ; its spread is encouraged by the practice of leaving the dead worms about instead of burning them.

Mulberries. — There are four varieties : *a*) with dentate leaves ; *b*) with deeply divided leaves, not so well liked by the worms ; *c*) with leaves pubescent along the veins, and *d*) the wild mulberry with pubescent leaves refused by the domestic silkworms. A trunk-rot is about the only disease seen.

FARM ENGINEERING.

557 - **Machines at the General Agricultural Show, Paris, 1914.** — RINGELMANN, MAX in *Journal d'Agriculture Pratique*, Year 78, Vol. I, Nos. 11, 12, 13, 14, pp. 341-344, 371-373, 399-402, 438-439. Paris, March 12, 19, 26 and April 2, 1914.

AGRICULTURAL MACHINERY AND IMPLEMENTS

This year the number of exhibitors was 619 as against 665 in 1913, The importance of the show, however, was not lessened and bore witness to the constant improvement in the construction of agricultural machines and implements. In this paper detailed descriptions and figures of several of the exhibits are given.

I. *Apparatus for the mechanical tillage of the soil.* — This class was represented by a large number of machines, including almost all those which took part in the Grignon and Trappes trials of last autumn. Among the tractors, windlass and hauling tractors, motor ploughs and rotary diggers, steam lorries and steam and petrol traction engines, the most noteworthy were the exhibits of the following firms : Compagnie internationale des machines agricoles de France, Bajac, G. Filtz, Stock, Bauche, Lefebvre, Doizy, Société de la Motoculture Française, Tourand and Derguesse, Foden, Société française de materiel agricole of Vierzon, Pécard frères, Lanz, de Mesmay, Case Co., Pavesi and Tolotti, Dion-Bouton, Lefébure, Landrin, and Amiot.

In the latest type of the DE MESMAY tractor, all four wheels are driving wheels, the object of this being to diminish the compression of the soil. Its width is only 50 inches so that it can be used in vineyards. It weighs empty about 3080 lbs. One of these machines (15 HP) took part in the international competition at Chassart in September 1913, when, according to the general report, it ploughed 6.92 acres to a depth of 6.3 inches in 15 hours 57 minutes, the work being excellent.

The CASE tractor (40 HP) weighs 7.26 tons when in working order; at Chassart it hauled a 6-furrow gang plough and ploughed 23.34 acres to a depth of 6.5 inches in 16 hours 4 minutes. It worked very regularly, never stopping for more than a few minutes to lubricate.

The LEFÉBURE windlass consists of a four-wheeled chariot bearing a vertical Abeille engine (12-15 or 20-25 HP), which drives a windlass mounted on a horizontal axis at right angles to the axles of the wheels. In ploughing, two of these machines are used as on the usual double-engine system. Each windlass weighs empty 5500 to 5900 lbs.

The LANDRIN windlass tractor carries a 45 HP engine and weighs about 5.4 tons ; it can travel at four different speeds, from 1.86 to 7.45 miles per hour. The driving wheels are provided with twelve adjustable cleats which can project up to 4.8 inches. The motor by itself proceeds rapidly, then stops, anchors itself and hauls in the cable also at four different speeds, from 0.9 to 3.7 miles per hour. It can wind up to 500 feet of cable.

AMIOT's motor plough with a 40 HP Abeille engine is mounted on a four-wheeled frame. The driving wheels are provided with oblique projecting cleats which are removed when travelling on roads. The plough is situated behind the motor ; it is a double three-furrow Flemish gang plough, which can be lifted by a kind of crane worked by the motor itself ; thus one man can drive and work the whole machine from his seat.

PAVESI AND TOLOTTI's motor plough consists of a triangular frame on three wheels, the front one being the steering wheel and the near hind one the driving wheel. The latter is provided with blades which project vertically from the lower part of the tire only, and are worked by a special excentric. The ploughs, from one to six in number, are placed at the side of the frame between the steering and driving wheels, so that the plough beam is pushed instead of being hauled. One man seated about the middle of the frame is sufficient to drive the machine. It is built in two sizes, 16 to 20 HP and 40 to 50 HP.

Among the ploughs exhibited in Paris, an improvement deserves to be specially mentioned, *viz.* A. BAJAC's movable equilibrium counterweight. As is well known, it is extremely fatiguing for the ploughman, when using the heavy two or three-furrow double Flemish ploughs, to turn them round at the end of the furrow, or to move them on a road or headland. In order to obviate this drawback BAJAC fit a sliding cast iron weight (176 lbs.) on to a horizontal hollow bar attached to the fore part of the plough (see figs. 1 and 2). The weight can be retained at the extremity of the bar by means of a pin. When the weight is behind the axle of the fore-carriage it increases the weight of the plough and presses it into the ground, while, when pushed to the extreme end of the bar, it counterbalances the weight of the plough and allows the latter to be easily handled. This principle has been applied by BAJAC in several different forms; in the case of the largest ploughs the counterweight and fittings weigh as much as 440 lbs. and the weight is shifted by a small winch.

Sowing machines and drills.— Of the numerous drills, that exhibited by O. JOERISSEN is a force feed with an obliquely fluted feed shell, varying in size according to the nature of the seed. The quantity drilled is regulated by the speed of the feeding shaft ; the gearing is enclosed in a casing and may be adapted to 16 different speeds.

In the « Baby » drill the fluting is double and parallel to the axle.

In LAVAULT's drills the feed consists of a series of claws acting alternately and varying in size according to the nature of the seed.

In CHARLIER FRÈRES's drills the shoe furrow openers are replaced by two disks set at an acute angle to each other.

Potato planters are represented by the MOLINE machines and by those of FASCIAUX ; in the latter a boy seated on the planter throws the seed potatoes into holes made in the ground by blades mounted on a disk revolving at right angles to the axle of the wheels ; by changing the gears the holes in the rows may be made at 18,20 or 22 in. apart.

Sprayers and sulphurers. — Various models were exhibited by a number of makers, among whom V. VERMOREL showed a very complete collection.

BERGÈS BACHASSE AND CO. showed a pack-saddle sprayer in which the two cylindrical reservoirs are fitted with a device to diminish or prevent the wave motion of the liquid in them which is so trying to the animal. It consists of a series of slotted felt disks arranged parallel to the ends of the reservoirs.

MIRANDE FRÈRES' sprayer is mounted on two wheels ; equilibrium is maintained by special harness and the whole can pass between rows of vines only 3 ft. 3 in. apart.

Harvesting machines. — S. PLISSONNIER exhibited a motor mower on Valloton's system ; it is on three wheels with a 6 to 8 HP engine ; it weighs about 1980 lbs. and cuts 3 ft 3 in. to 6 ft 6 in. according to the kind of crop and the slope of the field.

The SOCIETÉ LA FRANCE exhibited a motor reaper and binder. It carries a smale 3 ½ HP engine which drives the reaping and binding apparatus, while the team only draws the machine. Somewhat similar machines are shown also by some American firms, in which the engine is partly supported by a small wheel.

GARNIER AND CO. exhibit a horse rake with several improvements, among which is one to deaden the shock of the teeth.

Among the reapers and binders A. RIVET presented one in which the reel slats instead of being placed in planes parallel to their axis of rotation are disposed helically so as to throw the grain obliquely on the platform canvas; the binding is improved by this means, especially in the case of short straw.

G. RICHOMME exhibited a combined binder and thresher which on the whole resembles a common binder, but the elevator is replaced by three successive threshing devices through which the cereal ascends ; the straw then passes onto the binder deck and the grain is elevated by a belt and poured into sacks.

There were several POTATO DIGGERS and BEET ROOT LIFTERS, among the latter one built by GUICHARD & FILS provided with an elevator that loads the beets into a cart.

Motors.— A number of internal combustion motors were exhibited, some burning paraffin, others heavy oil, naphthaline and producer gas ; among these DUBOIS' two stroke motor is noteworthy for the distribution which is effected, not by valves, but by the displacement of the piston which uncovers alternately the opening for the escape and that for the admission of compressed air into the case.

Machines for the preparation of agricultural produce for market. — Several threshing machines were exhibited, each of them presenting some improved detail. There were fans and straw elevators forming part of, or working with. threshing machines or straw balers. Among the latter LEFEBVRE-ALBARET exhibited a baler which turns out bales weighing 77 to 88 lbs., and which is arranged so as to make small bales also, not exceeding 22 to 33 lbs.; and the COMPAGNIE INTERNATIONALE DES MACHINES AGRICOLES DE FRANCE exhibited a portable baler with a rapid stroke of the piston and carrying a 4 HP horizontal engine on its fore-carriage.

G. BARRAULT exhibited a pulp and straw mixer for the thorough mixing of small straw and beet pulp.

SIMON FRÈRES had a motor apple-crusher, being a combination of a small engine and a crusher on the same small chariot.

For wine making there were several labour-saving machines : MABILLE FRÈRES' *foulo-pompe* crushes the grapes and elevates them by means of a screw working in a horizontal cylinder, which, after crushing them, forces them up a vertical or inclined pipe. One of these machines driven by a 3 HP motor could crush and raise to a height of 50 feet from 12 to 15 tons of crushed grapes per hour.

Always with a view to saving manual labour many large hydraulic and motor wine presses have been built and exhibited. In MARMONIER ET MABILE'S presses the hydraulic pumps are driven continuously by a motor and a special device prevents the pressure exceeding a certain fixed limit.

In MARMONIER'S vertical pump a rapid displacement of 2.4 to 2.8 in. per minute can be obtained at first, which grows slower as the pressure increases. In MABILLE'S pump the pressure automatically rises again as soon as it has sunk owing to the flow of a certain quantity of must.

Other machines and implements. — Among pumps one exhibited by C. DUQUENNE for deep wells or borings is distinguished by a descending column of water under pressure playing the part of piston to an apparatus situated at the bottom of the well called an aspirator. GIGON exhibited an apparatus, connected with a small clock, which, on being set, will automatically discharge into a manger a previously prepared ration of fodder when the given hour is reached.

558 – **Motor Ploughing Competition of the North Kent Agricultural Association.** — *The Implement and Machinery Review*, Vol. XXXIX, No. 464, pp. 1089-1092. London, December 1, 1913.

On November 5, 1913, a motor ploughing competition was held by the North Kent Agricultural Association at Farningham, at which the following four machines competed, the prize offered being a gold medal;

Saunderson's « Universal » Model G, 18 to 20 H. P. agricultural motor and a Howard 3-furrow B. Z. plough,

The Ideal Agricultural Motors Co's « Ideal » agricultural motor and a Howard 4 furrow plough.

The « Stock » self-contained 6-furrow motor plough.

The « Ivel » old pattern 20 H. P. agricultural motor with a Cockshutt « Kid Kangaroo » 3-furrow plough.

To each machine a portion of land in the same field was allotted. The land was substantially of identical character throughout the four portions. The depth of the ploughing was in all cases approximately 7 inches and the quality of the work was fair. The consumption of fuel after running two hours was measured.

In making their award the judges made the question of first cost and economy of working an important factor. The other points on which the judging was based were: Acreage ploughed in a given time, quality and depth of work, weight on the land, fuel and oil consumption, ease of transport, simplicity of design and strength, accessibility and facility of repair, adaptability to other farm uses and ease of handling. For each point marks were awarded on a variable scale according to its relative importance. Full consideration was also given to interest on capital, depreciation, maintenance and repairs. In the results the points awarded were as follows:

« Universal »	357	« Stock »	276
« Ideal »	294	« Ivel »	158

The following table gives the principal results obtained at the trial:

	« Universal »	« Ideal »	« Stock »	« Ivel »
Price . . .	£ 267	£ 650	£ 1 050	£ 365
Acres ploughed in 2 hours. .	1	1	2 ¼	¾
Fuel consumed . . paraffin.	44 pints	—	—	36 pints
Fuel consumed . . petrol. .	2 »	52 pints	—	5 »
Fuel consumed . . benzol .	—	—	68 pints	—
Cost per day	£ 1 18*s* 0*d*	£ 2 12*s* 0*d*	£ 5 6*s* 4*d*	£ 2 0*s* 8*d*
Cost per acre.	4*s* 9*d*	6*s* 6*d*	5*s* 10*d*	7*s* 8*d*

559 – **New Hand Drills** (1). — Von Rümker in *Deutsche Landwirtschaftliche Presse*, Year XXXXI, No. 33, p. 409 + 1 fig. Berlin, April 25, 1914.

The writer points out the advantages of two hand drills (for one and two rows) and one machine for sowing single grains in holes, built by him and by H. Leidner.

The advantages of the drills consist in their continuous work, in their easy management and their suitableness for all seeds and methods of sowing. They allow a very uniform distribution of seed, even with small quantities per unit of surface ; they do not crush or otherwise injure the seed and they can be instantly emptied by tilting over. The two-

(1) See: No. 1207, *B.* Aug. 1912. (*Ed.*).

row machine allows of the rows being from 3 ¼ to 16 inches apart and it is so constructed that the seed can flow into only one funnel if so required. The field to be sown does not require any other preparation than that which is usual for team-hauled drills, nor is any harrowing required after drilling.

The marker is especially suitable where grains have to be sown singly. With three or four assistants upwards of 50 000 seeds can be sown per day.

These machines will be found especially useful in plant-breeding establishments, in gardening and forestry, and in scientific institutions where varieties are tested, and in general in all cases in which continuous and perfect seeding is required. The prices of the machines are the following: - One-row drill £5 8*s*, the two-row drill £7 7*s*, and the marker or single-grain seeder £9 16*s*.

560 – **Fletcher and Becker's Fruit Grader.** — *The Implement and Machinery Review*, Vol. XXXIX, No. 464, p. 1072. London, December 1, 1913.

The grading of fruits by machinery ensures a more rapid and uniform separation than when this work is done by hand, but some machine graders are liable to damage delicate fruit. With this new grader (see fig. 3, facing p. 808), however, bruising seems to be impossible. Apples, tomatoes, gooseberries and similar fruit can be separated into four grades at the rate of two bushels a minute and cleaned at the same time.

Each grading surface is composed of indiarubber belting, in which suitable sized holes are punched, laced round two rollers, and three such units at varying heights form the bottom of the main trough of the machine. Any of these belts can be quickly removed and replaced by others having smaller or larger holes. The rollers carrying the belts are driven by chain and sprocket gearing actuated by the operator, who stands at the hopper end of the machine.

The fruit as it is carried along by each belt comes into contact with suspended cleaning brushes, which also help the separation, the smallest size falling upon the first packing table and the largest passing out at the far end of the machine.

The packing tables are made of canvas and held in strong wooden framing; their height may be easily regulated.

561 – **"Germania" Potato Esicator with Oil Heating.** — *Maschinen-Zeitung*, Year 12, No. 4, p. 45. Berlin, February 15, 1914.

The Association of German Potato Dryers recently tested the two-cylinder potato esiccator "Germania" at the potato flake factory at Löbnitz near Cöthen. According to Prof. Parow's report the trial was very satisfactory.

The special character of this esiccator is that the cylinders are not heated by steam but by oil at a temperature of 250° C. (482° F.), heated in a special boiler, and then pumped into the cylinders. The work is quite free from danger, as the ignition point of the oil is 340° C. (734° F.) and neither the boiler nor the pipes have to bear any pressure. The return of the oil to the boiler is also very simple.

The whole plant, without woodwork and masonry, costs about £800. About £40 worth of oil is required.

562 – **The Manufacture of Agricultural Machines and Implements in Russia in 1911.** — *Landwirtschaftliche Maschinen u. Geräte*, Year 14, No. 13, pp. 15-22 and 40. Artern, Prov. of Saxony, March 28, 1914.

In 1912 the statistical division of the Bureau for Agricultural Machinery at St. Petersburg, considering it necessary to know the present state of the manufacture of agricultural machines and implements in Russia, collected material by enquiries addresed to manufacturers, to factory and Inland Revenue inspectors, to the Customs Department and to others, and has now published a book on the subject under the title: "The manufacture of agricultural machines and implements in 1911 and their importation into Russia.".

In spite of the great competition of foreign countries, the machine industry has developed of late years to such an extent that in 1911 it was in a position to place on the home market £6 502 400 worth of machines and implements, the output of factories, small workshops and private artisans being included in this sum. According to the enquiry, about 820 factories build agricultural machinery ; of these 665 are situated in European Russia, 110 in Poland, 37 in the Caucasus and 8 in Siberia. Their total output amounted in 1911 to £5 320 017. Table I shows the number of factories and the value of the machines built by them.

From this table it will be seen that the agricultural machine industry is most developed in South Russia, in the so-called New Russia and in the Northern regions. This is due, on the one hand, to the facilities for providing the raw material, iron and steel, and on the other to the demand for improved equipment in those districts.

The above sum of £5320 017 is distributed among the various groups of machines as follows:

TABLE II.

	£
Tillage implements	954 530
Sowing machines	804 500
Harvesting machines	1 312 321
Threshing machines	713 360
Cleaning and grading machines	239 796
Machines for preparing fodder	146 225
Gins and transmissions	298 053
Power motors	324 062
Other machines and implements and duplicate parts	527 170
	£5 320 017

Among the tillage implements, ploughs represent, about three-fourths of the total value. They are built in almost every "government", but especially in Southern Russia, where they were already manufactured on a large scale in the seventies of last century. The total number of ploughs built in Russia in 1911 may be set down at 650 000. The exact number and value of machines and implements constructed by private artisans

TABLE I.

Territories and "governments"	Number of works	Value of otuput £
Central agricultural territory: Kursk, Orel, Rjasan, Tambov, Tula, Voronesh	73	341 825
Middle Volga: Saratov, Simbirsk, Pensa, Nijni-Novgorod, Kasan, Ufa	63	169 168
Lower Volga: Samara, Orenburg, Astrakhan	9	19 243
New Russia: Bessarabia, Kherson, Taurida, Yekaterinoslav, Don province	157	2 876 913
South west: Kiev, Podolia, Volhynia	68	170 860
Little Russia: Kharkov, Poltava, Chernigov	40	436 242
Industrial district: Vladimir, Moscow, Kaluga, Tver, Yaroslav, Kostroma	48	328 715
White Russia: Minsk, Moghilev, Vitebsk, Smolensk	47	47 050
Lithuania: Vilna, Kovno, Grodno	11	48 953
Lake district: Pskow, St Petersburg, Novgorod, Olonets	9	10 573
Baltic provinces: Livonia, Courland, Esthonia	39	286 634
Urals: Vyatka, Perm	100	94 945
North: Vologda, Arkhangelsk	1	—
In 50 governments of European Russia	665	4 831 121
Poland: Warsaw, Kalisz, Kielce, Lomza, Lublin, Pietrkow, Plock, Radom, Siedlce, Suwalki	110	437 088
Caucasus: Kuban, Stavropol, Terek, Tiflis, Erivan	37	43 455
Siberia: Tobolsk, Tomsk, Amur prov., Lake district	8	8 353
The whole of Russia	820	5 320 017

cannot be easily determined; still, from enquiries made, their value may be estimated at about £740 000. Besides this, a number of factories

and workshops mount and repair agricultural machines, for, which they also make a certain number of duplicate parts. The value of this kind of work may be estimated at about £444 066.

The grand total of the output of the Russian factories and workshops is therefore about £6 502 400. But this is insufficient to meet the demands of the Russian farmers, who still import large quantities of agricultural machinery from abroad. According to the Customs returns in 1911 about £6 119 124 worth of foreign machines and implements were imported and in 1912 about £6 540 881. Among the imports of 1911, reapers, hay tedders and horse rakes figure for £2 524 621, threshing machines for £610 907 and scythes, sickles and forks for £264 325.

The consumption of agricultural machines has risen during the last 30 to 35 years from £845 840 to £12 581 870. In order to promote still further the use of good agricultural machines and implements, about two years ago the Russian Ministry of Agriculture set aside an area of 294 acres, near the agricultural school of Eugenfeld, for the establishment of a permament station for testing such machines. They are selected for trial by a special Bureau in St. Petersburg, which applies directly to foreign firms whose machines it wishes to test and informs them of the condition of the trials. This season most of the tests will deal with tillage machines: tractors, steam ploughs, etc.

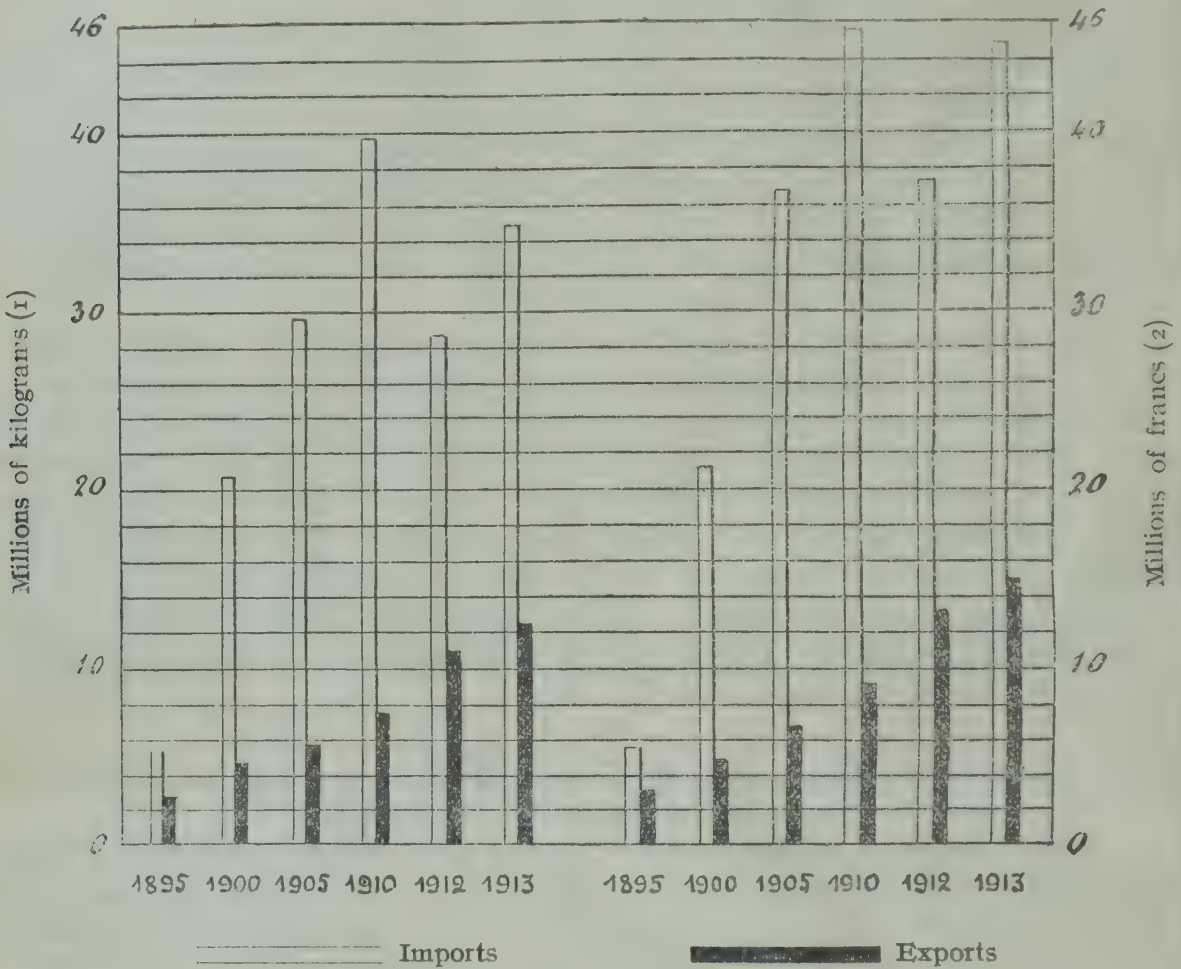
563 – **The Trade in Agricultural Machines in France.** — COUPAN, G. in *La Vie Agricole et Rurale*, Year 3, No. 18, p. 469. Paris, April 4, 1914.

There being no available statistics as to the quantities of agricultural machines and implements made in France, an idea of the development of this industry can only be formed from the statistics of the imports and exports. The annexed diagram shows the rapid increase of the imports since 1895 and the slow rise of the exports.

By far the greatest quantity of agricultural machines and implements imported into France come from the United States, namely from 55 per cent. in 1895 to 69 per cent. in 1912. The next most important country in this connection is the United Kingdom (37 per cent. in 1895 to 10 per cent. in 1912) followed by Germany, from 5 per cent. in 1895 to 10.5 per cent. in 1912.) As for the kinds of machine imported, mowers, reapers and binders occupy the first place. During the first 10 months of 1912 and of 1913 they amounted to about 70 per cent. of the total imports.

French machines are exported to many countries, chiefly however to the French colonies and protectorates.

French imports and exports of agricultural implements.



(1) 1 million kilos = 2 204 620 lbs.
(2) 1 million francs = £39 648 16*s* 8*d*.

564 – **Imports and Exports of Agricultural Machines and Implements into and out of Germany in 1913.** — *Maschinen-Zeitung*, Year 12, No. 4, p. 42. Berlin, February 15, 1914.

The following table shows the numbers and value of the most important agricultural machines imported into and exported from Germany during the year 1913:

	Imports		Exports	
	No.	Value £	No.	Value £
Threshing machines	526	—	20 189	441 176
Iron ploughs	5 362	—	292 610	653 593
Ploughs for power motors	268	—	326	—
Mowers and reapers	50 638	1 176 468	6 508	—
Milk separators	33 055	133 803	45 892	196 078
Machines for breweries, distilleries, and sugar, lime, clay and cement factories	—	24 510	—	1 862 741
Other agricultural machines	—	133 803	—	1 568 624

565 – Review of Patents

Tillage machines and implements.

Austria,	64 488. Toothed wheel gear for internal combustion ploughing machine.
	64 489. Spur wheel for steam plough traction engines, motor ploughs and the like.
	64 821. Hoeing apparatus.
Belgium,	262 502. Plough mouldboard with rollers and conveyers.
France,	464 667. One-way plough with metal beam.
	456 191. Motor plough.
	464 058. Motor tractor plough.
	464 232. Attachment for motor ploughs and the like.
	463 000. Double gang plough in which the turning, fixing and adjusting is done automatically by the team.
	463 001. Motor plough.
Germany,	272 006. Apparatus for driving agricultural machines by electric power.
	272 050. Hoe for agricultural motors.
	272 204. Driving wheel for motor ploughs in which skidding is prevented by radially moveable spuds worked by an excentric.
	272 538. Hoeing machine.
	272 539. Hand tilling implement.
	272 540. Device for simultaneous and uniform raising and lowering of plough shares in motor ploughs with revolving beam.
Hungary,	61 852. Plough drawn by electric power.
	61 947. Tilling machine.
	62 053. Motor ploughing apparatus.
	62 192. Hoeing machine.
Italy,	130 979. Ploughimg machine.
	132 899. Improvement in harrows.
	134 585. Improved coulter for ploughs.
	135 964. New non-skidding wheel for ploughing and other agricultural machines.
	137 552. Cultivator.
Switzerland,	63 482. Device for adjusting the gage of plough wheels while working.

566. - **The Shower-Bath System of Sheep Dipping.** — *The Implement and Machinery Review*, Vol. XXXIX, No. 468, p. 1660. London, April 1st, 1914.

BUILDING CONSTRUCTION

The accompanying illustration shows the new shower-bath system of sheep dipping, which appears to be finding favour in Queensland. It consists of a shed 40 ft. long by 12 ft. wide, the roof of which is of flat, perforated iron sheets. The dip is pumped by a 3 in. centrifugal pump

from a tank to the roof and falls through the perforations on to the 200 sheep beneath, the shower lasting about seven minutes. The roof edges are turned up to prevent the dip running off and the sides of the shed are enclosed to obviate the blowing about of the dip. There are about 35 holes to the square foot.

This method is proving entirely satisfactory, the cost in one case being stated to be ½ *d* per head. One thousand sheep per hour can be dipped without undue haste by four men.

RURAL ECONOMICS.

567 – **The Economic Importance of Beet Growing.** — SAGAWE, B. in *Archiv für exakte Wissenschaftsforschung*, Vol. 6, Part I, pp. 157-209. Jena, 1914.

The writer examines and discusses the importance of beet growing, and investigates the soundness of the frequently recommended principle: " extensiv organisieren und intensiv kultivieren " (cultivate intensively in extensive farming) which tends to increase the growing of forage plants at the expense of beets.

He mentions first the results of some investigations into the labour required for growing beets by WATERSTRADE, WERNER, DETTWEILER and LANGENBECK, wherein it is shown without exception, that the amount of labour in a farm increases with the proportion of the land under beets. On the other hand the results do not agree as to the difference of the amount of labour required in the most intensive and the most extensive farms. Before diminishing the acreage of beets in favour of forage crops in order to overcome the difficulty of procuring labur, it is necessary to have a clear idea of the consequences of such a change and of the other economic factors involved in beet growing, such as its profitableness, its value as a source of forage and its effect upon the utilization of labour.

All investigations made up to the present have shown that beet growing is one of the most important elements of profits of farms in arable districts. In part 180 of the *Arbeiten der Deutschen Landwirtschafts-Gesellschatf* (Transactions of the German Agricultural Association) LANGENBECK examined the effect of the acreage of root crops on farming conditions in 42 farms and came to the conclusion that the increase of root crops leads to the increase of live stock, to the increase of the value of the dead stock, to the increase of the outlay on artificials, concentrated foods, and salaries and to the increase of the returns from animal and vegetable products, of the net returns and of the capital invested. Part 214 of the *Arbeiten der D. L. G.*, dealing with farming in Silesia, as well as some previous work of the present writer on the profitableness of root crops (1), lead to the same results. The statististics of the Silesian Chamber of Agriculture show that when the farms are arranged according to the percentage of their area devoted to beets the same conclusion is reached. (Table I).

(1) See No. 407, *B.* April 1913. (*Ed.*).

TABLE I.

Root crops per cent of area	Total value per acre	Gross returns per acre	Outlay per acre	Net returns per acre	Interest per cent
	£ s d	£ s d	£ s d	£ s d	
1910-1911					
Under 15	33 2 6	4 14 5	4 17 1	5 2	0.8

Above 25	51 11 7	9 16 10	7 13 11	2 11 7	5.0

In their work on the returns of Moravian peasant farms (*Ertragsfähigkeit der mährischen Bauernbetriebe*, Brünn 1911) HOWARD and OSTERMAYER come to the same conclusion: that the rate of interest yielded by the capital invested depends directly upon the acreage of the root crops.

The question of the consequences of substituting forage for beet crops can only be correctly solved by a careful comparison of the amount of forage produced by the two crops. The writer makes this comparison, calculating the cost of the forage supplied by both according to their technical food value, and using the values of HOWARD and OSTERMAYER for the purpose. He assumes the leaves of beetroots to be one third of the crop, that the ratio of grain to straw is 1 : 2 in wheat and rye, 1 : 1.5 in oats and 1 : 1.33 in barley, and finds that the cost of production of one hundredweight of food units is as follows:

	According to Howard	According to Ostermayer
	s d	s d
Winter wheat	6 10	7 5
Winter rye	7 1	8 0
Barley	6 8	6 7
Oats	7 6	7 4
Beets	4 4	3 8
Mangolds	— —	8 10
Potatoes	7 11	9 2
Clover hay	— —	4 8
Meadow hay	— —	4 10

According to the above, beets produce the cheapest food units, cheaper than meadows and clover leys. But the question arises whether beets should be compared to hay or rather to fresh clover and grass, as in making hay a considerable loss of food units takes place and the cost of production increases. But as it is generally impossible to feed all the clover and meadow grass in its fresh condition, the writer is of opinion that the comparison of beets and forage plants should not be made between the former and hay, nor between the beets and the green food, but between the food value of part green food, part hay on the one hand and of beet leaves in the state in which they are utilized on the other. Not the quantity at the time of the harvest but the available quantity in the condition in which it is fed, should be calculated, because a certain loss of food units takes place during the storage of roots and leaves. On this plan, the writer has calculated the cost of production of forage, in the state in which it is fed, from twelve yearly accounts of several Silesian farms in different years, and determined the price of one hundredweight of food units in:

	s	*d*
Clover	3	0
Lucerne	3	2
Beets	4	4
Meadow grass	4	9
Mangolds	7	10
Potatoes	7	10 ½

from which it appears that the food unit in beets is dearer than in clover and lucerne, but cheaper than that of meadow grass.

The exclusive consideration of market prices leads to erroneous conclusions, as does the neglect of the unmarketable products produced on a farm, for the farm itself must be considered as the market. The valuation on physiologico-economical basis (1) is also erroneous, because by this method the price of the starch unit delivered at the farm is taken as basis, and thus the unmarketable products are given a value plus cost of carriage, while the marketable ones get a value minus the same. But apart from this it is a mistake to make the starch unit the basis of the price of foods which are not sold in the condition in which they are fed, for this way of valuing, though correct from the physiological point of view, is unsound from the economic point of view, because the unmarketable field products can only be made marketable by means of live stock.

The profitableness of beet growing is much influenced by the valuation of its by-products. If beet leaves could be sold on the market, their value on the farm would be the market price minus cost of carriage. If, therefore, their value is to be calculated from the market prices of the marketable foods, from every hundredweight of the farm forage the cost of transport per cwt. of marketable food must be deducted; the actual cost of carriage of the marketable food must not be set off against the total quantity

(1) See No. 166, *B.* Feb. 1914. (*Ed.*).

of the unmarketable produce. But for beet leaves it does not seem advisable to take the marketable foods as basis of their valuation, on account of the interdependance of beet growing and live stock for the production of stable manure and forage. Beet leaves must therefore be sold to the live stock at a price which leaves a margin of profit for the beet account. This intermediate value of farm bye products varies according to food units, or price per unit in marketable foods minus the cost of carriage per hundredweight, and the minimum value or manurial value plus cost of storage.

The writer then discusses the intimate connection between live stock and beet growing for the utilization of farmyard manure, and shows that from this point of view also a substitution of forage crops for beet would be equivalent to buying dearer forage and getting a lower value for the farmyard manure, and would result in a decrease rather than an increase in the profits from the live stock and consequently from the whole farm, provided that the growing of beets had not yet exceeded its most profitable limits.

With the increased acreage of beet, the utilization of labour improves. The writer proves this by classifying the farms which send their books to the book-keeping office of the Silesian Chamber of Agriculture according to the acreage devoted to beets, and calculates the ratio of outlay on labour to gross returns (Table II).

TABLE II. — *Wages in percentage of gross returns.*

Year	Acreage in root crops				
	less than 15 %	15-20 %	20-25 %	25-30 %	above 30 %
1910-11	39	35	31	28	26
1909-10.	41	36	32	27	23
1908-09.	35	36	31	27	60
Average . . .	38	36	31	27	23

The larger the relative acreage of root crops the smaller the outlay on wages required for the same gross returns. This result is due to the well known fact that with increasing intensity of farming labour diminishes in relation to the capital invested. The higher absolute outlay on labour is justified by the increasing profits of the farms, the means of which for the three years amount to 1.1, 2.8, 3.8, and 5.2 per cent. respectively for the first four groups.

The same results are obtained from farms under the book-keeping control of the D. L. G. using LANGENBECK's and OSTERMAYER's figures. In order to show that these results are not due to the improvement in the quality of the soil and in the economical conditions of the beet farms rather than to the increase of root crops, the writer shows that by grouping the farms according to their increasing total value, the amount of labour employed in the D. L. G. farms shows no difference, that the figures of the Silesian farms show an increase in the amount of labour employed but

that the increase is quite insufficient to account for the fall of the ratio with the increased acreage of root crops.

The statement that beet growing is often pushed beyond its most profitable limits is not confirmed by the results of the accounts, which show that the interest on the capital invested still gives an increase when the root crops attain upwards of 35 per cent of the total acreage, notwithstanding the fact that the proportion of net returns to gross returns or the factor "value according to returns" (Ertragswert) appears to reach its highest limit with about 30 per cent. of the total acreage under roots. In order to determine the optimum limit of any crop which has reached the ultimate profitable limit of outlay, it is not enough to consider only the absolute value of the net returns or the ratio of outlay to gross returns, but rather the rise or fall of the rate of interest on the total capital. The figures calculated on these lines for the D. L. G. farms show that cereal crops reach the optimum limit of profitableness and in the use of labour at about 60 per cent., while root crops attain this same limit at about 30 per cent. with regard to the use of labour but not with regard to the highest rate of interest. It follows that such districts as do not seem especially suitable to extensive forage crops on account of their position and natural conditions should only devote a relatively small percentage of their area to these crops.

568 – **The Consumption of Artificial Manures in Intensive Agriculture.** — HAGMANN in *Landwirtschaftliche Zeitschrift für die Rheinprovinz*, Year 15, No. 16, pp. 315-316. Bonn, April 17, 1914.

One of the most valuable means of judging the degree of intensity of the cultivation of a farm is a knowledge of the kind and amount of the artificials used on it; thus the average outlay on artificials in the year 1912-13 on 36 farms in the Russian Baltic provinces was 2*s* 6*d* per acre of cultivated land, on 145 farms in East Prussia 7*s* 4*d*, and on 18 intensive farms of the Rhine province £1 5*s* 4*d* per acre. These figures afford a better index of the degree of intensity than any other item of expenditure.

In the total outlay for the Rhine province, nitrate of soda and sulphate of ammonia amount to 6*s* 5*d*, "Ammoniaksuperphosphat" (a mixture of superphosphate and sulphate of ammonia) to 12*s* 10*d*, superphosphate and basic slag to 2*s* 4*d*, potash salts and kainit to 2*s* 5*d*, and lime to 1*s* 4*d*. If these figures be classed according to the percentage of the various elemental plant nutrients, it will be found that nitrogen represents about 60 per cent., phosphoric acid 25 per cent. and potash and lime each 15 per cent.

The two principal sources of nitrogen are farmyard manure and artificials. The question of the best proportion in which these two are to be used is of great importance with regard to the profitableness of the whole farm. As the number of live stock kept increases, the necessity of supplying nitrogen in the form of artificials decreases, as is shown in the 18 Rhineland farms which are divided into two groups according to the amount of live stock kept, with the following results (Table I):

Groups	Number of farms	Live stock per ahie		Outlay for artificials per acre					
		Total	Cattle	Total	Nitrate of soda and sulphate of ammonia	Superphosphate of ammonia	Superphosphate and basic slag	Potash and kainit	Lime
		£ s d	£ s d	£ s d	£ s d	£ s d	£ s d	£ s d	£ s d
I	9	8 1 1	4 9 8	1 1 0	0 5 8	0 10 10	0 1 11	0 1 11	0 0 8
II	9	5 19 5	2 11 12	1 9 7	0 7 1	0 14 11	0 2 11	0 2 12	0 1 11

The outlay on artificials is much greater in group II than in group I and especially is this the case for nitrogen. The gross and net returns are very similar in both groups, as the difference in the amount of live stock kept is not large. If, however, farms are taken where the difference is greater, the influence of the live stock on the amount of fertilizers purchased, especially of nitrogen, as well as on the profitableness of the farm is more evident. The writer has taken from the *Arbeiten der Deutschen Landwirtschafts-Gesellschaft*, Part 130, the figures relating to 20 sugar-beet farms in Saxony, 10 of which keep much live stock and the other 10 only a limited quantity, other conditions being equal. It appears that the first group, which keeps 31.56 units of live stock per 100 acres buys 337 lbs. per acre of nitrate of soda and sulphate of ammonia annually, while the second group, which keeps only 12.54 units per 100 acres, consumes every year 713 lbs. per acre. The consumption of « Ammoniaksuperphosphat » is approximately equal, *viz.* 301 lbs. per acre in the first group and 298 lbs. in the second. The net returns are £4 4*s* 11*d* per acre in the first group and £2 12*s* 5*d* in the second. The above figures prove clearly that the net profits are connected with the quantity of live stock kept on the farm and increase with it. The writer is therefore of opinion that in every farm where large quantities of nitrogenous fertilizers are bought regularly, it should be ascertained whether the amount of live stock could not be increased and the amount of purchased fertilizers correspondingly decreased.

AGRICULTURAL INDUSTRIES.

DAIRYING

569 – **Determination of the Viscosity of Milk as a Means of Detecting the Addition of Water.** — KOOPER, W. D. (Communication from the Laboratory of GERBER Co. LTD., Leipzig) in *Milchwirtschaftliches Zentralblatt*, Year 43, Part 7, pp. 169-179 and Part 8, pp. 201-208. Hanover, April 1 and 15, 1914.

The writer examined 50 different mixed milks, with the object of investigating the question of utilizing the viscosity of milk as a means of detecting the addition of water. The fat content and specific gravity

were determined at the same time by the Gerber and lactometer tests respectively, and the total dry matter was calculated from these values by Fleischmann's formula. The viscosity was determined by means of a specially constructed burette-shaped apparatus. This was first filled with distilled water, then with milk; for both, the time required for the outflow of 10 cc. was observed.

$$\text{Viscosity constant, V} = \frac{\text{outflow of milk, time in seconds}}{\text{outflow of water, time in seconds}}$$

In order to get comparable results, the tests must be carried out at uniform temperature, differences of 0.5° C. (0.9° F.) having a perceptible effect, and the bore of the outlet must be adjusted so that the outflow be neither too fast nor too slow. The milk must be thoroughly well mixed before being poured into the burette, without subjecting it to too violent shaking which might cause a change in the natural viscosity of the liquid. The time required for the outflow must be determined with precision to within one-fifth of a second.

A high viscosity constant is usually associated with a high fat content, but the rule is not infallible, nor is the ratio of the specific gravity to viscosity constant more reliable. On dividing the average viscosity constant (1.588) by the average dry matter of the milk (11.472 per cent.), the factor 0,1384 was obtained, and if there be any constant relationship whatever between viscosity and dry matter content, the dry matter of any one sample (or T) should be given by the formula :

$$\frac{V}{0.1384} = T$$

On comparing values thus obtained with those obtained by using the Fleischmann formula for the 50 samples investigated, it appeared that the greatest divergence between the two methods amounted in one case to 0.36 per cent. All the other samples showed smaller differences, so that the writer concluded that a direct relationship existed between variations in the viscosity and the dry matter content of milk.

In using the viscosity constant for detecting the addition of water to milk, experiments showed that under certain conditions watered milk can yield the same viscosity constant as unadulterated milk, in which case the value obtained for T is too high; the greater the amount of water added to the milk the greater is the difference between the real and calculated value for dry matter, owing to the fact that the watering causes the amount of dry matter to diminish more rapidly than the viscosity constant. If a milk for instance with 11.472 per cent. of dry matter and a viscosity constant of 1.588 be mixed with an equal quantity of water, the percentage of dry matter would be reduced to $\frac{11.472}{2} = 5.736$; but the viscosity constant would only be reduced to about $\frac{1.588 + 1}{2} = 1.294$. From this :

$$T = \frac{V}{0.1384} = \frac{1.294}{0.1384} = 9.349 \text{ per cent.};$$

that is, the difference between the real and calculated values for the dry matter would be :

$$9.349 - 5.736 = 3.613 \text{ per cent.}$$

The difference between the amounts of dry matter determined by the two methods therefore affords an easy and rapid way of ascertaining whether milk has been watered, and if so to what extent. The writer recommends that the question be further investigated.

570 – **Biorized Milk** (1). — KLUNKER, chief physician to the Institute of Hygiene at the University of Jena, in *Molkerei Zeitung*, Year 28, No. 33, pp. 625-626, No. 34, pp. 639-640. Hildesheim, April 29, May 1, 1914.

The above paper is a preliminary communication of an investigation of LOBECK'S milk sterilization process, carried out at the Institute of Hygiene, University of Jena, with an experimental apparatus capable of treating 2.64 gallons per hour. Samples of biorized milk from Leipzig, Chemnitz and Düsseldorf, where the process is in use, were sent for comparison, and the results obtained are as follows :

1. The whole apparatus is easy to handle, to dismount, to clean and to disinfect. The daily initial loss of milk is very small.

2. The biorized milk (called by LOBECK "enzyme-milk") is equal in colour, appearance, smell and taste to the best raw milk.

3. This milk is somewhat less easily skimmed than raw milk, but at the temperatures employed, *viz.* 131 and 135° F., the difference is so small that it would be imperceptible to consumers. Equally good results can only be obtained with heated milk if the temperature be kept below 113° F. and the heating be continued for half an hour ; no milk pasteurized in any other way approaches biorized milk in this respect.

4. The original enzymes (oxydases) of natural milk are not influenced by biorization ; the milk proteins undergo no change. On the other hand coagulation proceeds more slowly but is not weakened.

5. Biorization causes such a decrease in the germ content that the keeping quality of the milk is more than doubled. As moreover the heating to 131 and 135° F. does not destroy the lactic acid producers, there is no danger that the milk will be spoiled while on sale by the prevalence of spore-forming bacilli. Biorized milk can therefore compete with fresh, cleanly milked raw milk as food for babies.

6. Disease-producing germs, such as typhus, paratyphus, diarrhoea, cholera and diphtheria bacilli, are destroyed with absolute certainty. The destruction of the tubercle bacilli is less certain, but experiments seem to indicate that they do not resist the treatment.

The new process would appear to mark a distinct forward step towards supplying a hygienic, wholesome milk to the public..

(1) See: No. 743, *B.* June 1913; No. 1190, *B.* Oct. 1913; No. 1389, *B.* Dec. 1913. (*Ed.*)

571 – **The Effect of Certain Dairy Operations upon the Germ Content of Milk.** — HARDING, H. A., RUEHLE, J. K. etc., *New York Agricultural Experiment Station, Bulletin* No. 365, pp. 197-233. Geneva, N. Y., August 1913.

Bacterial counts were made in milk samples produced under various conditions of hand-milking. Neither plastering nor whitewashing the byre, nor clipping the udder and flank of the cows, nor the use of a vacuum machine for cleaning the cows preparatory to milking, seemed to have any effect on reducing the bacterial content of the milk; in fact the opposite effect was usually observed. A series of tests carried out on samples drawn from the milking pail, from the cooler, and after final straining, indicated that the germ content of the milk was not increased by the handling it received on the farm subsequently to the milking operation.

572 – **The Origin of Some of the Streptococci Found in Milk.** — ROGERS, L. A. and DAHLBERG, A. O. (Bureau of Animal Industry) in *Journal of Agricultural Research*, Vol. I, No. 6, pp. 491-511. Washington, D. C., March 1914.

A collection of cultures of streptococci was made, of which 42 were isolated from normal milk, 51 from infected udders, 114 from bovine faeces, and 39 from the mouths of cows. These were all subjected to a large number of tests and tabulated according to their behaviour on gelatine and in media containing dextrose, lactose, saccharose, raffinose, starch, inulin, mannite glycerin, dulcite and adonite. The cultures fall into groups according to the nature of the material from which they were originally isolated.

WINE-MAKING.

573 – **Improvement of Damaged Wines and Spirits.** — ZWEIFLER, F. in *Allgemeine Weinzeitung*, No. 18, pp. 185-186. Vienna, 1914.

The writer carried out some experiments on the improvement of damaged wines at the Agricultural Experiment Station of Marburg (Styria), during which the following results were obtained.

1. A turbid highly coloured wine with a musty odour and taste was treated with sesame oil, but ineffectually. On increasing the dose of oil the smell of the latter was communicated to the wine. On adding 0.16 oz. of Eponit (1) per gallon of wine and filtering it after six days, the wine became light coloured and clear, and tasted clean.

2. Another wine that had become dark brown was treated with 0.008 oz. of sodium bisulphite, 0.0096 oz. of gelatine and 0.008 oz. of tannin per gallon, with the result that the colour became clear and the wine kept well. Equally good results were obtained by using 0.064 oz. of Eponit and 0.008 oz. of sodium bisulphite alone.

3. A sour turbid wine with a taste of the cask (total acidity 12.7 per thousand) on being treated with 0.24 oz. of precipitated carbonate of lime, 0.0192 oz. of gelatine and 0.016 oz. of tannin per gallon, became clear and mild and pleasant to the taste. Sesame oil had no other effect than that of imparting its smell to the wine.

(1) "Eponit" is a vegetable charcoal, a new clarifier which has given good results. It is sold by the AKTIEN GESELLSCHAFT DER OESTERREICHISCHEN CEREIN FABRIK, late H. UJHELY AND Co., of Stockerau near Vienna.

4. White wine made with red grapes was decoloured in order to blend it with another white wine. In one case 0.12 oz. of Eponit per gallon was sufficient, while another wine required 0.16 oz. per gallon.

5. Two plum brandies which had become black were clarified, one with tannin and gelatine, and the other with skimmed milk; the results were imperfect in both cases, while 0.368 oz. of Eponit, though working slowly, rendered the brandy perfectly clear and its taste quite clean. An equally good result was obtained by adding water to the brandy and redistilling it.

PLANT DISEASES.

GENERAL INFORMATION.

LEGISLATIVE AND ADMINISTRATIVE MEASURES

574 – **Decree Placing *Mytilaspis citricola* (= *Lepidosaphes beckii*) amongst Notifiable Insects in Uruguay.** — *Revista de la Asociación rural del Uruguay*, Year XIII, No. 12, p. 883. Montevideo, 1913.

At the request of the " Defensa Agrícola ", and on evidence of damage caused by this insect to orange plantations in certain districts, the President of the Republic issued a decree, dated October 25, 1913, that *Mytilaspis citricola* (*Lepidosaphes beckii*) should be classed as an insect injurious to plants according to art. 7 of the law of October 21, 1911.

DISEASES NOT DUE TO PARASITES AND OF UNKNOWN ORIGIN.

575 – **Observations and Researches on "Dörrfleckenkrankheit" (Dry spot Disease) of Oats.** – HILTNER, L. in *Praktische Blätter für Pflanzenbau und Pflanzenschutz*, Year 12, Part 3-4, pp. 28-41, 1 fig. Stuttgart, March-April 1914.

A disease of oats generally called " Dörrfleckenkrankheit " has been observed in various districts in North Germany during recent years and has frequently appeared in Holland, Denmark and Sweden. The leaves develop normally at first, but fairly early lose their turgescence at the bends ; the wilted portions soon change colour and perish. If the disease appears when the plants are young, as is often the case, the yield of the crop is greatly reduced, since many of the panicles do not emerge from their sheaths.

The disease has been attributed either to a fungus, *Scolecotrichum graminis*, or to root nematodes, or to the frit fly (*Oscinis frit*). The majority of observers, however, consider it due to unfavourable soil conditions, particularly the percentage of lime.

Pot culture experiments carried out by the writer (Director of the Agricultural Botanical Station of Munich) show that : 1) the disease apparently does not occur on compact clay soils ; 2) it appears in cultures

of ordinary garden soil containing lime, without direct addition of lime ; 3) treatment of this soil with carbon disulphide does not prevent the outbreak of the disease ; 4) no disease appears on soil treated with quicklime and carbon disulphide, but carbonate of lime and carbon disulphide are without effect in checking the disease. The effect of the quicklime in combination with carbon disulphide is accounted for by its action on the increased ammonia produced after the treatment with carbon disulphide, resulting in increased nitrification and the formation of calcium nitrate.

In field cultures the disease increased considerably after abundant rain ; this causes the formation of bicarbonates of soda and potash by double decomposition of alkaline salts with the carbonate of lime in the soil.

Water cultures lead to the conclusion that the disease is not caused by the presence of lime itself, but by the resulting decomposition products formed either in the soil or in the leaves of the oats. The researches show that : 1) in nutritive solutions containing monopotassium phosphate, normal development of the oat and other plants is impossible when the solution is made with un-neutralised tap-water containing lime ; chlorosis develops rapidly owing to the alkalinity of the surface-film of the solution, and the functions of the roots are checked ; 2) in Knop's solution made with Munich tap-water neutralised with sulphuric acid, the oat plants develop relatively better, but the leaves are subject to the disease ; the chemical decomposition causing the alkaline reaction evidently takes place in the leaves in this case ; 3) since the addition of monopotassium phosphate to garden soil containing lime can cause the development of the disease in oats, it is concluded that as in the case of water cultures, the appearance of the disease is determined chiefly by the alkaline decomposition products formed in particular by the action of the bicarbonate of lime.

The different varieties of oats show varying degrees of resistance to the disease. Pot cultures have shown that the variety Leutewitzer Yellow is more resistant to the frit fly than Fichtelgebirg, and that it remains free from disease in garden soil rich in lime, whilst Fichtelgebirg is badly attacked. In soils poor in lime the disease does not appear in either variety. The writer considers the yellow varieties less susceptible to the metabolic disturbances which give rise to the disease. The fungus *Scolecotrichum* appears later on all the diseased plants, but it cannot be the cause of the disease since it is only developed to any considerable extent on certain types of soils.

The functional disturbances of the leaves may be prevented by spraying with a solution of iron salts. A diseased culture of Fichtelgebirg oats was effectively cured after four sprayings with ½ to 2 per cent. solutions of iron salts. Tartrate of iron gives the best results.

It has also been found that oats which have become chlorotic owing to the presence of alkaline substances in the nutritive medium, or which suffer from the disease owing to the formation of injurious alkaline products in the leaves, can be cured by spraying with salts of iron. This would explain the satisfactory development of oats which is often noted after spraying for wild radish with sulphate of iron.

The writer has also determined the identity of the disease known as "Hafersucht" in the Bavarian Alps, and "Holsternische Haferkrankheit" or "Moorkoloniale", with "Dörrfleckenkrankheit" The researches are being continued to determine the effects of acid and alkaline fertilizers.

576 – **The Presence of Endocellular Fibres in the Tissues of the Vine and of other Dicotyledons** (1). — MAMELI, EVA in *Atti dell'Istituto botanico dell'Università di Pavia*, Series II, Vol. XVI, pp. 47-65, plate VIII. Milan, 1914.

In this summary the writer fully confirms her preceding observations (2).

The presence of endocellular fibres is frequent, not only in the vines affected by bramble-leaf (roncet), but also in healthy ones (86 per cent.) ; vines grown in districts hitherto free from bramble-leaf and showing no exterior symptoms of this disease or of decay, may contain these endocellular fibres even in the two-year-old canes.

Between healthy vines and those suffering from bramble-leaf, there is no difference at all either in the form or in the frequency of the fibres : these may be rare or wanting altogether in both.

The formation of the fibres cannot be attributed to falls of temperature, because their presence has been ascertained by the writer in vines and other plants grown for several years in hot-houses.

The writer has found these fibres in *Vitis vinifera* L. and *V. heterophylla* Thunb., as well as in nineteen other dicotyledonous plants belonging to the most different families, so that their presence has no connection with any pathological condition of the plant which contains them. The origin and function of the endocellular fibres are in all probability mechanical.

BACTERIAL AND FUNGOID DISEASES.

GENERALITIES

577 – **Phytopathological Observations in the Grand Duchy of Baden, 1913.** – WAHL, C. von and MÜLLER, K. in *Bericht der Hauptstelle für Pflanzenschutz in Baden an der Gossherzogl. landwirtschaftl. Versuchsanstalt Augustenburg für das Jahr* 1913, pp. 70, + 5 figs., append. I and II. Stuttgart, 1914.

A list is given of the cultivated plants and their pests observed during 1913.

Phylloxera (*Phylloxera vastatrix*) was recorded for the first time in the Grand Duchy of Baden. *Conchylis ambiguella* caused serious damage, whilst the vine mite (*Phyllocoptes vitis*) and the vine tortrix (*Tortrix pilleriana*) have diminished.

American gooseberry mildew (*Sphaerotheca mors-uvae*) has spread everywhere.

Experiments on the destruction of meadow saffron (*Colchicum autumnale*) have been started ; the seeds are not distributed by irrigation,

(1) See No. 480, *B.* May 1914. (*Ed.*).
(2) See No. 1207, *B.* Oct. 1913 and No. 289, *B.* March 1914. (*Ed.*).

since they sink in water, but apparently by means of hay seeds; in 4 ½ lbs. of hay seeds 790 of these seeds were found.

Experiments on protective measures against plant pests.— Comparative trials of the fungicidal action on vine mildew (*Plasmopara viticola*) have been made with certain commercial fungicides and Bordeaux mixture. "Cerdidymsulfat", "Malacidschwefel" and "Laykoschwefel" were tried and found inferior to Bordeaux mixture. They were particularly useless against mildew in 1913, when the weather was very favourable to the disease.

Applications of 20 per cent. solutions of sulphate of iron were used against the "Grind" disease of the vine, with only partial success; the disease reappeared on the treated vines but in a less degree.

Experiments on the destruction of charlock and radish have shown again the value of a 20 per cent. solution of sulphate of iron, a dressing of kainit of about 90 lbs. per acre, and a 20 per cent. solution of "cuproazotin." (1). Calcium cyanamide at the rate of 1 cwt. per acre did not come up to expectations.

"Malacidschwefel" does not fulfil its claims in the destruction of aphids. "Urania-Grün", based on aceto-arsenite of copper, produces a more permanent suspension in water than "Malacidschwefel", but is not more effective.

Prof. Lang's "Schwefelaluminiumpatronen" were not successful against hamsters and rabbits, owing to the depth of their winter burrows, but they were effective against water voles.

Immersion of seeds in creolin, carbolineum, or formalin and coal-tar is not a safe protection against the attacks of birds. Carbolineum in 5 per cent. solution is injurious to the germinating power of the seeds.

Various observations.— The results of the investigations on the introduction of phylloxera into the Grand Duchy are not conclusive; it does not appear to have been due to winged individuals coming from Upper Alsace.

Winter spores of *Plasmopara viticola* have been found in abundance on vine leaves, and the perithecia of the powdery mildew (*Uncinula necator*) were abundant on vines near houses at Durlach.

Infection experiments on *Rhytisma acerinum*, the fungus of sycamore leaf-blotch, have confirmed former experiments, which showed that infection takes place on the under side of the leaf and not on the upper surface as maintained by Tubeuf.

The organization against plant diseases in the Grand Duchy has been still further improved by the collaboration of lecturers on fruit and vine growing, and by the creation of a station for purchasing the materials required. The Central Station for the Protection of Plants organises special visits to farms where modern methods of control are demonstrated and lectures are held to stimulate the interest of farmers in the aims of phytopathology.

FUNGI

578 – **Some Chinese Fungi** (1). — MIYAKE ICHIRO, in *The Botanical Magazine*, Vol. XXVIII, No. 327, pp. 37-56, plate I. Tokyo, March 1914.

A systematic catalogue of more than one hundred species and varieties collected by the writer in various localities during the summer of 1912. The majority were found on cultivated or economic plants. Of the seven species new to science the following are worthy of mention: *Rehmiella ulmicola*, on the leaves of *Ulmus* sp.; *Coniothyrium Tiliae*, on the leaves of *Tilia cordata; C. Spiræae*, on the leaves of *Spiraea pubescens; Septogloeum Anemones*, on the leaves of *Anemone* sp.

The following species are already known: *Gymnosporangium Yamadai* Miyake, common on leaves of *Pyrus Malus* and *P. spectabilis* near Pekin; the disease often spreads so rapidly in June and July that all the foliage turns yellow, dries up and falls; *Aecidium Mori* Barcl., on the leaves of *Broussonetia Kazinoki* and *Morus alba*, widespread and injurious in Japan; *Helminthosporium Onyzae* Miyake and Hori; from observations made by the writer, this latter fungus is not so widely distributed or dangerous in China as in Japan.

579 - **Wintering of Cereal Rusts in the Uredo Stage.** — MONTEMARTINI, LUIGI in *Rivista di Patologia vegetale*, Year 7, No. 2, pp. 40-44. Pavia, 1914.

The writer reviews the results of other workers on the persistence of the uredospore stage during the winter months. He records the fact that at Pavia and in its Province this form of rust occurs on wild and cultivated Gramineae, which continue green after harvest, and that it may reinfect the wheat plant at any time. Thus, autumn-sown wheat may be directly infected, and if the season is warm and late the disease makes its appearance. The uredo stage also appears to be able to resist several degrees of frost for many days. Further observations are required to determine the temperature which is fatal to the parasite. Under Italian conditions it seems more probable that the infection of the wheat crop takes place by means of uredospores from diseased plants during the autumn, rather than by transmission through the seed as supposed by Eriksson.

The spread of the disease is therefore influenced by the growth of grasses, the summer weather (during hot, dry summers, when grasses dry up, the uredo stage gives place to the teleuto stage), the period of sowing and the autumn and winter weather.

580 - **Inoculation Experiments on Potatoes with *Fusarium*, 1913.** — HIMMELBAUR, W. in *Oesterreichisch-Ungarische Zeitschrift für Zuckerindustrie und Landwirtschaft*, Year XLIII, Part I, pp. 1-16. Vienna, 1914.

Experiments were carried out in 1913 to confirm the results obtained in 1912 on a small scale. Inoculations were made, as in 1912, of vigorous material, using mycelium only. In addition to direct insertion in the tissues of the plant, inoculations of the soil were made in the immediate neighbourhood of the plants. The experiments were begun on the 10th

(1) See also No. 754, *B.* June 1913. (*Ed.*)

of July, and the inoculations were made on fine days between 6 and 8 a.m. in the open fields which had previously shown no sign of the disease. It was found that inoculations of the potato haulm resulted in the appearance of leaf-curl, thus proving that one form of leaf-curl in potatoes is due to infection of the haulms by the various forms of *Fusarium* (and also *Verticillium*).

581 – **A Leaf Disease of *Cycas revoluta*.** — MARCOLONGO, I, in *Rivista di Patologia vegetale*, Year 7, No. 1, pp. 6-8. Pavia, 1914.

For many years a number of specimens of *Cycas revoluta* in Naples have been attacked by a leaf-disease, characterised by small round yellow spots with dark edges, which extend until the whole segment of the leaf is yellow. A slight greenish mould appears on the underside of the leaf and thickens as the disease advances. Microscopic examination has shown that this disease is due to a new species of *Cladosporium*, provisionally described as *C. Cycadis*.

In gelatine cultures nothing has been obtained but a pycnidial form, capable of reproducing itself from the stylospores. Inoculations of healthy leaves with either the conidial (*Cladosporium*) or the pycnidial (*Phoma*) stage, have produced the characteristic symptoms of the disease.

582 – ***Cylindrosporium Juglandis* injurious to the Leaves of Walnut in Alabama.** — WOLF, A. in *Mykologisches Centralblatt*, Vol. IV, Part 2, pp. 65-69 + figs. Jena, March 1914.

During the last two years walnut trees at Auburn, Alabama, have shown a new leaf disease characterised by numerous irregular dry spots which appear on both sides of the leaf. The spots are brown in colour with a central grey spot indicating the point of infection. Some spots are uniformly brown and others become uniformly grey owing to the entrance of air below the raised cuticle. The adjacent tissue often becomes chlorotic. A single leaf may develop from 500 to 1000 or more centres of infection, which may remain distinct or may join up so as to cover the whole leaf surface. In the summer of 1912 a small plantation was so badly attacked that the trees were completely defoliated on two occasions before the normal period of leaf-fall.

The disease is caused by a *Cylindrosporium*, the fructifications of which appear on the under sides of the leaves. The fungus has been isolated in pure cultures and reproduced with success in various media, but no perithecia have been obtained in artifiicial cultures. Supposing that the conidial stage survives on the fallen leaves until the new leaves appear, it does not seem probable that perithecia are produced in the neighbourhood of Auburn. It is probable that the perfect form of this fungus could be produced under certain conditions, as in the case of other species of *Cylindrosporium*.

Experiments in 1913 showed that the disease could easily be kept in check by destroying all fallen leaves from the diseased trees, and using Bordeaux mixture on the appearance of the disease. The writer describes this fungus as *C. Juglandis*.

PARASITIC AND OTHER INJURIOUS FLOWERING PLANTS.

583 – **Experiments on the Destruction of Charlock *(Sinapis arvensis)* by Mechanical and Chemical Means.** — LEUTZ, J. VON in *Praktische Blätter für Pflanzenbau und Pflanzenschutz*, Year XII, Part 3-4, pp. 43-46. Stuttgart, March-April 1914.

The results of two years' experiments show that rolling is more effective than spraying with sulphate of iron for destroying charlock; it must be done as soon as the oats appear above ground. The rolling must be very thorough, so as to crush all the charlock seedlings, and is best repeated asecond time; on stony or cloddy land this method is not applicable.

INSECT PESTS.

GENERALITIES

584 – **Relation between the Larvae of Vine Moths (*Conchylis ambiguella* and *Polychrosis botrana*) and the Weeds of Vineyards and Other Plants.** — LÜSTNER, GUSTAV, in *Zeitschrift für Weinbau und Weinbehandlung*, Year I Part I, pp. 3-35. Berlin, 1914.

The writer has conducted numerous experiments to determine what foods other than the flowers and fruits of the vine are available for these insects during their larval stage. He tried the larvae with 92 species of plants, the majority being vineyard weeds, others hedgerow and ornamental plants.

In the case of the *Conchylis* larvae the experiments were carried out from the beginning of September to the middle of October. The larvae were observed to be distinctly polyphagous, even devouring Euphorbiaceous plants. It will therefore be difficult to prevent the larvae from feeding on the first buds and fruits by means of disagreeable substances. They are also ready to devour the parts of the plant (*e. g.* the tips of shoots and young leaves, etc.) that are not generally found to be attacked.

The experiments with *Polychrosis* larvae were carried out in the spring and the larvae were found to be equally polyphagous.

These experiments show that: 1) these pests may continue to feed on the shoots of the vine, or failing this, on common weeds, so that measures for the control of the pest by the immediate consumption of the fruit attacked, are not adequate; 2) enclosing the bunches of grapes in bags serves to protect the fruit, but does not decrease the danger of the spread of the insects; 3) brushing the first shoots showing signs of attack is not effective in destroying the larvae, since they find shelter elsewhere, and further this procedure is liable to cause damage to the young vine shoots.

MEANS OF PREVENTION AND CONTROL

585 – ***Thripoctenus brui* n. sp., a Chalcid Parasite of *Frankliniella robusta*, injurious to Peas in France.** — VUILLET, A. in *Comptes rendus hebdomadaires des séances de la Société de Biologie*, Vol. LXXVI, No. 13, pp. 552-555, figs. 1-3. Paris, April 10, 1914.

Garden peas are sometimes seriously damaged by attacks of the pea thrips (*Frankliniella robusta*), which, in 1913, caused considerable damage

near Montargis (Loiret). The writer describes a hymenopterous parasite of this insect, which is new to Science, under the name of *Thripoctenus brui*. The description is based on numerous specimens occurring among the larvae and nymphs of *F. robusta* in the flowers of peas, broad beans and sweet peas collected at Dercy (Aisne) in July 1913. *T. brui* is clearly distinguished by several characters from *T. russelli* Crawford, the only other known species of the genus, parasitic on the bean thrips (*Heliothrips fasciatus* Pergande) in the United States.

The writer received a large number of specimens of *F. robusta* from near Montargis in 1913, but found no specimens of the parasite which was so abundant at Dercy during the same season. It would appear useful to distribute the flowers of peas and beans containing *T. brui* with a view to controlling the spread of *S. robusta* in the same way that Del Guercio (1) has controlled the olive thrips (*Phloeothrips oleae* Costa) by means of *Tetrastichus gentilei*.

586 – **Destruction of *Conchylis* Larvae by Lad birds.** — LÜSTNER, GUSTAV in *Zeitschrift für Weinbau und Weinbehandlung*, Year 1, Part 2, pp. 65-69. Berlin, 1914.

The writer has observed that the larvae of the first generation of *Conchylis ambiguella* Hub. are devoured by the adult *Coccinella septempunctata* when aphids are lacking. They are not attacked by the larvae of *C. septempunctata* and only to a slight extent by the adult *C. decempunctata*. When protected by their silky web they are not attacked by any *Coccinella*.

587 – **The Destruction of Woolly Aphis *(Schizoneura lanigera)* and Pear Scale *(Epidiaspis betulae)* by Fumigation with Hydrocyanic Acid.** — LÜSTNER, GUSTAV in *Deutsche Obstbauzeitung*, Part 8, pp. 174-176, 1 fig.. Stuttgart, April 15, 1914.

Hydrocyanic acid fumigation has long been employed in America, but was introduced into Germany by the writer. Attempts to fumigate apple and pear trees to destroy *Schizoneura lanigera* and *Epidiaspis betulae* (= *E. pyricola*) have not met with success, and the expense is so great as to make the method impracticable for the treatment of fruit trees.

588 – **The Chinch Bug (*Blissus leucopterus*), injurious to Cereals in Kansas.** — HEADLEE, THOMAS J. and MC. COLLOCH, JAMES WALKER, in *Kansas State Agricultural College, Agricultural Experiment Station, Bulletin No.* 191, pp. 285-353, figs. 1-13, plates I-VII. Manhattan, Kansas, 1913.

The chinch bug existed in Kansas before the country was colonised. It hibernates on bunch grass (*Andropogon scoparius* Michx.), big bluestem (*A. furcatus* Muhl.) and false red-top (*Triplasis purpurea* Walt.), from which it migrates in early spring to wheat and other cereals. The first generation reaches maturity just after harvest, and finding itself short of food, it migrates to adjacent crops of maize and sorghum, where the second generation reaches maturity in the autumn. The insect then hibernates on waste grasses.

The larvae as well as the adults damage their host plants by piercing

(1) See No. 3027, *B.* Aug.-Sept.-Oct. 1911. (*Ed.*).

the cortex, extracting the sap and destroying the tissues adjacent to the wound. The damage to crops in Kansas amounts to several million dollars annually, owing to the reduction in the yield of wheat and sometimes complete destruction of the maize and sorghum crops.

Dry seasons are particularly favourable to the development of this pest. Moist weather effectively destroys it by burying the eggs and larvae and by exposing the adults to the attacks of the fungus *Sporotrichum globuliferum* Speg,, which is the only natural parasite of this insect. This fungus is widely spread throughout the regions affected by the pest, and when conditions are favourable it becomes a powerful epidemic. The most favourable conditions are a temperature of 24° C. and humidity approaching saturation.

Careful experiments have shown that it is not possible to spread the infection of the fungus by artificial means, and much money has been uselessly expended in adopting this method of control in Kansas. The most precise experiments have shown that destructive measures can be successfully applied twice a year, *viz.* during the migration of the first generation from the cereal crop to maize and sorghum, and again after hibernating. The writers have found that firing the winter quarters of the insect is the most economical and practical method of destroying it.

589 – ***Tomaspis flavilatera*, n. sp. (Hemiptera) on Sugar Cane in British Guiana** (1). — URICH, F. W. in *Bulletin of Entomological Research*, Vol. V, Part I, p. 43, figs. 1-2. London, April 1914.

The writer gives a technical description of a new froghopper, *Tomaspis flavilatera* (fam. Cercopidae), occurring on herbaceous plants and occasionally on sugar cane in British Guiana.

590 – ***Polychrosis botrana* and *Conchylis ambiguella* in Piedmont in 1913: Biology and Control.** — VOGLINO, P. in *Osservatorio consorziale di Fitopatologia in Torino. Osservazioni sulle tignole della vite eseguite nel Piemonte nel* 1913, pp. 35. Turin, 1914.

As the result of a conference between the Agricultural Committee of Turin and the Subalpine Vine-growers' Society, held on Febraury 22, 1913, a Commission was appointed to study the means of controlling the ravages of vine moths and to determine the value of tobacco extract for this purpose. The Commission met on the 1st of March and decided to appeal to local bodies and to the Ministry of Agriculture for financial help; the carrying out of the experimental work was entrusted to the Turin Phytopathological Observatory. (2).

Towards the end of April, measures were taken for the establishment of special stations for observation in various districts of the provinces of Turin (Moncalieri, Rivoli, Caluso), of Cuneo (Alba, Dogliani, Barolo), of Alessandria (Cassine, Mongardino) and of Novara (Briona). These

(1) See No. 352, *B.* Jan. 1911; No. 649, *B.* Feb. 1911; Nos. 1558 and 1584, *B.* May 1911; No. 1698, *B.* Dec. 1912; No. 1306, *B.* Nov. 1913, and No. 188, *B.* Feb. 1914. (*Ed.*).

(2) See article in *B.* July 1913, pp. 1000-1005. (*Ed.*).

stations were definitely established at the end of April and beginning of May. At each station one or two vines were planted in wire-netting cages, and a small meteorological observatory was erected. With a view to regulating the observations of the different stations, a special scheme of questions was drawn up, and a practical and scientific control was effected by means of special control cages of very fine wire-netting for rearing the insects, at the Observatory at Turin; periodic visits were made to the various stations and important vine-growing districts. Observations were also made in disttricts without special stations as follows: Acqui (province of Alessandria), Gattinara (province of Novara) and the Susa valley (province of Turin).

The results obtained in 1913 show that in Piedmont *Polychrosis* is more widely distributed than *Conchylis;* the latter was occasionally numerous (50-80 per cent.) in colder districts at the mouths of the mountain valleys (province of Turin), and was also frequent (50-65 per cent.) at Gattinara. In the true vine-growing districts exposed to the sun, in the provinces of Turin, Alessandria and Cuneo, *Conchylis* was found in proportions varying from 2 to 4 per cent., exceptionally 10 per cent.: the larvae and moths found were largely *Polychrosis*.

The development of *Polychrosis* is in direct relation to the humidity of the air, being favoured by damp; abnormal changes of temperature in the spring, which have an injurious effect on the growth of the vines, have little effect on the development of the insect. The damage was caused by the spring and summer generations; the autumn generation consisted of a limited number of moths, only occurring locally, which did not produce larvae until after the vintage was mostly finished.

The spring emergence of moths occurred throughout May both in the laboratory at Turin and at the several stations; in one station only (Rivoli) they continued to appear until the beginning of June, with a maximum during the second ten days of May. They lived from 13 to 15 days and deposited their eggs on the stalks of the bunches and the pedicels of the flowers, especially in the second half of May, but also in the first week in June. The larvae of the first generation appeared towards the end of May and pupated from the second ten-days of June until July.

The summer generation of moths first appeared at the Observatory station on the 26th of June, and at the Stations during the first few days of July, with a maximum emergence during the second ten days (14th to 22nd); they lived 11 to 14 days and began depositing eggs on the grapes about the 15th of July, continuing into early August. The larvae of the second generation appeared during the third ten-days of July and especially in August and began pupating at the end of August.

The autumn brood of moths only appered in certain districts (Mongardino, Dogliani, Barolo), from the 17th to the 22nd of September, shortly after the vintage. Only at Barolo was there supposed to be a third generation of larvae on the Nebiolo vine.

The season 1913 was not favourable to a biological study of *Polychrosis*, owing to the low humidity of the atmosphere, and the late spring frosts.

which in many places retarded the development of the shoots, thus depriving the moths of suitable places for depositing their eggs. Further researches are necessary to complete the biological study, especially with regard to pairing, oviposition, development of larvae of the second generation and the resistance of the pupae to insecticides and extreme temperatures.

The mode of cultivation has considerable influence on the development and spread of the pest. Where the canes or wooden supports are replaced by iron, sandstone or reinforced concrete, the number of insects is considerably reduced.

The programme for 1914 does not require an increase in the number of stations but an extension of regular and careful observations and the use of small cages made of fine wire netting and a sheet of mica. A certain number of pupae should be introduced into the cages in the spring and summer periods. By suspending these cages along the rows, it is easy to observe the first appearance of the moths and thus to regulate the application of insecticides. Cages are preferable to lamp-traps, since *Polychrosis* only flies at dusk.

Tobacco extract caused scorching in some places when used in 3 per cent. solution, but rarely in 2.5 per cent. solution, though combined with Bordeaux mixture ; a concentration of 2 to 2.5 per cent. was found to be most appropriate. It was not always effective in keeping the moths away from the vines, and in some places was hardly satisfactory for destroying the larvae, though in others two applications during the period indicated by the flight of the adults were completely effective. The addition of sodium carbonate (1 lb. in 100 gallons) to the tobacco extract (without Bordeaux mixture) increased its efficiency ; an intermittent jet should be used.

Tobacco dust damaged the vines in only two places, but was entirely without effect against the larvae.

Lead arsenate in 1 per cent. solution gave good results, combined with Bordeaux mixture, or used for dipping the young bunches.

The best results are obtained by employing arsenate of lead to destroy the first generation larvae, at least until tobacco extract can be obtained with a guaranteed nicotine content so as to avoid danger of damaging the young shoots. During July and August it is preferable to use tobacco extract (2 to 2.5 per cent.), since it acts as an insectifuge and avoids the difficulties of arsenate. The treatment should not continue later than the first few days of August, owing to the danger of affecting the flavour of the wine. In spraying, care should be taken to cover the neighbouring shoots with the liquid, since the moths kept away from the bunches would otherwise deposit their eggs on the leaves, and the larvae might reach the bunches.

In 1914 attention should be paid to clearing the vine stocks and removing hiding-places suitable for the hibernation of the pupae. On small holdings it would be useful to resort to hand picking of the larvae, without neglecting the use of insecticides.

The distribution of their natural enemies should be promoted by exposing during the winter badly attacked grapes in tubs covered with fine netting. Further, many pupae may be trapped by placing dark muslin or bunches of straw among the old wood of the vines.

591 – ***Agromyza pruinosa* (Diptera) on River Birch (*Betula nigra*) in America.** — GREENE, CHARLES T. in *Journal of Agricultural Research*, Vol. I, No. 6, pp. 471-474, plates LX-LXI. Washington, D-C., 1914.

The writer describes the different stages of development of *Agromyza pruinosa* Coq., the larva of which, unlike those of other species of *Agromyzidae*, bores into wood ; this species produces borings, known as " pith ray flecks ", in the cambium of the river birch (*Betula nigra*).

During July and part of August 1912 considerable damage was caused by this insect at Chain Bridge in the District of Columbia, whilst in 1913 it was only recorded on a few trees in this locality. The attacked trees appear quite healthy externally, the borings in the cambium being only visible on raising the bark.

The writer reared six adults of *A. pruinosa* during the spring of 1913 and found that it resembled very closely *A. carbonaria* Zett. which causes considerable damage to birches in Europe. He records *Sympha agromyzae* Rohwer, as parasitic on the eggs of *A. pruinosa*.

Root-Nodosities of Crosses between Swedes and Turnips

by

L. HELWEG

Director of experiments, Copenhagen.

The Danish Experimental Organization for Crops (1) has undertaken fairly exhaustive researches on crosses between swedes and turnips and the nodosities occurring on their roots. A short account of the information obtained may well be of general interest.

As is well known, swedes are derived from rape (*Brassica Napus*) and turnips from *Brassica campestris* (2). No nodosities form on the roots of crosses between two *Napus*-forms or two *campestris*-forms, but they occur when a *Napus*-form is crossed with a *campestris*-form, whichever be the female parent. If, for instance, the Bullock turnip is crossed with the Shepherd swede the offspring bear nodosities on their roots; but when Bullock is crossed with a summer *campestris*-rape or Shepherd vith a summer *Napus*-rape, no such formations occur, although Bullock and Shepherd are much more alike than *campestris*-rape and *Napus* rape. Both Bullock and Shepherd have round, thick, yellow-fleshed, green-topped roots; they are biennials with orange-yellow flowers. The two kinds of summer rape both have forked, woody and not fleshy, white roots, and are annuals with lemon-yellow flowers. Anyone not specially acquainted with the subject would be much more likely to expect root nodosities when such dissimilar plants as Bullock and *campestris*-rape or Shepherd and *Napus*-rape were crossed than when Bullock was crossed with Shepherd.

Notwithstanding the outward similarity of Bullock and Shepherd, there must be a decided inner difference between them, to judge by the antipathy exhibited in their sexual union; they show this by the appearance

(1) See article: « Organization of Field Experiments in Denmark, » by H. C. LARSEN, in *B.* Oct. 1913, pp. 1479-1483. (*Ed.*).

(2) There seems to be no English name to distinguish the *campestris*-rape (rübsen) from the *Napus*-rape (raps), so that the Latin names will be used here. (*Ed.*).

of the monstrous growths which we call " nodosities due to crossing" (Kreuzungsknoten).

The nodosities are of various forms according as the hybrid in question is rape-like, swede-like or turnip-like; they therefore merit separate description.

1) In the *rape-like hybrids* the nodosities are quite small, but are so closely crowded along the branches of the roots that they appear almost as swellings with small transverse wrinkles and folds reaching the whole length of the root (see Fig. 1). Occasionally hemispherical nodosities occur; these have the flat face towards the fork of the root (see Fig. 1, right). In rape-like hybrids the swellings predominate, nodosities, when present, being of secondary importance.

2) The *swede-like hybrids* are characterised by the size and abundance of the nodosities and the slight development of swellings. The nodosities occur on the bulb and on the fibrous roots, and vary from the size of hen's eggs to that of peas (Fig. 2, A); exceptionally, they may reach 4 to 6 in. in diameter (Fig. 2, B), and even form clusters, thus giving the bulb a more or less misshapen appearance (Fig. 2, C). The nodosities of these swede-like hybrids differ from those of the rape-like and turnip-like hybrids in being sharply defined and generally only joined to the bulb (Fig. 2, B) or the rootlet (Fig. 2, A) by small areas of union. The surface of the nodosities is very much wrinkled and uneven, something like the top of a cauliflower.

The rule mentioned above, that in swede-like hybrids nodosities are more abundant and swellings less so than in rape-like hybrids, is not true under all circumstances. The opposite is especially liable to occur in swede-like hybrids when the bulbs are unable to develop owing to the plants growing too thickly, to very late sowing or to other similar causes Thus, when conditions prevent the formation of the bulb, the swede-like hybrid resembles the rape-like one (Fig. 1) in its root-characters.

3) In *turnip-like hybrids* the nodosities generally appear as characteristic tumour-like bunches on the bulb itself (cf. Fig. 3, D, and Fig. 4, B and A) and are attached to it by large surfaces; they never occur on the fibrous roots. They are not wrinkled like those of the rape-like and turnip-like hybrids, but quite smooth and sometimes shining (Fig. 3, A and B).

As is shown in Fig. 3, A, large clusters of nodosities may occur in turnip-like as in swede-like hybrids (cf. Fig. 2, C). It will also be noted that the turnip-like hybrids are not behind the swede-like ones as regards the size of the nodosities; but they may be quite small as in Fig. 3, C, in which the bulb might pass for a typical Yellow Tankard but for the small nodosity on the middle of the left side.

The swellings at the places where the roots branch are even more characteristic in turnip-like than in rape-like hybrids, but are by no means so abundant. The roots on which they occur are disproportionately thickened throughout their whole length (see Fig. 4, C); as in the rape like hybrids these swollen parts are transversely furrowed. Sometimes these swollen side-roots are double (Fig. 4, C), apparently owing to the union of two rootlets throughout their length,

Among the turnip-like hybrids it is not uncommon to find plants like D in Fig. 4, in which the bulb has hardly developed at all, but is replaced by a number of short, much-swollen side roots.

Further attention should be drawn to the fact that turnip-like hybrids never produce a feature occasionally seen in the other two types, namely the occurrence of a certain number of adventitious shoots bearing rudimentary leaves arising from on or among the nodosities (see Fig. 5 and Fig. 2, D). Such shoots remain below ground and are consequently chlorotic throughout, unless they arise from roots at a very slight depth, when they may project to a maximum of 4 or 5 inches and become green.

As these nodosities occurring on hybrid swedes and turnips are liabl to confusion with those caused by the finger-and-toe organism (*Plasmodiophora Brassicae*), it may be well to describe briefly the means of distinguishing them. Fig. 6 shows on the left three plants of Fynische Bortfelder and on the right three of Bangholm's. The distinguishing characters of finger-and-toe disease are evident under the microscope, and in doubtful cases one may be obliged to have recourse to this method ; but as a rule a little practice serves to distinguish the two without difficulty. The first thing to be noted is the presence of characteristic spindle-shaped swellings on the side roots (see Fig. 6, A, B and C). In general shape they may somewhat resemble the swellings on the roots of turnip-like hybrids (cf. Fig. 4, C), but cannot be confused with them, as the surface of the finger-and-toe swellings is smooth and they never show the closely-placed constrictions so characteristic of the swellings on the roots of the hybrids. Though these swellings do not occur on every diseased root, they are sure to be found among a number of roots taken from a field where finger-and-toe is prevalent. Another distinguishing feature of the finger and-toe swellings is that they often show the beginning of cork formation on the upper part; this never takes place on the nodosities of hybrids. On the larger finger-and-toe swellings a considerable development of rough greyish-brown cork generally takes place ; the dark central part of Fig. 6, E, is a cork layer of this nature. Attention should also be drawn to the swellings near the tip of the root in Fig. 6, F; a swelling in that position fairly frequently occurs in both swedes and turnips attacked by the disease. In this case it differs from the nodosities of hybrids in narrowing equally above and below. Finally, a special characteristic of the deformed parts of roots attacked by finger-and-toe disease is the almost invariable presence of irregular brown streaks in the flesh, as may be readily seen on cutting the swellings across ; such streaks never occur in the nodosities or swellings due to hybridisation.

The elucidation of these points has been of considerable importance for the seed trade. To this work is due the fact that in the season 1913-14 the wholesale dealers in turnip seed were able to undertake to guarantee the trueness to variety and strain of the Danish swede and turnip seeds sold abroad, in conformity with the law of the 8th of June 1912 on penalties for erroneous designation of goods. This law gives the foreign purchaser the right to full compensation in case the crop grown from the Danish swede or turnip seeds contains so may hybrids or degenerated roots that the yield

is distinctly reduced. The fact that the Danish wholesale seedsmen have been able to assume without risk such a comprehensive liability for compensation is due to the demonstration by the Experimental Organization of the certain characters by which swede and turnip hybrids can be recognized. In careful selection of Danish strains of swedes and turnips carried out for a number of years, the seedsmen have thus been in a position to undertake such a thorough elimination of all plants tending to degeneracy that the stability of the strains may now be considered as thoroughly established.

Present State of Fruit Growing in Spain. (1) (The Principal Fruit Trees of the Rosaceae).

by

JUAN MANUEL PRIEGO,

Professor of Horticulture at the Madrid Agricultural College.

Almost all the fruit trees grown in the different parts of the world grow in the open in Spain; from the chestnut woods which cover the northern slopes of the Cantabro-Asturian mountains to the plantations of bananas and guavas which adorn the orchards of Malaga and Cadiz, almost all kinds of fruit trees are well represented.

Limiting ourselves to the most widespread fruit trees, we shall consider pear and apple among hard fruit, and peach, apricot, plum and cherry among stone fruit.

Conditions and importance of fruit growing in Spain. — The Iberian Peninsula, covering seven degrees of latitude from the Straits of Gibraltar to the Cantabrian coast, and possessing various conditions of altitude, aspect, soil and geological formation, is very favourable for the growing of the above fruit. Indeed fruit is grown in all the 47 provinces on the mainland, and in some districts, such as Aragon and Rioja, it forms one of the chief sources of wealth.

The progress of fruit growing in Spain has been slow, on account of the former slowness and insufficiency of the means of transport. The development of the railways led to the spread of the use of fruit among all classes and to the extension of the plantations, though not to the same extent as in some other countries, nor in all the districts suitable for fruit.

Only meagre data on the fruit plantations of Spain and their production are available. According to the " Avance estadístico de la producción de frutales en 1910 ,, (Statistics of the production of fruit in 1910), published by the General Direction of Agriculture, Industry and Commerce, the total area under the above-mentioned kinds of fruit is 121 526 acres, distributed as shown in Table I.

Totals	12 382	8 462	13 012	9 364	26 261	52 045

The numbers in the Table are only approximate and leave out a large number of fruit trees scattered among other crops, or in gardens, vineyards and fields, since the precise valuation of the surface they occupy is very difficult.

The estimate of the amount of fruit produced is also below the reality. The fruit crop of 1910 was bad almost all over the country, owing to late frosts and summer drought. The 300 000 tons to which such produce approximately amounts, valued at the average price of 15 pesetas per quintal (11*s* 10 ½*d* per cwt.), which was the price adopted by the Commission appointed for the study of the transformation of the tax on consumption, give a value of nearly £ 1 800 000. In the work of the above Commission the value of the average crop of the fruit here considered was taken at £ 1 920 000, being based on older data as to the acreage under fruit.

The exportation is of no great importance, as may be seen from Table II.

If the data concerning the acreage under fruit trees, the yield and the exportation be compared with those of other countries under conditions similar to those of Spain, it will be seen that the latter is still far from having taken full advantage of its favourable conditions. Nevertheless its production is increasing, though not so rapidly as that of some other crops for which the country is less suitable. The land not devoted to field crops, such as much of that which is still uncultivated and a great part of the vineyards

destroyed by phylloxera, is eminently suitable to fruit growing. The market of the country are far from being amply provided, considering that the aver age amount consumed by the population is about 40 lbs., worth 2*s* 1½*d* per head per annum. Whole districts consider fruit as an article o luxury. The exportation of fruits is stationary and very limited ; England Germany, Denmark, Sweden and Russia hardly know the pears and peache of Aragon, Rioja and Lerida, the apricots of the Balearic Isles, Castelló and Murcia, and the cherries of Lugo, Orense, etc. France, whose consump tion of fruit per head of population is four times that of Spain, export fruit to the value of half a million sterling every year, and Belgium, whic is inferior in extent to two Spanish provinces, reaches nearly the same figure

Distribution of fruit in Spain. — Though fruit growing has not the sam importance in all the provinces, in all of them fruit trees are grown. Th various species are distributed as follows :

Hard fruit. — Pears and apples are cultivated almost throughou Spain. Table varieties have little or no importance in seven provinces, *viz* Leon, Cuenca, Malaga, Huelva, Valladolid, Guadalajara and Seville.

The most important plantations of *pears* are those of Aragon (basin of the Ebro, Jalon, Jiloca and Guadalope), Castellón de la Plana, Burgo (districts of Aranda), Galicia (Pontevedra, Orense and Lugo), the mount ainous districts of Andalusia, the Sierra de Córdoba and the territories o Baza and Guadix in the province of Granada. The first belt produces no less than 20 000 tons in average years; the pears are of such excellen quality that the Royal Household obtains its supplies from here. Th varieties most extensively grown are Sanjuaneras, Deagua, D. Guindo Bergamotas, and Roma ; these and some winter ones are exported i ever-increasing quantities into the South of France.

The area under dessert *apples* is very nearly the same as the above des cribed area. These apples, however, prevail in the Lerida district, ex tending also into the province of Gerona, in the Levante district, wher the summer and early autumn varieties thrive very well, and in the provinc of Cordoba (Cordoba, Baena and Cabra).

The cider varieties of both species cover the northern slopes of the Cantabrian mountains in the provinces of Navarre, Guipuzcoa, Biscay, Santander and Oviedo, and the slopes and valleys near the coast in the territory of Pontevedra and Lugo (Galicia). The province of Oviedo is the greatest producer of cider. The total crop of all this belt is from 8 to 11 million bushels of cider apples.

Stone fruit. — The most important stone fruit is the *peach,* both for the acreage devoted to it and for the value of the fruit produced. It is grown in 40 provinces, but its produce is really important only in those of Saragossa, Teruel, Logroño, Lerída, Barcelona, Orense, Murcia, Jaén and Castellón .The first four provinces form a belt in the basin of the Ebro and its tributaries, producing an average of about 4000 tons of excellent quality. The free-stone and Pavia peaches of Lerída, the clingstones of Sástago and Escatrón, the yellow peaches of Campiel, and the large peaches of Saragossa are equal or superior to the most esteemed of other countries and supply Madrid, Barcelona, etc., during the season, following the earlier ones from Castellón, Valencia and Murcia. Of all these peaches a certain proportion is exported to Paris, London and Hamburg.

The southern belt of the province of Madrid and its valleys of the Tagus and the Tajuña are rich in various fruits, including productive and highly esteemed peaches and plums. Its principal centre of production is Aranjuez which supplies a good deal of the fruit consumed in Madrid.

Under the form of "orejones" (peaches halved and dried), great quantities of the crop are prepared and preserved, as it would be difficult to export them fresh to great distances. The dried peaches of Malaga and Logroño are held in high esteem everywhere.

In point of importance the *plum* follows the peach. It is more regularly distributed, thanks to the greater resistance of its fruit to bad weather. Toledo, Granada, Almeria and Lerida rival Aragon in the production of plums. Greengages are, to a certain extent, exported to Paris and other capitals. In the Llobregat territory, plums are grown with apricots. They are also widely spread in the above-mentioned belt of the province of Córdoba, whence they are also exported to a certan extent. This productive tree, so reliable in its yield and having the advantage of producing fruit easily dried or preserved, deserves to be held in still greater consideration than it is.

Apricots, which are the most exacting as to climate of all the species here mentioned, naturally occupy the most limited area. At the same time they are grown in 36 of the provinces of Spain and are totally wanting only in the North and in a part of the North-west of the peninsula and in some provinces of Western Andalusia. The apricots of Toledo are distinguished by their keeping quality and resistance to carriage, due to the fact that they acquire a pleasant taste before they are quite ripe. The apricots of Levante are large, tasty and early. In Murcia they form part of the early produce exported to Central Europe. In the Balearic Islands they occupy about 2500 acres and give rise to an important export trade of fresh fruit and pulp for preserves; indeed they constitute the most valuable crop.

Egriots, morellos and *cherries* have been abandoned in a number of provinces; the central plateau of the two Castiles and the provinces of Salamanca, Lugo, Orense, Lerida and Castellón are the greatest producers of these fruits. Those grown along the Segre and the Cinca are profitably exported. The still earlier cherries of Sagunto and the Segures valley are packed in small boxes and sent to Paris. The large cherries, such as the Costalera, Corazón de Cabrito and some others with very firm flesh, being suited to extensive farming and possessing great resistance and keeping qualities, are especially advisable in the large bare plains and in the small ranges of Tertiary calcareous rocks so frequent in Spain.

Observations on cultural methods in Spain. — In almost all the above mentioned districts fruit trees are intermingled with other crops, chiefly in market gardens. In some districts, especially the Basque provinces, fruit trees are planted on grain land or pasture ; in some parts of Aragon and Levante they are grown in vineyards ; less frequently, as in the Toro neighbourhood, they form pure plantations.

The drawbacks of intermingled crops, especially of trees with field crops, are well known. The former cast an injurious shade on the latter and these in their turn take up much moisture and plant food from the soil. Manures to suit all the different plants cannot be prepared, and the operations of tillage and irrigation do not always coincide. This interplanting of fruit trees with other crops, which is so frequent in Spain is, we believe, one of the chief causes of the fact that fruit growing is not so profitable as it might be. The farmer devotes more care to the garden crops, the cultivation of which he generally knows better, whilst he is ignorant of the practice of treating and pruning the fruit trees.

In these various types of fruit plantations the different kinds of trees are generally mixed together. But besides these plantations there are many scattered trees, chiefly apricots and plums, in either enclosed or open fields.

Economic data. — Yield of fruit trees in Spain. — If the returns of fruit growing were to be estimated upon the figures supplied by the " Avance " of the General Direction of Agriculture, to which we have already referred, the conclusions would not be very favourable. The figures are the following :

	Yield per acre — cwt.
Pears	51
Apples	58
Peaches	30
Plums	43
Apricots	40
Cherries	40

But, as we have already said, the 1910 crop was generally bad and these yields are certainly inferior to the average. The data collected by us in the chief producing centres are the following :

Pears. — Standard pears begin to produce at the age of 15 years. When in full bearing they yield about 1 cwt. of fruit per tree. The value

of this fruit varies, like that of all other kinds, with the variety and the season. Those produced in Aragon, sold on the spot under normal conditions, may be valued at 8*s* per cwt. A certain proportion of the good autumn and winter varieties are exported and fetch more than double the above price. In the province of Saragossa the variety most esteemed for exportation is the De Roma. In a regular plantation in rows about 100 pear trees are grown to the acre ; they yield about 5 tons of fruit, worth about £40.

Apples. — The bearing and yield of apples vary still more than in the case of pears. We believe that the figures of the above " Avance " may be taken as correct for average years. The apples supplied to the Madrid market come for the most part from the Valenza and Teruel districts, where their price ranges between 6*s* and 12*s* per cwt.

Peaches. — Peach trees begin to bear at the age of four or five years. Their average yield may be taken at 44 lbs., and as in one acre there are about 120 trees, the yield per acre is about 47 cwt. of fruit ; in normal seasons this is worth, at the orchard, never less than 12*s* per cwt., the gross returns being thus about £28 per acre. Peaches are the most esteemed fruit, even in the home market ; especially choice and early fruit fetches high prices. They are frequently sold by the dozen, and on the spot where they are grown the large peaches of Saragossa and Lerida, or early or late varieties, command as much as 1*s* 7*d* per doz. The peaches of the Segre, Cinca and Llobregat valleys supply Barcelona, and some are shipped from that port. A certain amount of exportation takes place from Castellón de la Plana. The peaches of Saragossa, Teruel and Rioja are consumed in the interior or used in the local preserve factories.

Plums. — This tree is grown almost always as a standard and develops well in the whole of Spain, producing, when fully grown, as much as 130 lbs. of fruit per tree. Of all the fruit trees it is the one least frequently grown by itself. The price of its fruit varies very much; its dimensions, form, colour, taste and keeping qualities (the latter never being high) also differ largely in the different varieties. In years of abundance their price falls as low as 2*s* 5*d* per cwt. Greengages, when well packed, are worth eight or ten times as much on the great markets.

Señor GAJON, a well-known fruit grower of Saragossa, calculates the yield of a plum tree as follows: 10*d* at the age of six years ; 6*s* 4*d* at twelve years ; 9*s* 6*d* at sixteen ; 11*s* 10*d* to 15*s* 10*d* at twenty and upwards, always provided that the fruit be placed on a good market.

Apricots. — The yield of this tree, which is never very regular, may be valued at 132 lbs. per tree every other year. Reckoning 112 trees per acre (real distance apart about 20 feet), the average produce per acre per annum would be about 66 cwt., which, at a minimum price of about 10*s* per cwt., amounts to an average gross income of £33 per acre.

The plantations of Murcia, Aranjuez and Toledo supply the Madrid market ; Castellón and the Llobregat valley that of Barcelona. These districts and Murcia export a good number of boxes. This fruit has acquired considerable importance in the island of Majorca, where it now occupies

about 2250 acres and is yearly extending. The apricot preserve exported every year from the Balearic Islands is valued at £24 000.

Cherries. — The produce of this tree, which is more reliable than that of the apricot, is estimated at 330 lbs. per tree; the fruit of good varieties sells at 8*s* to 12*s* per cwt. Where the cherry trees attain their full development not more than 40 can be planted to the acre, in which case the gross returns may be estimated at least at £40 per acre.

The first cherries to appear on the Paris market are from Spain. Unfortunately the number of boxes exported is limited, as the production barely keeps pace with the home consumption and it is difficult to understand why a fruit that is in such demand both at home and abroad is not more widely planted.

Cost of production. — The cost of producing fruit varies very much according to the locality and the systems of cultivation adopted; the difficulty of ascertaining such cost is greater when the fruit trees are interplanted with other crops. When they are grown by themselves, the cost of production is but little higher than that of growing olives. There is no doubt, however, that they leave the grower a satisfactory margin of profit and that fruit growing is destined to develop considerably in the near future.

The Dairy Industry in Italy at the Present Time

by

Prof. Carlo Besana,

Director of the Royal Experimental Station for Cheesemaking, Lodi.

Statistical data on milk production.

No accurate and recent statistics on milk production in Italy are available, and the data given in the present paper have been obtained indirectly or are merely personal estimates. The last live stock census, taken in 1908 by order of the Department of Agriculture, forms a positive point of departure; from it are taken the following figures dealing with the classes of animals producing milk:

	Number of head
Sheep	11 162 926
Cattle	6 198 861
Goats	2 714 878
Buffaloes	19 366

The dairy industry depends chiefly on sheep and cattle. The scarcity of the bovine species, which is the more important in milk production, is quite evident both when the numbers are considered in relation to the number of inhabitants, or when compared to various other European states. With regard to the distribution of the cattle over the twelve regions of Italy,

more than half the total numbers, or 3 662 813 head, are found in the valley of the Po, and of these over one million are in Lombardy, where the density of cattle is at its maximum; Emilia, Veneto, Piedmont and Sardinia follow in the order given at no great distance apart. Lower Lombardy, which includes the fertile irrigated plains of Pavia, Milan, Cremona, Brescia, Mantova, is the zone of most intensive milk production. Owing to irrigation, four crops of hay may be obtained annually, and on the so-called " marcita " fields, near Milan and Pavia, the number rises to seven or eight. The quadrangle bounded by the rivers Ticino, Po and Adda and the parallel running through Milan is characterised by its dairy farming, the milk production per unit area or per head of the population being higher than in any other part of the world. Emilia too, in the provinces of Reggio, Parma and Modena, has made great strides since 1881 with regard to increasing the number of its cattle, its forage crops and its milk production, so that to-day the density of cattle for the whole region (Emilia) is higher than that of any other whole region in Italy, *viz.* 18.1 per square mile. In fact the number of cattle increased in all parts of Italy from 1881 to 1908, the total increase being almost one and a half million head, or about 30 per cent., and its quality has improved at the same time.

Sheep are most abundant in the southern Adriatic region, where about two million head are found, while the southern Mediterranean region, Sardinia, Latium, and Tuscany follow in order, having over a million head each. The density is highest in Latium. In a general way it may be said that the number of cattle per acre decreases going from north to south while on the contrary the number of sheep per acre increases. Goats abound in the southern Adriatic region but in no other parts. Buffaloes are pastured on swampy ground where no other domestic animal could live; herds are found in certain localities in Latium and in the southern parts of the country (Salerno, Caserta, Foggia, etc.)

As the 1908 census does not state the number of females which may be considered milking stock in each of the above classes of live stock, an approximate estimate must be made to arrive at the milk production in Italy. Assuming that the percentage of milking stock in the total registered be 60, 70, 55, and 50 for cattle, sheep, goats and buffaloes respectively, then the numbers of milking stock in Italy would be approximately as follows:

Cows	3 600 000	head
Sheep	7 800 000	»
Goats	1 500 000	»
Buffaloes	10 000	»

It is not easy to calculate the average quantity of milk produced by the above stock, owing to the heterogeneousness of the breeds and to the dissimilarity of systems of management.

Cow's milk. — Leaving aside the question of breeds, there are two opposite systems of management of milch cows in Italy, *viz.*: permanent housing and free ranging. In the north, where milk is an important industrial

substance, the cows are housed permanently or almost permanently ; thi system is also in vogue in parts of Central Italy (Tuscany, Umbria), wher however, the milk is chiefly used for calf rearing. Free ranging is met wit in the central regions beginning in Latium, in the southern part of th country and in the islands, where the milk is partly employed for cal rearing and partly for cheese making on a small scale. In the latter cas yields are small owing to the not infrequent scarcity of fodder and to th exposure of the cattle.

Where milk production is carried on intensively, as for instance i Lombardy, calves are usually removed from their mothers a few days afte birth and almost the entire production of milk is available for cheese making In the central regions, on the contrary, the cows are never milked, bu merely suckle the calves, in which case the period of lactation is greatl reduced. An intermediate system exists in Sardinia, where it is usual t milk the cows once a day during a part of their lactation period, *i. e.* durin April, May, June, and October.

To estimate the average production of milking cows in Italy, thos which are only used for suckling calves and those which are only milke for a very brief period should be excluded, *i. e.* about 1 000 000 head, whic reduces the number of milking cattle from 3 600 000 to 2 600 000 The average annual production per head varies from 25 hectolitre (550 gallons) in Lombardy to 10 hectolitres (220 gallons) for Alpine cattle an 4 hectolitres (90 gallons) for free ranging cattle in Sardinia, so that assumin an average production of 12 hectolitres (265 gallons) for the above 2 600 00 cows the estimate will be conservative. On this basis 31 200 000 hectolitre (7 million gallons approx.) would be produced annually, of which part i used for direct consumption and part is worked up into other dairy produce

The population of Italy, consisting of 34 million inhabitants, consume very little cow's milk, the consumption being highest in the northern prov inces and least in the central and southern regions, where many Italian never drink cow's milk at all, partly because it is not customary to do so an the product is expensive, and partly because they use ewe's or goat's mil instead. The average consumption per head may be estimated at 18 litre (4 gallons) per annum, or 0.05 litre (0.1 pint) per day, which is a negligibl quantity compared with the consumption in Germany, Denmark, Holland Sweden and Norway. On this basis 6 120 000 hectolitres (150 millio gallons) are consumed directly, leaving 25 080 000 hectolitres (550 millio gallons) for the production of other dairy products.

Ewe's Milk. — The milk production of ewes varies from 100 litr (22 gallons) per annum in Sardinia to 40 litres (10 gallons) in some of th flocks on the mainland. Assuming a mean yield of 70 litres (15 gallons) p head per annum, the annual production of ewe's milk available for th dairy industry is 5 460 000 hectolitres (120 million gallons).

Goat's Milk. — Goats yield more milk per head than do ewes. In Sa dinia their annual yield is estimated as 140 litres (30 gallons), but f present purposes 100 litres may be taken as the average figure per he

after deducting the amount required for raising the kids. This is equal to a total annual production of 1 500 000 hectolitres (33 million gallons).

Buffalo's Milk. — Milking buffaloes may yield from 5 to 8 hectolitres (100 to 180 gallons) per annum, but the semi-wild state in which they are kept causes their milk yield to vary considerably from year to year. For present purposes their yield may be estimated at 4.5 hectolitres (100 gallons), which gives a total annual production of 45 000 hectolitres (1 million gallons).

The following table summarises the data dealing with the milk production of the bovine and ovine species, this being not only the most important source of supply but also the one capable of eventual increase.

	Cattle	Sheep
Total numbers (1908 census)	6 198 861	11 162 926
Females	3 600 000	7 882 727
Milking animals	2 600 000	7 800 000
Average yield per head . . . . . galls.	265	15
Total annual production . . . . . million galls.	700	120
Milk used for direct human consumption » »	150	—
Milk worked up industrially . . . . » »	550	120

It is important to emphasize the fact again that of the above figures, only those of the 1908 census are absolute, the others being the result of estimates.

Utilization of Milk.

Cow's milk. — This is put to three chief uses:

1. Condensation. — Carried out in two factories in Lombardy; only accounts for a very small proportion of the total produce. Milk powder is also prepared in small quantities.

2. Direct human consumption. — City dairies, which deal with this section of the industry, are to be found in the principal Italian cities, but even the most modern and up-to-date examples are very modest compared with the large establishments of this kind which exist in other countries, such as at Vienna and Berlin. Much improvement has taken place with regard to the handling of milk, but even now the greater part is sold by small local dealers. The retail price consequently varies with the abundance of the local production, and prices increase from North to South of the country, the minimum and maximum being 2*d* and 6 ½*d* a quart respectively. Of late years prices have tended to rise. The wholesale prices obtained in Lombardy and Emilia have risen gradually from 5*d* to 7.7*d* per gallon during the last ten years. In all the principal cities, the retail milk trade is subject to inspection by local hygiene officers.

3. Cheesemaking. — About five-sixths of the total milk production is turned into cheese, butter, and their bye-products. The factories dealing with this section of the industry may be grouped into three classes: private factories, where the producer of the milk turns it into cheese and butter

himself; industrial factories, such as exist in Lower Lombardy, where the milk is bought from the producers and worked up—as much as 4 400 gallons being dealt with per day; and cooperative factories, which are chiefly to be found in the Alpine districts, but which also exist in Emilia, while a few isolated examples may be found in Sardinia and in the South. The number of these cooperative factories fluctuates considerably, as new ones are started every year while others close down. They are most numerous in the province of Udine, where they number several hundreds, while the total number in the country must amount to almost a thousand. The most modern example and the one which deals with the largest quantity of milk is that at Soresina (Cremona prov.).

Cow's milk cheeses. — These are of three kinds:

1. Moulded cheeses—such as Stracchino, Gorgonzola, Robiole, Fresa.

2. Hard cheeses — Grana (including Parmesan, etc.) Fontina, Bitto, Asino, Montasio, Bra; the skim milk (so-called Swedish) cheeses; "Margarinati" cheeses (in which butter fat is wholly or partially substituted by margarine); and the Swiss cheeses, Emmenthal, Gruyere.

3. Soft cheeses - whose name alters with their shape: Caciocavallo, Provolone, Scamorza, etc. Ricotta, a white curd sold in Italian cities, is usually a bye-product obtained from whey, but may also be prepared from fresh milk.

Stracchino and Gorgonzola are chiefly produced in Lombardy and to a slight extent in the adjoining plains of Piedmont; Fresa is a Sardinian speciality; grana comes from Milan, Southern Lombardy and Northern Emilia; Fontina and Bitto from the Alps to the west and north; Asino from Vicenza; Montasio from Udine, and Bra from Piedmont. Swiss cheeses are made in Lower Lombardy and the soft cheeses which used to be a speciality of the Abruzzi, Latium and the South are now also being manufactured in the North.

Butter is chiefly produced in Lombardy, either in the cheese factories or in special creameries; appreciable quantities also come from Veneto, Piedmont and Emilia. In certain southern provinces butter-fat is enclosed in a kind of bag made of soft, elastic curd, the whole being called "manteca".

With regard to bye-products, lactose is only prepared by a very few factories; the extraction of casein is rather more general, and is supplanting the manufacture of skim-milk cheeses, which is no longer remunerative on account of over production. Other bye-products are "vituline", a kind of calf meal, and dairy waste, which is used for pig feeding.

Ewe's Milk Cheeses. — This group of products has developed considerably of late years owing to their growing importance in the country's exports, and flocks are in consequence receiving more attention. The type of cheese varies from place to place, as a considerable proportion is still made for local consumption; the following may be mentioned as typical examples: Pecorino Romano, Cotronese, Moliterno, Pecorino Sardo, Cacio fiore, Incanestrato di Sicilia. Of these, the Pecorino has acquired commercial importance during the last twenty years. It originated in Latium, which is still the centre of production, but its manufacture has been considerably

extended in Sardinia, where up-to-date cheese factories have now been erected for the purpose.

Goat's Milk Cheeses. — These are small and only made for local consumption. Goat's milk is frequently mixed with cow's milk or ewe's milk to form so-called " mixed cheeses ".

Buffalo's Milk Cheeses. — Small, round, soft cheeses are made with buffalo's milk, which is rich in fat. These are somewhat sweet with a pronounced flavour and find a market in the southern towns where they are sold under the names of: mozzarelle, uova di bufala, provole, provature.

Value and amount of cheese produced.

In estimating the amount of cheese produced, it is assumed that:

cow's	milk	yields	7	per cent.	of cheese
ewe's	»	»	15	»	»
goat's	»	»	10	»	»
buffalo's	»	»	20	»	»

After deducting from the cow's milk the amount used for butter-making, the annual production of which is estimated at about 50 000 tons, the amount available for cheese making is reduced to 23 000 000 hectolitres (505 million gallons). The production of cheese is, therefore, as follows:

cow's milk	16 100	tons
ewe's »	8 100	»
goat's »	1 500	»
buffalo's »	90	»
total	25 790	tons

To obtain the value of the total produce, butter and cheese are taken at the wholesale prices of 260 lire per quintal (11.8*d* per lb.) and 160 lire (7.3*d* per lb.) respectively as follows:

	annual value	
butter	£	5 200 000
cheese	»	16 505 000
bye-products	»	640 000
total	£	22 345 000

Foreign Trade.

Exports. — According to statistics published by the Ministry of Finance, exports of dairy products in 1913 were as follows:

	Amount tons	Value £
Fresh or sterilized milk	226	18 108
Fresh, sterilized and peptonised cream	0.75	528
Condensed milk, unsweetened	8	3 620
» » sweetened	251	120 588
Fresh butter	242	286 656
Salted butter	30	35 032
Cheese, Grana	916	916 480
» Swiss	94	79 084
» Pecorino	917	880 896
» Caciocavallo	211	227 748
» other hard types	155	148 808
» Gorgonzola, Stracchino	916	696 324
» other moulded types	7	4 916
Total		3 418 788

It will be seen from the above table that the largest exports consist of Grana, Pecorino and Gorgonzola cheese. The principal importing country is the United States, followed by Argentina, the cheese being consumed there by the large Italian immigrant population. Gorgonzola, however, goes chiefly to England, France and Switzerland.

Exports of cheese, have increased steadily since 1871, as shown by the following figures :

Year	Exports tons
1871	176
1879	266
1883	383
1887	503
1894	722
1899	1 043
1902	1 308
1906	1 919
1907	2 114
1911	2 785
1912	3 062
1913	3 277

Exports previously consisted almost exclusively of Grana, but both the amount and the number of kinds exported have now largely increased.

Imports. — A little butter and a considerable amount of cheese (about one-sixth of the export value) are imported annually, the imports for 1913 being :

Butter	40	tons
Swiss cheese	450	»
Other hard cheese	97	»
Soft cheese	12	»
Total annual cheese imports	559	»

valued at £549 868.

The cheeses mostly come from Switzerland; other hard cheeses are mostly Pecorino from the Levant. Imports were at their highest in 1887, when they reached 1235 tons; then they decreased rapidly and remained practically stationary at 450 tons until 1913.

SECOND PART.

ABSTRACTS

AGRICULTURAL INTELLIGENCE

GENERAL INFORMATION.

AGRICULTURAL EDUCATION

592 – **Agricultural Education in South Africa.** — *Journal of the African Society*, Vol. XIII, No. 51, pp 288-295. London and New York, April 1914.

Agricultural education in South Africa is controlled by the Union Department of Agriculture, and under this head are embraced the activities of four Schools of Agriculture with Experiment Farms, eight Experiment Stations, and four Stud Farms, also a Household Science branch. For the better administration of these Institutions, a separate division of the Department was recently created, under the control of one of the Under Secretaries. There exist, in addition, Experiment Stations connected with the work of the Tobacco, Cotton, Horticultural and Botanical Divisions, but these are directly under the control of the Chiefs of these Divisions.

The annual vote for agricultural education, inclusive of salaries, general maintenance, and development, amounts to about £120 000, but this amount does not include grants through loan funds or votes on the Public Works Department's estimates for buildings. During the current year these amounted to no less than £60 000.

The principal schools are:

A. *Cape Province:*

1. ELSENBURG, the oldest established of the Schools, with between thirty and forty students, is situated about thirty miles from Cape Town. Area of station 1 700 acres. Special features at this institution are horticulture, viticulture, wine-making, cereals and tobacco (Turkish).

2. GROOTFONTEIN, outside the town of Middelburg (Cape) with about eighty-five students. Area of station 25 000 acres. Special features at Grootfontein are agriculture (including irrigation under Karroo conditions), ostriches, Merino sheep and Angora goats.

B. *Transvaal Province:*

POTCHEFSTROOM, about eighty-three miles to the southwest of Johannesburg, with about sixty-five students. Area of station 4 000 acres. Spe-

cial features of the instruction are agriculture representative of High-Veldt conditions, cultivation of crops under irrigation and otherwise, cattle, maize and other cereals.

Natal Province :

CEDARA, fourteen miles to the north of Maritzburg. The station covers about 3 600 acres, and has some thirty students. Special features are sub-tropical agriculture, forestry (including wattle growing), cattle and maize.

Orange Free State Province :

There is no similar institution at present, but one is in course of establishment at Glen, near Bloemfontein. Arrangements have been made to receive students in 1915. A farm was purchased for the purpose at a cost of £20 000, and £40 000 has been provided on "loan funds" for the erection of the necessary buildings.

593 – **Technical Organization in German East Africa.** — *Deutsches Kolonialblatt*, Year XXV, No. 2, pp. 66-67. Berlin, January 15, 1914.

The following information has been received concerning the projected technical organization in German East Africa and the foundation of a native school for training practical mechanics at Daressalam :

The "Kolonial Wirtschaftliche Komitee" proposes opening three technical bureaus in the colony at Daressalam, Tanga and Lindi. These will be placed under the direction of competent certified engineers who have already had much experience in the colonies and will act as central consulting bureaus on all technical matters. The engineers will visit existing machinery on the plantations, advise, suggest improvements, etc. No fees will be charged for consultation other than the travelling expenses of the engineers.

At the same time a school for training practical native mechanics will be erected at Daressalam. The Committee have already rented a plot of land (23 680 square feet) from the Government up to October 1, 1919. The cost of building the school and its working expenses for the years 1914, 1915 and 1916 will be defrayed by funds voted by the metal and machine industry. The Government has already declared itself willing to instruct its officials in the different localities of the colony to select the most promising youths for instruction and to send them to the school. The number of pupils is at present limited to thirty.

The objects of the school are the following ;

1. To train native mechanics and engine drivers. Only youths who have had some preliminary education and who are accustomed to working will be admitted. As encouragement they will get regular pay as soon as they enter the school.

2. To provide the railways, mines, internal navigation companies, factories and plantations in the colony with cheap technical labour, and, in time, to supply other German colonies also.

3. To act as an experiment station where German machines and implements will be tested and compared with foreign ones. People in the colony who are interested in machinery will be invited to attend the tests in order

to encourage useful discussions, and the Government will also be represented.

The education given in the school will be chiefly of a practical nature and will be adapted to the character of the natives. The first course will consist in rendering them familiar with all smiths', mechanics' and fitters' work, with the management of agricultural machinery and with the carrying out of all sorts of repairs. The second course will be more specially devoted to rendering the pupils capable of managing engines of all kinds, *i. e.* steam ploughs, machinery for hemp, cotton, rubber, etc., motor cars and boats and their repairs.

The machines and implements of the permanent exhibition will be included among the material available for the school. At the examinations held at the end of the course a Government commission will be present.

The chief stimulus to the foundation of the above school has been the scarcity of people capable of managing the cotton harvesting and other machines needed in the colony — a want which has hitherto been a serious handicap and prevented the extended use of machinery.

ORGANIZATION OF EXPERIMENTAL AND ANALYTICAL WORK.

594 – The New Standards adopted in Germany for the Trade in Sugar-Beet and Mangel Seeds. — EDLER, W. in *Fühlings Landwirtschaftliche Zeitung*, Year 63, Part 8, pp. 268-277. Stuttgart, April 15, 1914.

Owing to the difficulties which have arisen from alterations of the so-called Magdeburg standards, formerly universally recognized in the German beet-seed trade, the interested parties have drawn up a new set of rules. These differ from the earlier ones in that mangel and sugar-beet seeds are treated separately ; further, instructions for the taking of samples and for the calculation of the deduction to be made on seeds not coming up to standard, but yet saleable, have been added.

German standards for the trade in sugar-beet seeds (1914).

The following bodies have taken part in the drawing up of the clauses given below : Ausschuss für Handelsgebräuche (representing the Deutscher Landwirtschaftsrat, Deutsche Landwirtschafts-Geselleschaft, Bund der Landwirte, Reichsverband der deutschen landwirtschaftlichen Genossenschaften für Deutschland and Vereinigung der deutschen christlichen Bauervereine), Verein der Deutschen Zuckerindustrie (Crude-sugar factory section) and the Gesellschaft zur Förderung deutscher Pflanzenzucht. These are valid where no other agreements are in force.

§ 1. — The sugar-beet seed should be delivered in good condition, fit for use, and, except for the screening necessary in cleaning, not graded according to the size of the clusters. The seed must belong to the variety named and must agree with the particulars of the other paragraphs.

§ 2. — The seed should contain at least 85 per cent. of dry matter (15 per cent. moisture). It is saleable with the dry matter down to 83 (17 per cent. moisture), but in that case the difference must be allowed for in the price (formula, § 5).

§ 3. — The purity should be at least 96 per cent (pure seeds after subtraction of impurities including clusters passing through a 2 mm., = 0.08 in., sieve). Seed is saleable down to 94.5 per cent., but the difference must be made up (formula, § 5).

§ 4. — One kilogram (2.2 lbs.) of seed must give in 14 days a minimum of seedlings as follows :

a) large-cluster seed	60 000
b) medium-cluster seed	65 000
c) small-cluster seed	70 000

Of this number, 70 per cent. must be up in 7 days.

One hundred clusters must give in 14 days a minimum of seedlings as follows :

a) large-cluster seed	80
b) medium-cluster seed , ...	75
c) small-cluster seed	70

Large-cluster seed is reckoned as containing not more than 40 clusters to the gram, medium-cluster 41 to 50, and small-cluster 51 or more.

§ 5. — Seed not fulfilling the conditions of §§ 1-4 is not saleable.

If the price is to be reduced under *either* § 2 *or* § 3, the reduced price is obtained by the following formula :

$$\frac{\text{price agreed upon} \times \text{value of seed delivered}}{\text{guaranteed value}};$$

but if *both* § 2 *and* § 3 require a reduction, the price is obtained by the formula:

$$\frac{\text{price agreed upon} \times \text{actual dry matter} \times \text{actual purity}}{85 \times 96.}$$

§ 6. — In the absence of any other agreement, samples must be taken within three days of the delivery of the goods, and by a sworn sampler. The directions for sampling are given in the appendix.

§ 7. — The determination of the conformity to agreement of the seed delivered is made by a station belonging to the Union of Agricultural Experiment Stations of the German Empire (Verband landw. Versuchsstationen im Deutschen Reiche) according to the method prescribed by this Union.

Each of the parties has the right to stipulate that the examination be made by a particular station belonging to the Union. The average of the two results is taken. Either party may also require a decisive analysis ; no reasons need be given for this, but notice must be sent in within four days of the receipt of the first results ; such analysis is to be made by a third station, selected by agreement or by drawing lots. In the demand for the decisive analysis it must be stated which determination is to be remade. In this case the average of the decisive analysis and the one which comes near-

est it on the disputed point is taken ; if the decisive analysis is half way between the other two, it is accepted.

Each party pays for his own original analysis, while the decisive analysis is paid for by the party requiring it.

§ 8. — If the presence of foreign beets, such as mangels, in the seed is complained of, a cultivation experiment is to be carried out in the same or the following year, using a certified seed sample. This is to be entrusted to an experiment station selected as for the decisive analysis. Each party may send an expert to judge of the result ; the director of the station fixes the day for this and acts as umpire.

Appendix. — Directions for sampling sugar-beet seeds.

1. *Taking the sample.* — Samples must only be taken from unopened consignments in sacks ; these must be so arranged that their number can be counted, or, if they are piled up, fairly accurately estimated. The lots must also be labelled in such a way that no doubt can arise as to their identity.

If the lot numbers more than 100 sacks, a sample must be taken from at least every twentieth sack ; if there are between 20 and 100 every tenth must be sampled, while for fewer than 20 sacks half must be sampled.

The sampler chooses the sacks from which he wishes to take samples ; these should be well distributed through the lot ; further the different samples should come from different parts of the sacks, and for this purpose he may have a certain number of the sacks emptied. At the request of one of the parties concerned, all the sacks to be sampled may be turned out. If, for want of room or other reasons, it is not practicable to empty the sacks, this fact must be noted in the report. The use of a sample bore is only allowed provided there is no possibility of its damaging the seed.

The sampler must be provided with the necessary labour for the work of sampling.

Sampling in a railway truck is allowable ; the same directions apply in this case.

2. *Treatment of the sample.* — The average sample made up from the small portions is thoroughly mixed and then divided into separate samples according to the number of analyses required.

The samples for the determination of moisture and purity are to be enclosed in clean and dry air-tight vessels of glass or tin ; the openings are then to be sealed with sealing-wax, rubber, wax or some similar substance; ground-glass stoppers should be greased. The samples must be tightly pressed into the glasses or tins. Each sample must weigh at least 200 gms. (7 oz.).

The samples for the determination of germination capacity are to be preserved in cloth bags or double paper bags ; they may not be enclosed in air-tight vessels. Each of these samples must weight at least 200 gms. (7 oz.).

The samples must be sealed or leaded by the party or parties present in such a way it that is impossible to open them without damaging the cover-

ing. When the samples are sealed, the sampler must label them ; for tins a properly adhesive sealed paper label is used, for bags a tie-on label ; in either case he must write on it the reference number from his diary, place and date of sampling, brand and number of the sacks making up the lot, name of the purveyor or receiver (even supposing him to be only temporarily in possession of the seed), and the apparent nature of the packing ; this information he certifies by his signature. If the sample is taken in a railway truck, the number of the truck must also be entered on the label.

If required, the sampler must provide a duplicate copy of this label, describing the nature and appearance of the seal or lead.

The sampler must see to the provision of the implements and materials necessary for the sampling.

3. *Number and destination of the prepared samples.* — The sampler has to prepare, according to instructions, 4 or 5 samples in glass vessels or tins and the same number in cloth or paper bags. He must send off those required within twenty-four hours to the addresses furnished by the person under whose instructions he is proceeding. He must also send one duplicate sample each to the purchaser and the vendor, while one he keeps himself.

The samples should be kept in dry unheated rooms. The sampler must keep his sample for a whole year, and must not part with it or deposit it for judgment except on the combined demand of vendor, purchaser, committer and receiver.

A duplicate copy of the label should be given to the temporary possessor, provided he is not the committer.

If the interested parties require it, the sampler may make more than the 4 or 5 samples, in return for a proportionate fee, but these must only bear his seal.

4. *Obstacles to sampling.* — If the sampler finds himself unable to observe these instructions, he must abandon the sampling.

German standards for the trade in mangel seeds (1914).

The following bodies have taken part in the drawing up of the clauses given below : Ausschuss für Handelsgebrauche (representing the societies named above), Gesellschaft zur Förderung deutschen Pflanzenzucht, and Vereinigung der Samenhändler Deutschlands. These are valid where no other agreements are in force.

§ 1. — The mangel seed must be delivered in good condition and fit for use ; it must belong to the variety named and must agree with the particulars of the other paragraphs.

§ 2. — As for sugar-beet seed.

§ 3. — As for sugar-beet seed, except that purity as low as 94 per ent. is allowed.

§ 4. — One kilogram (2.2 lbs.) of seed must give in 14 days a minimum f 60 000 seedlings. Of this number, 42 000 must be up in 7 days. The eed is saleable with only 50 000 seedlings per kilo, but the deficit below o 000 must be allowed for in the price.

One hundred clusters should give in 14 days a minimum of 75 seedlings for large-cluster seed and 70 for small-cluster seed. The seed is saleable with these figures down to 70 and 65, but the deficit must be made good. Large-cluster seed is reckoned as containing not more than 45 clusters to the gram of pure seed, small-cluster 46 or more.

In calculating reduction of price, an excess or deficit of seedlings per kilo may be set against a deficit or excess of germinating clusters, but the minimum value must come up to the standard. At the same time no raising of price is allowable. For the calculation of the reduction of price the formulae given in the Appendix are to be used.

§ 5. — Seed not fulfilling the conditions of §§ 1-4 is not saleable.

§ 6. — As for sugar-beet seed.

§ 7. — Differs from that for sugar-beet seed in that the station to make the decisive analysis is not to be selected by drawing lots ; if the parties cannot agree within eight days, the president of the Deutscher Landwirtschaftsrat nominates a station belonging to the Union. Further, in case of delivery contrary to agreement the vendor bears all the costs of analysis.

§ 8. — If the purchaser considers the colour (within the variety) of importance, he may propose a determination of this by germination tests ; any complaint on this point must be made within eight days of the receipt of the examination certificate. If complaint is made as to the correctness or purity of the variety, a cultivation experiment made in the same or the following year, using a certified seed sample, is to decide the question. This is to be carried out by a station selected in the same way as for the decisive analysis. The result is judged as under § 8 for sugar beets.

Appendix. — Directions for sampling mangel seeds.

Unless carried out by a sworn sampler, the sampling takes place as follows :

For lots up to 10 packages, all the packages must be drawn upon in the preparation of the sample ; with more than 10, one in ten must be used, with the proviso that at least 10 remain unopened.

Injured packages are not to be used even when accepted by the purchaser.

The packages selected are to be opened in such a way that samples may be taken from the top, the middle and the bottom, or else so that they can be turned right out and the seed well mixed ; at least ten samples are then to be taken from the heap (top, middle and bottom). The samples so obtained are to be put together, carefully mixed and divided into at least four equal parts. Each of these parts must weigh at least 200 gms. (7 oz.).

The samples for the determination of moisture content are to be enclosed in air-tight glass bottles or tins (as for sugar-beet seed). Those for germination tests are to be packed in linen or double paper bags, and must not be kept in air-tight vessels. All must be labelled in such a way that their origin can at any time be ascertained.

An impartial witness must be called in for the sampling; he stamps the seals or leads of the closed samples with his seal. The sample remitted must be accompanied by the witness' certificate of sampling, on which it must be stated that the samples were duly taken in his presence. The other samples must be kept in a dry unheated room in case they should be required for further investigations.

The vendor has the right to have similar samples taken on the purchaser's property, at his own expense, for examinations which he wishes made. If both parties have had samples taken, each must send in his sample for comparison in case a decisive analysis is required; the average of these two samples is taken as the decisive figure.

Formulae for the calculation of reduction of price on seeds below standard but saleable.

In the formulae, the values for dry matter and purity may only be inserted if they are within the limits set out in the regulations.

A balancing of excesses and deficiencies is only allowable in germination values (see § 4 above). No latitude is allowed outside the limits for delivery given in the regulations.

If the price is to be reduced under *either* § 2 *or* § 3 the following formula is to be used:

$$\frac{\text{price agreed upon} \times \text{value of seed delivered}}{\text{guaranteed value.}};$$

but if *both* § 2 *and* § 3 require a reduction, the price is obtained by the formula:

$$\frac{\text{price agreed upon} \times \text{actual dry matter} \times \text{actual purity}}{85 \times 96}.$$

If reduction is to be made under § 4 it is obtained as follows:

$$\text{price agreed upon} \times \frac{\dfrac{\text{seedlings germinating in 14 days in 1 gm.}}{60} + \dfrac{\text{clusters germinating in 14 days}}{75 \text{ (or } 70)}}{2}$$

In the last formula, the two figures for germination must both be entered, even when one of them is up to or above standard.

If reduction is required under §§ 2, 3 and 4, the corrected price from the second formula is substituted for " price agreed upon " in the last formula.

595 – **Agricultural Shows.**

AGRICULTURAL SHOWS AND CONGRESSES

Argentine Republic.

1914 Aug. 15-23. Buenos-Aires. — Agricultural show organized by the "Sociedad Rural Argentina".

Belgium.

1914 Aug. 29 (opening). Arlon. — Regional agricultural competition, organized by the "Société agricole de Luxembourg"; there will also be an agricultural exhibition, including several international sections. Address to "Secrétariat de la Société agricole du Luxembourg", Arlon, Belgium.

Canada.

1914 Sept. 3-12. Vancouver. — Agricultural and industrial exhibition.

Egypt.

1915 Feb. or early March. Cairo. — Agricultural show organized by the Khedivial Agricultural Society.

France.

1914 Sept. 11-13. Quimper. — Show of Breton Black-and-white Cattle. Also exhibition of agricultural machines and implements, and trials of potato-diggers.

Dec. 24-28. Paris, Grand Palais. — International Poultry and Rabbit Show, held by the "Société nationale d'Aviculture de France". Address of the Society: 34, rue de Lille, Paris.

1915 March 4-8. Nice. — Great Triennial Flower Show, organized by the "Société d'Horticulture pratique de Nice."

Germany.

1914 Sept. 19-23. Siegburg. — Provincial show, held by the "Landwirtschaftlicher Verein für Rheinpreussen."

Oct. 3-5. Hamburg. — Fourth fat stock show.

1915 May 8-11. Karlsruhe. — First fat stock show for Baden, organized by the city of Karlsruhe and the Chamber of Agriculture of the Grand Duchy of Baden.

Italy.

1914 Sept. 20-30. Quistello (Mantua). — Dairy industry show. Also national poultry show, interprovincial pig show and exhibition of agricultural produce.

United Kingdom.

1915 Edinburgh. — Competition for potato-planters. Address to: J. Stirton, 3 George IV Bridge, Edinburgh.

United States.

1915 Jan. 1-Dec. 31. San Diego (California). — International Exhibition, with the following sections: Agriculture; Food Products; Commerce and Industry; Domestic Economy.

596 – Agricultural Congresses.

Austria.

1914 Sept. 5-13. Göritz. — Ninth Austrian Wine-makers' Congress. Address: Geschäftsleitung des österreichischen Reichs Weinbauvereines, Wien III, Fasangasse 48.

France.

1914 Aug. 3 (opening). Lyons. — National congress on technical education in industry, commerce and agriculture. General Sec., 5 rue Jussieu, Lyon.

1915 April 6-9. Marseilles. — 53rd Congress of the Sociétés Savantes.

Hungary.

1914 Sept. 6-17. Budapest. — Eighth Congress of the International Union of Forestry Research Stations. Excursions will include: Szabadka (trials of fixation of shifting sands, stands of *Robinia*); Kiralyhalom (Secondary Forestry School); Puszta of Déliblát (old stands of Scots and Austrian pine, and plantations of *Robinia* carried out in a special way on shifting sands); Vadászerdö (forests of pedunculate oak, plantation of foreign trees and experimental plots): Gödöllö (Arboretum of the Archduke Joseph); Selmeczbánya (Central Hungarian Forestry Research Station, comprising: arboretum, nursery, experimental plots, meteorological station); Ohegy (domainial forest); Lake of Csorba, at 4500 ft. — Persons wishing to attend the excursions and meetings should send their names to the Secretariat of the Union, 3 rue de Louvain, Brussels.

CROPS AND CULTIVATION.

597 – **Variation in the Nitrate Content of the Soils in Scania, Sweden.** — WEIBULLL, M. in *K. Landtbruksakademiens Handlingaroch Tidskrift*, Year 53, No. 2, pp. 65-93. Stockholm, 1914.

The writer employed the Grandval-Lajoux method of estimating nitrates in soils, which proved very delicate and reliable. Samples were taken from different points of a soil and tested separately, not mixed to form a composite sample, as the variation from point to point may be considerable; care was also taken not to sample a soil twice in the same place, as each disturbance causes increased aeration and influences nitrification.

During five years the soil of a field was systematically tested for nitrates both on cropped and uncropped plots, to follow the variations due to season and soil management; manurial dressings were identical on the cropped and uncropped plots. The results are set out in Table I (p. 860); the treatment of the field was as follows:

1907. — Seeds: mown in June, dunged, ploughed and harrowed and sown with wheat on September 2.
1908. — Winter wheat: received 180 lbs of nitrate of soda per acre on April 24, harvested on August 12, dunged and ploughed September 12.
1909. — Sugar beet: receved a dressing of nitrate of soda May 20, lifted October 21, ploughed November 15.
1910. — Spring wheat: sown April 8, harvested in August, dressed with liquid manure and ploughed November 11.
1911. — Peas: sown in May, harvested August 10.

The nitrate content never exceeded 22 parts per million on cropped soil, while on fallow land it rose to 33. Among the cropped plots, those under beets contained up to 14 parts of nitrogen, those under wheat and peas only 8 or 9 parts, and those under seeds least of all (*viz.* 1.5 parts), but as soon as the latter were dunged and ploughed up nitrates increased to 6 parts per million and continued to accumulate right up to November, developing a nitrate content of 21 parts per million. Then the content decreased owing partly to absorption by the growing wheat and partly to washing out by rain, a loss which was verified later on other fallow plots. In the spring, nitrates were scarce; nitrification began again at seeding time but the nitrate content only became appreciably higher after the application of nitrate of soda, *i. e.* towards the middle of May. During the early summer the nitrate content generally increased, as did nitrate assimilation, evidenced by the difference between cropped and uncropped plots.

Influence of cultivations and vegetation on the nitrate content of soils. — In 1910 a piece of new ley (clover and grass in equal quantities) was divided into three equal parts of 10 sq. metres (107 sq. ft.) each; one of these was left in seeds, the second was freed from grass and clover and

Mean . .	2.4	6.5	11.3			

Nitrate content of the control plot in seeds remained low, averaging 2.4 parts per million and reaching a maximum of 4.3 parts at the beginning of July when vegetation was already in an advanced condition ; this plot was always driest. In the bare weeded soil the nitrate content was about three times as large and did not attain its maximum till later in July. In the dug over plot the nitrate content was about twice that of the second plot, but the moisture content remained approximately equal.

Influence of nitrate content on yield. — Samples of soil were taken throughout the growing season on a certain number of farms from plots having received a dressing of nitrate of soda, superphosphate and potash and from unmanured plots ; these samples were analysed for nitrates. The results show that soils in Sweden do not generally contain sufficient nitrate to provide for the requirements of plants, and this is especially the case with land under cereals or grass ; corn fields will only attain a nitrate content of 10 parts per million if they have been dressed with nitrogenous fertilizers and will reach their maximum at the end of May or beginning of June ; grass fields are usually lowest of all. Land under root crops or fallow is usually richer, and root fields may contain as much as 10 parts per million towards the end of June. When land is broken up after harvest, nitrification be-

comes active and nitrates accumulate more than at any other time. The maxima reached earlier in the season are only maintained a very short time, for nitrification decreases and plant assimilation is active ; on unmanured fields, nitrates become scarce after one or two months and crops suffer from starvation ; on manured soils a somewhat higher nitrate content is maintained for some time.

The writer investigated the question as to whether it were possible to detect the point at which nitrogenous manuring becomes necessary. Soils under beets were analysed during July and August ; the results are set out in Table III.

TABLE III — *Soils under beets.*

Place of trial	Yield on unmanured soil	Increase due to complete manuring	Nitrates as N in parts per million					
			July I	July II	July 21	Aug. I	Aug. II	Aug. 21

Mean			9.9	6.4	4.0	2.5	2.6	1.9

In the course of the two months, the mean nitrate content fell gradually from 9.9 to a minimum of about 2 parts per million. If the time at which this minimum content is first observed in each case be considered in relation to the increase in the crop caused by the nitrogenous manuring, it would appear that when the depletion of nitrate (2 parts per million) occurs early in the season, *i. e.* before the beginning of August, a nitrogenous dressing causes a fairly large increase of crop, but that the increase is less considerable if the scarcity of nitrates does not make itself felt till the middle or end of August ; these dates would be liable to modification with the character of the season. The nitrate content of plots dressed with nitrate of soda never sank to such a low level as that of the unmanured plots.

Under normal climatic conditions then, a nitrate content of 2 parts per million at the end of July in unmanured fields of beets would indicate the necessity of applying a nitrogenous dressing, while if this low level does not appear till the middle or end of August, the natural content of the soil would be sufficient for the crop. According to RÉMY, it is just in July that beets develop a high capacity for assimilation, so that the results obtained above would not be unexpected. Probably a similar

period of maximum assimilation exists for other cultivated plants and it would be of great interest to extend investigations to other crops. Three trials carried out with forage crops gave in one case a large increase with a nitrogenous dressing, in the second case an appreciable increase, and in the third no increase, while the nitrate content of the respective soils sank to the critical point (2 parts per million) in June and before August in the two first cases, while the scarcity was never apparent in the third case. In one trial with potatoes the nitrate content of the soil sank to 2 parts per million on July 1, and a handsome increase was obtained with a nitrogenous dressing. In three trials carried out with spring corn, scarcity of nitrates was observed in one case in May and in the two other cases on August 1 and August 11; response to nitrogenous dressing was only obtained in the first case.

598 – **Experiments on the Rate of Nitrification.** — BEESLEY, R. M. in *Journal of The Chemical Society*, Vols. CV and CVI, No. DCXVIII, pp. 1014-1024. London, April 1914.

The rate of nitrification was determined for the following substances: carbamide, thiocarbamide, uric acid, asparagine, glycine, acetamide, aniline sulphate, methylamine sulphate, ammonium oxalate and ammonium sulphate and a special form of apparatus was devised so as to enable samples of the nitrifying solutions to be withdrawn without exposing the contents to accidental contamination from the organisms contained in the atmosphere. A suitable mixed culture of hydrolytic and nitrifying organisms was obtained from the secondary contact beds of a local sewage works. The course of hydrolysis and nitrification in the various solutions was traced by means of periodic determination of the ammoniacal, "nitrous" and "nitric" nitrogen figures. The ammoniacal nitrogen was determined by direct Nesslerisation of diluted portions of the nitrifying solutions. During the early stages of fermentation the "nitrous" nitrogen was determined by means of the anaphthylamine and the sulphanilic acid test, but as the concentration reached 3 parts per hundred thousand, Duyk's volumetric method using iodine was adopted. The first appearance of nitric acid was detected by means of brucine and sulphuric acid, and the quantity of "nitric" nitrogen was determined as ammonia by reduction with a zinc-copper couple.

No nitrification took place in the solutions containing thiocarbamide and aniline sulphate. Ammonia was produced in the latter to the extent of 90 per cent. of the original nitrogen in solution, showing that the aniline was merely hydrolysed. However, no phenol was detected, probably owing to its destruction by bacterial agency. Nitrification took place in all the other solutions at approximately the same rate. In the case of the ammonium salts there was a temporary disappearance of nitrogen between the 30th and 60th days of fermentation. This loss of nitrogen becomes noticeable before any nitrate makes its appearance, and since the oxidation from nitrous to nitric acid consists of only one step it appears that it is in some stage of oxidation between ammonia and nitrous acid that the nitrogen becomes non-realisable.

The writer therefore concludes that intermediate substances of the nature of hydroxylated ammonium radicles are formed in the bacterial oxidation of the ammonium radicle.

599 – **Humus in California Soils.** — LOUGHRIDGE, R. H. in *California College of Agriculture Experiment Station, Bulletin* No. 342, pp. 49-92. Berkeley, Cal., January 1914.

The soils of California are characterised by the presense of humus to beyond twelve feet below the surface. There is not the sharply defined change of the black humus colour to grey at a depth of 6 or 9 inches, characteristic of normal humid soils. In some of the heavy clay soils a change in colour takes place at a depth of three feet, but for the most part the change in tint is very gradual downward through many feet. The average quantity of humus in 109 Californian soils is 1.35 per cent. for the first foot and a sum of 3.17 per cent. for the first three feet, equivalent to about 126 800 lbs. per acre. The average humus content of 280 humid soils of the United States is 2.63, or approximately 105 000 lbs. per acre.

Thus, even excluding the humus below a depth of 3 feet, the arid soils of California contain more humus than the humid soils of America. The wonderful endurance of drought on the part of plants in Californian soils is due to this distribution of humus through a depth of many feet and the consequent deeper root penetration.

Professor Lipman has shown that nitrifying bacteria are present and active in California soils to a depth of six feet, and ammonifying bacteria are present through a depth of twelve feet, thus making available the nitrogen content of the humus to these depths.

Phosphoric acid is present in the humus of Californian soils to the extent of from 0.01 per cent. to 0.08 per cent. throughout the entire depth, though usually most abundant in the upper few feet.

600 – **Soils with a Mineral Acidity.** — LOEW, O. in *Landwirtschaftliche Jahrbücher*, Vol. 46, Part 1, pp. 161-164. Berlin, 1914.

According to the writer, in considering soils with an acid reaction, a distinction is to be drawn between those in which this property is due to the presence of humus, and those which have a mineral acid reaction.

Soils with mineral acidity have recently formed a subject of research for agricultural chemists. Daikuhara, who was the first to turn his attention to this question, reported seven years ago that soils devoid of humus might have an acid reaction, and that this acid property was due to the clay. He also found that such soils exist, not only in Japan, but also in Corea and along the Chinese coast, countries in which the frequent summer rains may wash the basic elements out of the soil. Acid clays are also found fairly frequently in Germany and in the United States. According to Daikuhara these soils, when manured with neutral salts, as, for example, chloride of potash or sulphate of ammonia, become even less fertile than they would be without any manure, because the insoluble acids of the clay, uniting with the bases, liberate acids (in this case sulphuric and hydrochloric), and thus increase the acid nature of the soil. The writer concludes that acid soils should only be manured with basic fertilizers.

601 — **The Influence of Irrigation and Crop Production on Soil Nitrification.** — McBeth, I. G. and Smith, N. R. in *Centralblatt für Bakteriologie, Parasitenkunde und Infektionskrankheiten*, Vol. 40, No. 1-8, pp. 24-51. (article written in English). Jena, February 16, 1914.

These nitrification studies were carried out on the Greenville Farm belonging to the Utah Agricultural Experiment Station. The soils are of sedimentary origin and contain no particles larger than "fine sand". Chemical analysis shows them to be exceptionally rich in the mineral plant food constituents, but characteristically low in humus and possessing only a fair nitrogen content. The surface soil to a depth of one foot contains 43 per cent. of calcium and magnesium carbonate in the ratio of 1 lime : 2.8 magnesia.

The influence of irrigation and growing crops on nitrification was determined by measuring the rate of nitrification of ammonium sulphate and dried blood when added to samples of the soils. Water from the Logan River was used for irrigation and was of fairly constant composition during the season. Analysis showed it to have a very low fertilising value and to contain less than 400 parts of total residue per million.

The results obtained in these experiments are as follows :

1) The nitrifying power of the surface foot of soil was ten times that of the second foot and many more times that of the third, fourth, and fifth foot respectively.

2) Irrigation decreases the nitrifying power of soils, especially in the first two feet. This effect continues during the following season.

3) More than 50 per cent. of the full water capacity of the soil is required for maximum nitrification, but the quantity varies considerably with different soils. Maximum nitrification is generally secured when the soil is just on the point of becoming sticky. Too small a supply of moisture has a greater effect in retarding nitrate formation in these soils than a too liberal application.

4) The additon of a quantity of nitrogen as ammonium sulphate greater than 170 parts per million showed an inhibiting action on the nitrifying organisms. In no case was as much 50 per cent of the nitrogen added as ammonium sulphate recovered in the form of nitrate.

5) Growing crops such as afalfa, potatoes, oats and corn increase the nitrifying power of the soil, the effect being greatest in the case of alfalfa.

6) The greatest gain in nitric nitrogen was obtained from the alfalfa land when ammonium sulphate was used as the nitrifiable substance ; when dried blood was substituted for ammonium sulphate, the greatest gain was from the oats land.

7) The smallest gain with both ammonium sulphate and dried blood was obtained from the fallow land.

609 — **The Great Artesian Basin of Australia.** — *Journal of the Royal Society of Arts*, Vol. LXII, No. 3202, pp. 438-440. London, April 3, 1914.

The largest of all artesian basins is that in the eastern half of Australia, and it has been brought into prominence recently by the discovery of

a serious falling off in the supply. A Conference of the most eminent geologists and engineers from all the States was appointed with the object of discovering the cause, in view of arresting the decline in the output, and now its report has been published. The basin in question is roughly triangular in shape, and about 1000 miles in maximum length from north to south and about the same from east to west. The intake surface beds which supply nearly all the water are on the eastern side of the basin, being in a more rainy country than on the west, and they coincide generally with the western slope of a belt of high country parallel to and about 200 miles from the coast. This belt is for the most part composed of porous Triassic freshwater sandstones. It has been estimated that 13 200 million gallons daily reach the stratum down to which bores are being driven, while about 700 million gallons are being drawn from the wells. As in most artesian basins, the lip of the subterranean basin dips in some places and allows a certain amount of water to escape ; in this particular case also, it has been ascertained that there is a considerable escape at the north end into the Gulf of Carpentaria.

The first discovery of artesian water was made in 1879; since then 84 000 square miles of country in New South Wales and 376 000 square miles in Queensland were found to be water bearing under natural pressure. Large areas of these tracts are within the 10-inch and the 20-inch average yearly rainfall, these amounts being also exceedingly irregular in incidence. Therefore as bore sinking advances vast pastoral districts in which millions of sheep died in drought times, are gradually being transformed into areas in which access to water is ensured, and great losses of stock are avoided.

According to latest returns 2 336 wells have been sunk, yielding, as said above, 700 million gallons daily. The maximum and minimum depths are 5 045 feet and 5 feet, and the temperature of the water ranges from 148° F. to 70° F., increasing approximately 1° for every 44 feet.

The wells are almost exclusively used for watering stock, but in some places they have been used for township water supply and for the production of power, but not for irrigation, the quantities being generally too small. The recent Conference has advised prohibiting (with some exceptions) the employment of the water for any purpose other than that of watering stock.

The diminution in the supply had been noticed in a few cases since 1894, but about 10 years ago it became clear in many instances and since then it has become more or less marked over all the area of the great basin.

It was thought by some that local escape through defective casing of the bores or occasional drought over the intake beds might be the cause of the mischief, but the evidence before the Conference was not considered sufficient to confirm these opinions.

The Conference, in spite of the voluminous evidence collected, has not been able to come to any definite and complete conclusion as to the cause of the decline in the supply, and it has confined itself to recommending that more data be furnished to a Permanent Board sitting annually and that the laws affecting artesian water supply be made uniform in all the States.

603 – **Progress in Irrigation in South Africa.** — *Daily Consular and Trade Report*, Year 17, No. 40, p. 786. Washington, February 27, 1914.

Under the system of irrigation boards, no fewer than 30 districts have been proclaimed in the Cape Province alone, the capital expenditure involved being $4 136 000 ; a number of Government irrigation settlements exist in the Cape, Transvaal and Orange Free State Provinces. Boring is proceeding on nearly 500 farms and during the year ended March 31, 1913, 93 holes were completed having a total footage of 18 440 and a yield of 1 321 500 gallons per day.

The pumps most in use in South Africa are a reciprocating type suitable to varying capacities and heights and to installations where the water supply is irregular.

In regard to motive power for small pumping installations, oil engines up to 6 HP are very commonly used. For larger installations suction gas plants are extensively employed, the most important to date being a 108 brake HP equipment at Grahamstown. In some districts anthracite coal is available and cheap to use, but suction gas plants are more widely in demand and are already the accepted type for irrigation works of any size.

604 – **Technical Precautions Necessary in the Electrification of Crops.** — PRIESTLEY, J. H. (Some recent experiments in the application of electricity to plant production) in *The Gardeners' Chronicle*, Vol. LV, No. 1424, pp. 245-247 and No. 1425, p. 271. London, April 18, 1914.

Previous experiments have been carried out in ignorance of the complication and sources of error attendant in the management of high potential discharges. The techinical difficulties to be overcome are :

1. Adequate insulation of the wires.
2. Changes in the area of distribution of the discharge by wind.
3. A simple and accurate method of determining the electrical condition of the atmosphere above each plot.

The changes in the direction of the discharge produced by changes in the intensity and direction of the wind will confuse the issue of all experiments, however carefully planned otherwise, if precautions are not taken to ensure normal electrical conditions for the control plots. The difficulties of controlling the electrical conditions without interfering with the other physical conditions of the plots are so great that it is necessary to make accurate records of the electrical condition of each plot throughout the experiments before the results can be interpreted satisfactorily. Further, no comparisons of experiments made in different localities, or at different times, can be made, unless the particular electrical conditions prevailing at the time are considered.

Efficient insulators and a simple apparatus for the determination of the distribution of the electrical discharge have been divised. With a due appreciation of the importance of these factors, the application of electricity to growing crops becomes a simple matter, and distinct improvement in the progress of this study is to be expected.

MANURES AND MANURING

605 – **Production and Consumption of Fertilizers in the World.** — INTERNATIONAL INSTITUTE OF AGRICULTURE, BUREAU OF AGRICULTURAL INTELLIGENCE AND PLANT DISEASES, *Production et consommation des engrais chimiques dans le monde*, Second edition, pp. 162. Rome, 1914 (1).

The production, consumption and trade in fertilizers is of an eminently international character, as no country is in a position to provide for all its own wants in that respect; moreover, while the use of artificial manures is gradually spreading to all cultivated parts of the globe, the raw material from which they are produced is concentrated in only a few points. The present edition of the above publication has been completed with regard to the world movement of fertilizers by data for the colonies which were not available in 1913.

Production.— The world's production of the principal fertilizers during 1910, 1911 and 1912 is given in Table I, together with similar data for 1903.

TABLE I. — *Total production of fertilizers (metric tons).*

	1903	1910	1911	1912
Phosphatic manures.				
Mineral phosphates	3 098 866	5 609 760	6 181 199	6 852 343
Basic slag	3 243 500	3 275 845	3 506 500	3 988 000
Superphosphate	5 130 900	9 604 260	10 000 000	11 000 000
Guano	71 100	61 000	83 000	72 000
Total	10 544 366	18 550 865	19 770 699	21 912 343
Potash manures.				
Potash salts	4 078 268	9 285 408	10 985 760	12 531 216
(containing K_2O)	(366 421)	(857 883)	(939 927)	(1 009 219)
Indian saltpetre	18 711	16 140	14 910	15 036
Others (given as K_2O)	—	28 000—44 000		
Nitrogenous manures.				
Nitrate of soda	1 485 279	2 465 415	2 522 120	2 586 975
Sulphate of ammonia	582 206	1 053 994	1 198 363	1 327 508
Cyanamide	—	30 000	52 000	95 000
Nitrate of lime	25	25 000	50 000	75 000
Total	2 607 510	3 574 409	3 822 483	4 084 483

The Seychelles have recently provided a new source of guano, producing 22 260 metric tons in 1911.

(1) Price 3.50 fr., to be obtained of the International Institute of Agriculture, Rome

The figures for the total amount of phosphatic manures are too high, as the mineral phosphates are counted twice over, being largely used in the manufacture of superphosphate.

It is not possible to give exact figures for the total production of potassic manures, but the great bulk of these is in the form of potash salts (Stassfurt). Modern developments in the production of potash manures consist in the extraction of potash; 1) from seaweed in the United States, by which means it is estimated that an annual yield of 1 000 000 tons of potassium chloride (equivalent to 630 000 tons of K_2O) might be obtained; and 2) from the felspars, also in the United States, by which means a possible annual yield of 400 000 tons of potash is estimated.

With regard to the nitrogenous fertilizers, the production of sulphate of ammonia is five times as large as it was twenty years ago, and there has lately been introduced a new method of extracting it from peat; the process, known as the Mond-Frank-Caro process, extracts from 90 to 180 lbs. of sulphate of ammonia from one ton of peat. The production of synthetic nitrogenous fertilizers since 1903 is given below, together with estimated figures for 1913 and 1914 (in brackets).

	Calcium cyanamide	Nitrate of lime
	metric tons	metric tons
1903	—	25
1904	—	550
1905	—	1 600
1906	500	1 600
1907	2 200	15 000
1908	8 300	15 000
1909	16 000	25 000
1910	30 000	25 000
1911	52 000	50 000
1912	95 000	75 000
1913	(97 000)	(140 000)
1914	(208 000)	—

Particulars as to the place of production of mineral phosphates, basic slag and sulphate of ammonia are as follows:

Mineral phosphates.

United States	3 216 046 metric tons

As in Table I, the totals are again somewhat too high on account of the mineral phosphates being employed in the manufacture of superphosphate. The value of the total consumption was below £ 80 million in 1910 and above that figure in 1912.

Table III is a first attempt to determine the intensity of consumption of fertilizers in the different countries. The figures in the last column represent the order of intensity according to the following scheme:

	Mean consumption of fertilizers in quintals per hectare of agricultural land
1	over 2 quintals (180 lbs. per acre)
2	1 to 2 » (90 to 180 »)
3	0.5 to 1 » (45 to 90 »)
4	0.1 to 0.5 » (9 to 45 »)
5	0.01 to 0.1 » (0.9 to 9 »)
6	less than 0.01 » (0.9 »)
7	undetermined
8	no data

An extensive bibliography is appended to the publication, which, in its present (second) edition, forms the starting point for the half-yearly Review (*Revue semestrielle du mouvement international des engrais chimiques*). The publication of this Review was decided upon at the last General Assembly of the Institute (Inst. Int. d'Agr., 4ème Ass. gén., Décis. II, Rapp. Pioda-Laur, 1913) and the first number will appear on September 1, 1914.

606 – **Five Years' Manuring Experiments in East Prussia.** — STUTZER, A. in *Arbeiten der Deutschen Landwirtschafts-Gesellschaft*, Part 258, 236 pp. Berlin, 1914.

The writer, with his collaborators, carried out in the five years 1909 to 1913, 66 field manuring experiments on 15 different estates, and 17 trials of manures for meadows and pastures on several farms. The most important results obtained are the following.

1. *Potash.* — According to the literature on the subject, potash manures are credited with protecting winter cereals and other plants against frost, and this when the potash manures have been spread before sowing and the plants have taken up and elaborated the potash. According to the writer, it is very probable that the effect of potash manures in this direction depends rather upon certain accessory circumstances than upon the plant-food potash itself.

In the experiments, the 40 per cent. potash salt proved better them kainit as a winter top-dressing.

In sowing clover under spring grain (oats or barley), manuring with potash should not be neglected, as it is important for the cereal and still more so for the succeeding clover. In manuring experiments on permanent pastures and meadows, potash manures have proved especially necessary.

2. *Nitrogen.* — The experiments have confirmed the observation that dunged mangels which received nitrate of soda as well as potash and phosphoric acid made much better use of the potash in the manure and in the soil, and also of the nitrogen in the farmyard manure.

Further experience has been gained as to the good effects of the nitrogen in nitrate of lime.

The effect of cyanamide in these experiments was considerably inferior to that of nitrate of soda or of nitrate of lime. The troublesome dust produced by cyanamide when broadcasted could be avoided by mixing with it 10 to 15 per cent. of iron pan. This also improves its action, as the presence of iron oxide assists in the transformation of cyanamide into urea. This mixture as a top-dressing for winter grain gave an increase in the yield and a better utilization of the nitrogen, *viz.* from 48 to 62, 29 to 59, 37 to 78, 49 to 87, 42 to 57 and 46 to 64 (as percentages) in the various experiments.

Cyanamide freed from carbide by treatment with steam gave a higher yield of grain than ordinary cyanamide in field trials with oats. The same result was obtained by adding organic substances to cyanamide.

Sulphate of ammonia obtained by Haber's process (combination of atmospheric nitrogen with hydrogen to form ammonia) proved equal in field trials to the product of coke and gas works.

The writer has also made observations on the action of a combined dressing of sulphate of ammonia and rock-salt on sugar beets in a very good year and a very bad year. In the good year this mixture gave decidedly better results than nitrate of soda ; in the bad year the weather was very dry till the end of June and the beets developed very late : the result was that the amount of sugar produced on a given area was greater on the nitrate of soda plot.

Among new manures, urea obtained from atmospheric nitrogen, and nitrate of urea, gave good results ; their value was determined partly in field trials and partly in pot cultures. The urea used contained 43 to 44 per cent. of nitrogen, the nitrate of urea 33.60 per cent. In the pot cultures in the summer of 1913 oats were used ; out of 100 parts of nitrogen supplied as manure, the following were recovered in the crop :

Manuring	Soil used: Loam	Soil used: Peat soil
Nitrate of soda	80.5	80.5
Urea	83.5	88.5
Nitrate of urea	94.5	77.0

In experiments with tobacco, nitrate of urea beat all other nitrogenous manures.

Three other compounds built up from atmospheric nitrogen, *viz.* calcium nitrite, aluminium-nitrogen and silicon-nitrogen, turned out to be of little value or quite useless.

In experiments on permanent pastures and meadows, small dressings of nitrogen have sometimes given highly satisfactory results ; but it is not yet clear under what soil conditions such manuring is likely to be successful.

Stimulants (catalytic manures) have also been tried : mixtures of manures with various metallic oxides and salts of metals have sometimes given good results, sometimes none. It appears that different plants behave differently towards these bodies.

607 – **Comparative Effects of Nitrate of Soda and Nitrate of Lime** (1). — CHATEAUCLOS, R. in *Journal d'Agriculture pratique*, Year 78, No. 22, pp. 688-690. Paris, May 28, 1914.

Good results were obtained by using nitrate of lime on certain sandy and granitic soils poor in lime in the departments of Vienne and Haute Vienne.

608 – **The Manufacture of Calcium Cyanamide in Dalmatia** (1). — *Landes-Amtsblatt des Erzherzogtumes Österrich u. d. Enns*, Year 10, No. 9, pp. 69-70. Vienna, 1914.

The manufacture of calcium cyanamide, which is making such great progress in all parts of the world (2) has of late become established also in

(1) Cf. article : " The Use of Artificial Nitrogenous Manures in Austria " by F. W. DAFERT, in *B.* Dec. 1912, pp. 2547-2550.

(2) The estimated output of the world for 1913-1914 was 27 500 tons.

Dalmatia. The cyanamide factories which have been erected in that country derive their power from the falls of the Kerka near Sebenico and of the Cetina near Almissa, not far from Spalato. When completed, the factory at Almissa will produce about 2 ½ times as much as the one at Sebenico. The falls of the Cetina are not inconsiderable, and the driving power developed by the force of the water is thus fairly high ; when the works are completed, there will be annually available about 80 000 HP.

609 - **Austrian Experiments in Inoculating Leguminous Crops with Nodule Bacteria.** — KÖCK, G., in *Monatshefte für Landwirtschaft*, Year VII, Part 1-2, pp. 24-27. Vienna, January-February 1914.

The Vienna Phytopathological Station has carried out, on its experimental grounds in various parts of Austria, experiments in the inoculation of seed with nodule bacteria. The experiments were carried out with serradella, beans, and lupins.

In one case serradella gave the greatest yield of green forage after treatment with Azotogen (1) while in two others Nitragin (2) was the most effective, Azotogen having very little influence. In one experiment Nitragin gave a yield of green food 2 ½ times, and Azotogen twice, as large as that produced by the untreated area. The yield of seed was also, roughly speaking, doubled by the use of either agent as compared with the untreated area. The nodule bacteria from the Institute of Agricultural Botany at Munich also exercised a remarkably beneficial influence on the yield. No influence was observable, as a result of these experiments, from the inoculation on leguminous plants raised the following year on the same land.

With beans and blue lupins no noteworthy results were in either case to be recorded, while in another experiment, part of the blue lupins shewed a considerably increased yield. In this same experiment white lupins did not respond at all to the application of various bacterial cultures.

It is, of course, impossible to generalize from the results obtained, without taking into account the nature of the soil and of the plants grown. Trials on his own land can alone afford the farmer conclusive information as to the economic value of this kind of treatment as applied to the various leguminous crops.

610 – **Composition of Various Starches.** — TANRET, C. in *Comptes Rendus des Séances de l'Académie des Sciences*, Vol. 158, No. 19, pp. 1353-1356. Paris, May 11, 1914.

AGRICULTURAL BOTANY. CHEMISTRY AND PHYSIOLOGY OF PLANTS

The writer observed that all starches contain amylopectin and various amyloses in different proportions. They may also be distinguished from one another by the effect of water on the amylopectin and by the solubility of the amyloses in hot water. Analytical methods are discussed and the composition of various starches is given as follows :

(1) Azotogen cultures supplied by HUMAN and TEISLER, of Dohna.

(2) Nitragin cultures supplied by A. KÜHN'S Agricultural Works, Bonn-on-Rhine.

Amylopectin and amylose content of various starches.

Starch	Amylopectin	Amylose	Starch	Amylopectin	Amylose
Oats	71.5	28.5	Maize	70	30
Banana	79.5	20.5	Barley	73	27
Wheat	67.5	32.5	Pea	78.5	21.5
Chestnut	67	33	Apple	76	24

611 – **The Determination of the Quality of Starch in Rice Grains.** – WARTH, F. J. and DARABSETT, D. B. — 1. Disintegration of Rice Grains by means of Alkali, in *Agricultural Research Institute, Pusa, Bulletin* No. 38, pp. 1-9, + plates I-VI. — 2. The Fractional Liquefaction of Rice Starch, in *Memoirs of the Department of Agriculture in India, Chemical Series*, Vol. III, No. 5, pp. 135-146, + I plate. Calcutta, February 1914.

I. Chemical analysis reveals no differences in composition between different varieties of rice such as would account for their differences in hardness, milkiness, and milling qualities. With the object of divising some method of distinguishing the quality of the starch, rather than its quantity, in different types of grain, these investigations on the disintegration of rice grains by means of alkali were commenced. Rice grains immersed in dilute solutions (one per cent.) of alkali show disintegration in a few hours owing to the solution of the protein constituent. At concentrations of alkali of 2 and 3 per cent. the starch granule are attacked and the whole of the grain becomes gelatinised. It was found that the degree of milling or polishing has no effect on the rate of disintegration, but that different varieties show considerable differences.

II. After a series of comparative trials, it was found that immersion in a 1 per cent. solution of potassium hydrate for 24 hours produced satisfactory results without causing appreciable breakage of the starch granules. Various samples of rice were disintegrated in this way, and, after neutralisation, were subjected to fractional liquefaction by conversion of the starch with malt extract at different temperatures. After conversion the solutions were filtered with kaolin to remove the unliquefied granules. The liquefied starch was estimated in an aliquot portion of the filtrate by hydrolysis with hydrochloric acid, the glucose content being determined by Fehling solution using permanganate for estimating the cuprous oxide. The quantities of permanganate required are proportional to the amounts of starch liquefied at a given temperature, and may be used in comparing the qualities of the starch of the different varieties of grains.

The results obtained with various samples of rice are as follows:

1) Glutinous rices contain starch which liquefies appreciably at 60° C. and is almost completely liquefied at 70° C.

2) Hard vitreous rices do not begin to liquefy to any appreciable extent before 65° C. and reach completion at about 75° C. A sudden breakdown of starch takes place between 70° and 75° C.

3) In almost all types of rice there is a residue of 7 or 8 per cent. of more resistant starch which only breaks down gradually.

From these results it appears that the cooking quality of rice is distinctly correlated with its starch quality. Comparisons of the rate of disintegration in alkaline solution show that there exists some correlation between disintegration and starch quality. Further work is necessary to determine the exact relationship between protein content, rate of disintegration and starch quality.

612 – **The Movement of Potash in Plant Tissues.** — MAQUENNE, L. and DEMOUSSY, E. in *Comptes Rendus des Séances de l'Académie des Sciences*, Vol. 158, No. 20, pp. 1400-1404. Paris, May 18, 1914.

Branches of various plants were subjected to electrolysis in a jar containing distilled water in order to dissociate ionisable compounds. The cathode liquid was then examined: more than four-fifths of its contents consisted of potash. The anode liquid on the other hand contained traces of phosphoric acid, and smaller traces still of sulphuric and hydrochloric acids.

613 – **The Action of Manganese on Plant Growth.** — 1. KELLEY, W. P. (The Function of Manganese in Plants) in *The Botanical Gazette*, Vol. LVII, No. 3, pp. 211-227. Chicago, March 1914. — 2. SKINNER, J. J. and SULLIVAN, M. X. (The Action of Manganese in Soils) in *Bulletin of the U. S. Department of Agriculture*, No. 42, *Contribution from the Bureau of Soils*. Washington, April 3, 1914.

Previous experiments on the effect of manganese on plant growth show very variable results. Two views have been put forward to account for the observed effects, *viz. a*) the stimulation of the activity of oxidising enzymes in soils and plant tissues; and *b*) the increased solubility of the mineral constituents of soils. The inadequacy of these views to account for all the facts has led to the present investigations.

1. — *The function of manganese in plants.*

The writer has studied the effect of manganese on plant tissues microscopically and chemically. He finds that changes take place in the protoplasmic contents of the cells of the roots and leaves. Occasionally the protoplasm contracts from the cell walls and the nuclei become brown. In some plants (pineapple) the chlorophyll undergoes decomposition and starch formation ceases. This action is shown to be independent of the activity of the oxidising enzymes. The ash analyses of numerous plants show that manganese is absorbed in considerable quantities, that the ratio of lime to magnesia is increased and that the percentage of phosphoric acid is decreased.

From these results, the writer is led to suggest that manganese affects the permeability of the protoplasm to calcium and magnesium salts and that the consequent change in the rate of absorption of these salts may react beneficially or otherwise according as the ratio of lime to magnesia in the soil is less or greater than that required for maximum growth.

2. — *The action of manganese in soils.*

Experiments were carried out to study the effect on growing crops of adding manganese salts to soils and to water cultures containing aqueous

extracts of soils. The effect in the oxidation of the soil of plots containing growing crops was also determined. The results obtained are summarised as follows :

a) Manganese chloride, sulphate, nitrate, carbonate and dioxide have a stimulating effect when applied to unproductive sandy loam soil. The best results were obtained when the salts were applied in amounts of from 5 to 50 parts of manganese per million.

b) On a productive loam the various salts of manganese had no stimulating effect.

c) The effect of manganese on the oxidising power of the roots and on the general growth of plants growing in aqueous extracts of soils varies with different soils. With poor, unproductive soils, especially those containing harmful organic compounds, the addition of manganese increased oxidation and growth. With productive soils, oxidation was increased but the growth was decreased, probably owing to excessive oxidation.

d) On soils of an acid nature the addition of manganese decreased the oxidising power of the soil and plants as well as the crop production.

e) The oxidising power of a soil depends not so much on the amount of manganese as on its form, and on the nature of the organic matter. Organic matter in a state of autoxidation increases the oxidising action of manganese.

The writers suggest that the beneficial action of manganese in certain soils may be due to its function of aiding and increasing the oxidation and other vital processes in the plant as well as in the soil, and by this means changing or destroying some noxious products detrimental to plant growth.

614 – **Action of Thorium on Seeds.** — MUÑOZ DEL CASTILLO, JOSÉ (Lecture before the Spanish Farmers' Association) in *Boletín de la Asociación de Agricultores de España*, No. 58, pp. 50-56. Madrid, March 1914.

Since 1912, the Radiological Institute of Madrid University has undertaken a series of investigations into the action of radium, thorium, and radioactive manures. By this means it has been confirmed that with regard to increasing the growing-power of seeds, the action of thorium is superior to that of radium as regards cereals and other food-plants, and that plants grown from seed subjected to thorium-radiation possess a stronger growth.

The most complete investigations were made with barley, the seed being placed in two earthenware pots filled with ordinary earth. In one of the pots small particles of thorium ore had been placed beforehand ; the other pot acted as a control. From the seed produced by the pot containing the thorium, other cultures were started in two more pots, one filled with ordinary earth, and the other with similar earth containing thorium ore. The result, which the writer illustrates by means of photographs and a diagram, was as follows : the third generation of barley exposed to the action of the thorium had the leaves so highly developed that it looked like a new variety.

The writer observes that there are plenty of soils possessing radioactivity on account of thorium emanations, and that they ought to be used particularly for seed production. Analysis of soils to determine the presence of this property would therefore be useful.

615 – **Breeding Experiments which Show that Hybridisation and Mutation are Independent Phenomena.** — GATES, R. R. in *Zeitschrift für Induktitive Abstammungs und Vererbungslehre*, Vol. II, Part 4, pp. 209-278, + 25 figs. (article written in English). Berlin, March 1914.

Hybridisation experiments between *Oenothera rubricalyx* and *O. grandiflora* give results wich cannot be interpreted in terms of Mendelian unit-characters. The red pigmentation characteristic of *rubricalyx* is dominant in F_1 and shows segregation in F_2, but the ratios of pigmented to unpigmented offspring were different in different families. It is therefore concluded that different F_1 individuals possess different *degrees of prepotency* as regards the percentage of pigmented plants in their offspring. Crossing back the F_1 with either parent produced offspring of a darker or lighter shade respectively, showing that the amount of pigment produced by the individual cells is *quantitatively* inherited.

The characters for height were inherited according to the ratio 3 tall : 1 dwarf in one family and 1 tall : 2 dwarf in another. When the reciprocal cross was made the ratio was 7 : 1. These results can only be accounted for by assuming different degrees of prepotency in different F_1 individuals.

The numerous differences in foliage, buds, pubescence and in physiological development between *grandiflora* and *rubricalyx* are non-Mendelian or blending characters. In all these cases there is neither dominance nor segregation, but every conceivable degree of intermediacy is represented.

From these and other results the writer concludes that the Mendelian conception of fixed and unmodifiable unit characters which can be redistributed and shuffled regardless of the organisms themselves which exhibit these characters, is unsound, for the individual organism is the real unit. The presence-absence hypothesis implies a misconception of the nature of the differences between alternative characters, and of their interactions with each other.

Various mutants and aberrant forms occurred among the above hybrids. One of these, known as *lata rubricalyx*, was examined cytologically and was found to contain 15 instead of the usual 14 chromosomes. This work will be described elsewhere.

616 – **A Case of Correlation in Wheat.** — PARKER, W. H. in *Journal of Agricultural Science*, Vol. VI, Part II, pp. 179-181. Cambridge, May 1914.

In investigating the variation of the density of ear in a variety of wheat (Squarehead's Master) a striking case of correlation was observed between the average length of internode of the ear and its total length. The average internode-length is obtained by dividing the total length of rachis in millimetres by the total number of internodes. Measurements were made of the main tiller of 1887 plants and the calculated correlation coefficient

proved to be 0.9099. Considering the very small deviation of the actual internode-lengths compared with those estimated, the use of the more easily determined total rachis-length as a measure of the density of ear would appear to be justifiable. The writer also considers that the relation between internode-length and rachis-length would be a more satisfactory basis for the classification of wheats according to the density of their ears, than that of the internode-length as used by NILSSON-EHLE, or the method of grouping them into classes by eye alone as is done at Svalöf.

617 – **Rice Breeding in Java** (1). — VAN BREDA DE HAAN, J. in *Bulletin économique de l'Indochine*, Year 16, No. 100, pp. 11-28. Hanoï, January-February 1913.

6400 samples of paddy were collected from various parts of Java for trial at the " Research Laboratory for Rice and Other Crops. " They were first separated into two divisions by staining sections of the grains with dilute iodine solution, which turns *Oriza sativa* a dark violet and *O. glutinosa* a red brown. They were further subdivided under the following headings: 1) dark glumes and awns ; 2) red awns ; 3) yellow awns and 4) awnless, and in each division the varieties were classed according to the colour of the grain and the length of the awn. In this way 715 groups were established for *O. sativa* and 41 for *O. glutinosa* and each group was provided with a genealogical register on which the external characters of the group were entered, particular note being taken of the appearance of hairs on the nodes and of the size and surface of the ligule.

The more promising varieties were subjected to pedigree culture with good results, and under these conditions a yield of 76 pikols per bouw (5900 lbs. per acre) was obtained from Tanggerang rice, which was imported from Carolina fifty years ago. In order to extend these results to other conditions of soil, climate and irrigation, it is proposed to establish seed gardens in other parts of the Island.

Hybridisation experiments are also being carried on, but good results are reached more slowly than with the method of selecting and breeding pure lines, on account of the difficulty of isolating constant types.

At Buitenzorg rice flowers open from 6 a. m. to 3 p. m., being most active from 10 a. m. to noon. The flowers on a panicle do not all open at the same time : in fact a panicle may take up to six or ten days to open all its flowers.

In the course of the experiments, it was found that the heaviest grains are usually situated in the uppermost third of the panicle, that the heaviest grains could not be detected with certainty by the immersion method and that density of grains used as a factor in selection gave very irregular results.

618 – **Tobacco Breeding in Java.** — HONING, J. A in *Mededeelingen van het Deli Proefstation te Medan*, Year VIII, No. 5, pp. 135-153. Medan, March 1914.

An account is given of tobacco breeding in the two centres of production in Java, — Djember and Klaten.

At Djember tobacco is cultivated up to an altitude of 1800 ft., and a

(1) See also No. 27, *B.* Jan. 1913; No. 120, *B.* Feb. 1913. (*Ed*).

large number of varieties are required to fit the changing climatic conditions. The most popular variety comes from Deli, but this is not sufficiently hardy to be cultivated above 200 to 300 ft. and has to be replaced by a Kadoe variety, which is more resistant but of inferior quality. By crossing the two varieties, a hybrid has been obtained possessing the good qualities of both parents ; crosses of a Japanese variety, Hatano, with the Kadoe variety have also yielded hybrids but of inferior quality.

The breeding work has hitherto been done by the planters themselves; they raise fresh hybrids every year employing native women to carry out the manual labour. Recently an experimental station has been created which will take charge of the breeding work and attempt to isolate a suitable type of plant instead of having to raise hybrids every year.

At Klaten the experimental stations have chiefly sought to improve tobacco by selection. Several cultivated varieties were investigated and two types known as the Y and the Kanari were isolated and gave very satisfactory results; unfortunately their very uniformity proved a disadvantage on the market accustomed to a more varied product, and experiments, are now being made to produce varieties which will comply more fully with the market requirements.

619 – **Impurities in Seeds in Victoria, Australia.** — *Communicated by* S. S. CAMERON, *Director of Agriculture.* AGRICULTURAL SEEDS

Report on seed examined in March 1914.

Variety of seed	Country of origin	Weed seeds		Percentage of non-germinable seed	Percentage of diseased seeds	Quantity examined	Remarks
		Species	Percentage				
Millet Seed (*Panicum* sp.) . .	Turkey	Nil	Nil	8	Nil	3 oz.	A small percentage of grit and loading. This has been imported for birds' food.

620 – **Effect of Low Winter Temperatures during 1913-1914 on Wheat in the Ardennes.** — DENAIFFE in *Journal d'Agriculture Pratique*, Year 78, No. 20, pp. 620-621. Paris, May 14, 1914. CEREAL AND PULSE CROPS

A large number of varieties of wheat growing in the experimental fields of Carignan (French Ardennes) were exposed to very low temperatures during the winter 1913-1914. From December 27 to January 10 the plants were protected by a covering of snow, but from January 10 to 19 they were exposed to temperatures of — 18° to — 20° C. (0° to — 4° F.) without a single thaw. The proportion of plants destroyed by the frost was recorded and varied from 0 to 80 per cent.

621 – **Manurial Experiments on Malting Barley carried out at the Vienna Experimental Station.** — DAFERT, F. W. in *Monatshefte für Landwirtschaft*, Year VII, Nos. 1-2 and 3-4, pp. 5-19 and 50-58. Vienna, January-February and March-April 1914.

In 1906 manurial experiments were carried out witth malting barley at the Vienna Experimental Station in order to determine the effect of application of phosphoric acid on the yield and quality of the grain. The experiments consisted of a series of 46 trials, in which plots were dressed with superphosphate at the rate of 180 lbs. per acre; all plots were duplicated. The average results were as follows:

Plot	Mean of 46 trials		Mean of 27 trials	
	Grain in lbs. p. acre	Increase due to manure, lbs. p. acre	Percentage of nitrogen in grain	Difference between manured and unmanured grain
Unmanured	1 919	—	9.38	—
Superphosphate	2 044	125	9.44	+ 0.06

The application of superphosphate produced no very marked influence on the yield, while the difference in nitrogen content between the manured and unmanured grain was less than that between the seed and the harvested grain, which was estimated in 28 trials and amounted to 0.61 per cent., showing that climatic conditions are more important than manurial treatment with regard to the composition of the grain. When the barleys obtained were grouped according to the phosphoric acid content of the soils in which they had been grown, the following results were obtained:

No. of trials	Percentage of phosphoric acid in soil	Increase in crop due to superphosphate, lbs. per acre
5	over 0.2	145
9	0.15 to 0.2	123
21	under 0.15	79

These results are unexpected, inasmuch as the soils richest in phosphoric acid have apparently profited most by the dressing of superphopsphate. Similar results have already been obtained in other places, but they cannot be considered as generally applicable.

622 – **Influence of Potash and Phosphoric Acid on the Quality of Malting Barley.** — SCHÜL, L., in *Landwirtschaftliche Jahrbücher*, Vol. XLV, Part 5, pp. 641-712. Berlin, 1913 (Published January 15, 1914).

The experiments here described were made by the writer on the experimental ground of the Agricultural Institute at Giessen University in 1909. The soil is a fairly strong loam, is drained, and stands at 500 ft.; the average rainfall is 550 mm. (22 in.); the previous crop was winter wheat.

The subject of the experiment was a barley of the Imperial type, called New Burton Malting. The barley was drilled in on the 10th of April, in rows 9 in. apart. On the 26th and 27th of April a mixed potassic and phosphatic dressing was applied. To ascertain whether the substances under investigation were present in the minimum amounts required by the crop they were applied in three progressiveley increasing quantities:

	40 per cent potash salts	Superphosphate (18% water-soluble phosphoric acid).
	cwt. per acre	cwt. per acre
Light dressing	0.4	0.8
Medium »	0.8	1.6
Heavy »	1.6	3.2

By combining the above quantities, fifteen different dressings were obtained.

3 potash alone: light, medium, and heavy.
3 phosphates alone: » » » »
3 combining a light potash dressing with each of the 3 strengths of phosphates
3 » » medium » » » » » » » » »
3 » » heavy » » » » » » » » »

In addition, there were 5 plots with no manure, and the whole was run in duplicate, making a total of 40 plots, each measuring 12 sq. yds. To ensure the action of the potash and of the phosphoric acid, a dressing of 2.4 cwt. of nitrate of soda was applied to the manured plots on the 30th of April. All the manures were hoed in and the plots raked over. The whole experimental area had been limed with 16 cwt. per acre of 96 per cent ground quicklime.

The weather began by being cool in April, was finer and warmer in May, then became cool and wet for the first three weeks of June, but the temperature reached summer level for the last ten days; July, however, was cool and rainy, and heavy rain at the end of the month lodged some of the barley. The crop was harvested dead-ripe on the 14th of August. No definite statement can be made as to any difference in the ripeness of the various plots, but the results of analysis seem to point to there having been such a variation.

The corn was threshed and the yield ascertained on the 18th and 19th of August. The judging of the quality, which was not carried out till June 1910, had reference to: protein and water content, weight of grain, evenness of the sample, fineness of the husk, colour, germinating capacity and energy, impurities, damaged grain, sprouted grain, foul odour.

The writer obtained the following results:

1. In every case the soil profited by a phosphatic dressing, which caused a fuller utilization of nitrogen and potash. A quite remarkable demand for potash was observed to be brought about by the medium and strong dressings of phosphates.

2. The potash-phosphate dressings always effected an increase in the gross yield.

3. The use of 40 per cent. potash salts and of superphosphates as a top-dressing proved suitable.

4. The pretein-content, which was very high on account of the nitrogenous dressing, was decreased by the application of combined potash and phosphates and this decrease corresponded to the increase in the yield.

5. The proportion of dry matter shows a nearly regular increase with the use of combined potash and phosphates, independently of the yield. It was not possible to find out whether this is due solely to a more advanced stage of ripeness, owing to the better nourishment of the barley, or to a larger deposit of potash and of phosphoric acid in the grain. In cases where no increase in yield was found on plots with heavy potash dressings and phosphoric acid, as compared with those with moderate potash dressings, a superfluous consumption of potash is to be assumed.

6. Not regularly, but still in the majority of cases, the double dressing gives an increase in 1000-grains weight and in the size of the grains, and a decrease in the proportion of husk.

7. Increase of the 1000-grains weight is generally accompanied by increase in the number of grains which will not pass through a 2.8 and a 2.5 mm. sieve. The weight of husk varies inversely.

8. Combined potash and phosphate manuring improves appreciably the germinating capacity and more still the germination energy.

9. Barley dressed with potash and phosphoric acid has nearly always a canary-yellow colour.

The writer concludes that in order to obtain a high-class sample, nitrogen should be present in as small a proportion as possible. If a maximum yield and the highest quality are incompatible, it is none the less possible, up to certain point, to obtain by means of a nitrogenous manuring an increase in yield without injuring the quality. The attainment of this point depends essentially on the quantity of potash and phosphoric acid employed. In discussing his results the writer quotes those obtained by several other investigators.

FORAGE CROPS. MEADOWS AND PASTURES

623 – **Argentine Lucerne Seed.** — *Dirección General de Agricultura y Defensa Agrícola, Boletín del Ministerio de Agricultura,* Vol. XVII, No. 1, pp. 82-89 + 3 coloured plates. Buenos-Aires, 1914.

At the present time, Argentina produces all the seed necessary for her great crops of lucerne, and will be able, at no distant date, to become an exporter. The quality, however, does not correspond to the increase in quantity, since the seed leaves a great deal to be desired in the way of purity, absence of dodder and germinating capacity. But on the other hand the native seed gives more hardy and lasting plants than any imported variety.

The seed from the irrigated districts of Mendoza, San Juan, La Rioja, part of San Luis, north of Córdoba, Salta, Jujuy and Catamarca, generally contains a large amount of dodder (*Cuscuta corymbosa* R. et P. and a variety of *C. racemosa* Mart.) and seeds of *Melilotus parviflorus* Desf., and sometimes

a large quantity of *Lippia nodiflora* Rich., *Schkuhria bonariensis* Hook., *Bidens leucanthus* Wold., *B. scabiosoides* H. et Arn.., *Panicum colonum* L., *Chenepodium opolifolium* Schr., *Madiola latoritia* Schm., *M. malvifolia* Gr., *Anoda triangularis* Db., and *Sida rhombifolia* L. The seeds of this last species constitute, together with those of dodder and melilot, a real menace to farming. *Sida*, being perennial, is difficult to destroy.

Another serious drawback to native seeds is the presence of hard grains, 50 per cent on an average, only half of which are capable of germinating, the other half being pure loss.

In a second area, comprising the south of Córdoba, part of San Luis, the north of the Pampa, the west and north-west of Buenos-Aires and the department of San Rafael de Mendoza, the seeds of lucerne are less well developed, and in some cases, as at San Luis, very small indeed, although well shaped. In this area there is less dodder, but there are usually several other extraneous seeds: *Chenopodium, Amaranthus, Cnicus, Centaurea, Anthemis, Plantago, Rumex*, etc. Hard seeds occur in a proportion of 25 per cent. The germinating capacity is undoubtedly superior and the plants produced last a long time and resist drought well.

To the third area belong the south of Buenos-Aires, Rio-Negro and Chubut. The seeds from there are fairly popular, both on account of their size and on account of the small quantity of extraneous seeds present. There are, however, 50 per cent. of hard seeds in the two latter provinces, and 30 per cent. in that of Buenos Aires. Dodder is not often found.

To sum up, it may be said that Argentine lucerne seed grown without irrigation surpasses in germinating capacity all the foreign varieties of lucerne, but that it has nevertheless the following faults:

1. It is impossible to obtain large quantities of good seed of even quality.

2. A large proportion of the native seed is so impure that diligent cleaning would be required before it could be sown; but this cleaning cannot be effected, owing to the small difference in price between good and bad seed, and because purchasers prefer a low price without troubling about quality.

3. A large quantity is found of the seeds of *Cuscuta racemosa* Mart., and of *C. corymbosa* R. and P., the size of which makes it impossible to separate them from the lucerne seed.

4. A large quantity of hard seeds are present; these cause a considerable reduction in the germinating capacity and energy.

To obviate these faults, it would be necessary: 1) for the producers to eradicate weeds in the lucerne fields, abandoning those fields which cannot be cleaned; 2) for the purchasers to pay attention to buying good, well-cleaned samples of seed instead of seeds offered at a low price.

624 - **Determination of Certain Species of *Carex* by their Vegetative Characters.** — KUSNEZOV, W. in *Bulletin für angewandte Botanik*, Year 7, No. 1 (65), pp. 18-41 + 10 plates. St. Petersburg, January 1914.

The writer has prepared the following schemes for the determination of species of *Carex*.

A. *Determination of the ten chief species of Carex growing in swamp-meadows by field examination of the vegetative parts.*

1. The plants form dense or more or less open clumps 2
   Plants with creeping stems, not forming clumps 6
2. Very open clumps, not forming tussocks. 3
   Dense clumps, forming more or less well-developed tussocks 4
3. Membrane of the leaf-sheath veined, wearing to a delicate filamentous network *C. paludosa* Good.
   Membrane of the leaf-sheath veinless, not wearing to a network . . . . . *C. acuta* L.
4. Membrane of the leaf-sheath veined, wearing to a delicate filamentous network *C. stricta* Good.
   Membrane of the leaf-sheath veinless, not wearing to a network 5
5. Cross-section of upper part of leaf-blade showing reflexed margins . . *C. vulgaris* Fries.
   Cross-section of upper part of leaf-blade semicircular or channeled without reflexed margins . . . . . *C. paradoxa* Willd.
6. One side of the leaf-sheath forming a thin, semitransparent, whitish membrane . . 7
   All three sides of the leaf-sheath thick, foliaceous, green . . . . . *C. disticha* Huds.
7. Membrane of the leaf-sheath veined, wearing to a filamentous network 8
   Membrane of the leaf-sheath veinless, not wearing to a network 9
8. Leaves soft, whitish within . . . . . *C. ampullacea* Good.
   Leaves rigid, bright green within . . . . . *C. vesicaria* L.
9. Plant greyish-green or bluish-green . . . . . *C. panicea* L.
   Plant green or yellowish-green . . . . . *C. teretiuscula* Good.

B. *Determination of the ten chief species of Carex growing in swamp-meadows by examination of the vegetative parts in hay.*

1. One side of the leaf-sheath forming a thin, semitransparent, whitish membrane . . . 2
   All the sides of the leaf-sheath thick, foliaceous, green . . . . . *C. disticha* Huds.
2. Membrane of the leaf sheath veined, wearing to a filamentous network 3
   Membrane of the leaf-sheath veinless, not wearing to a network 6
3. Leaf-blade soft, whitish within . . . . . *C. ampullacea* Good.
   Leaf-blade stiff, green or greyish-green within 4
4. Leaf-blade bluish-green below . . . . . *C. paludosa* Good.
   Leaf-blade greyish-green or light green below 5
5. Leaf-sheath tinged with reddish . . . . . *C. vesicaria* L.
   Leaf-sheath light or dark brown . . . . . *C. stricta* Good.
6. Cross-section of leaf-blade channeled, the central and upper parts with reflexed margins 7
   Cross-section of leaf-blade channeled or semicircular, without reflexed margins . . 9
7. Leaf-blade bluish-grey-green or bluish-grey . . . . . *C. panicea* L.
   Leaf-blade green, greyish-green or yellowish-green, not blue grey 8
8. Upper part of leaf-blade with slightly reflexed margins . . . . . *C. acuta* L.
   Upper part of leaf-blade with strongly reflexed margins. . . . . *C. vulgaris* Fries.
9. Ligule continuous with the top of the leaf-sheath membrane, the two forming a collar round the stem or the shoot . . . . . *C. teretiuscula* Good.
   Ligule distinct from the leaf-sheath membrane, not forming a collar . *C. paradoxa* Willd.

625 – **Large Scale Field Trials with Mangels.** — VON RÜMKER, K., and ALEXANDROVICH, J., in *Landwirtschaftliche Jahrbücher*, Vol XLV, Part 4, pp. 503-596 + 6 figs. Berlin, December 23, 1913.

In 1912 the writers carried out field trials on a large scale in collaboration with R. Leidner, K. Schröter and O. Bormann, with 35 different varieties of mangels. Six plots were devoted to each variety and the seed was drilled in. The yield, percentage of dry matter, and sugar-content were ascertained, and a description of the quality and quantity was given in the report. In working out the results, experimental errors were reduced by algebraic compensation.

On completion of the experiments, the writers make suggestions for the profitable carrying out of large scale field trials. The object of the investigations is to classify more exactly, according to quality and quantity, the numerous varieties on the market. The more direct testing of each individual variety composing a group which the large scale field trials seem to point to as suitable for certain conditions, must be left to the farmer. Trials covering one year only, but embracing a wide variety of soils and climates, carried out in different districts and repeated periodically, are more satisfactory than large scale trials lasting over several years in the same district, especially on account of the greater rapidity with which information can be obtained by the former method.

626 – **Studies in Indian Cottons. Part I: the Vegetative Characters.** — LEAKE, H. MARTIN, in *Memoirs of the Department of Agriculture in India, Botanical Series*, Vol. VI, No. 4, pp. 115-151, + 3 maps + 9 plates. Calcutta, February 1914. FIBRE CROPS

Studies of the vegetative characters of Indian Cottons have been in progress in the United Provinces since 1905.

As a result of these and other studies of various herbarium collections the writer classifies the various types as follows.

MONOPODIAL.

Perennial ; secondary branches ascending sharply at an acute angle. Leaf factor (1) less than 2 ; plant almost glabrous. Bracteoles small, triangular ; margin entire or dentate. Corolla yellow.

Gossypium obtusifolium (Roxburgh *Flora Indica*) Gammie and Watt . . . . . Type 1.

Perennial ; secondary branches spreading . Leaf factor less than 2. Stem and leaves densely covered with short hairs. Bracteoles deeply auriculate or reniform, deeply serrate, spreading in fruit. Corolla yellow, petals small. Stigma heavily glandular. Capsule inflated and nearly spherical with a sharp mucronate apex.

G. herbaceum (Linn.) Todaro and Gammie, and *G. obtusifolium* var. *Wightiana* Watt . . . . . Type 2.

(1) It may be defined as the ratio of the length of the middle lobe to its greatest breadth. For explanation see *Journal of Genetics*, Vol. I, No. 3, pp. 220. (*Ed.*).

Perennial "tree cotton"; secondary branches ascending sharply at an acute angle. Entire plant deep red or purple. Leaf factor greater than 3; frequently an extra tooth on one or both sides of the central lobe. Bracteoles small, triangular; margins entire or with the tip dentate. Corolla deep red. Stigma eglandular. Capsule usually 3-celled, ovate.

G. arboreum (Linn. sp. Pl.) Parlatore and Todaro, and *G. arboreum* Gammie and Watt . . . . . Type 3.

Plant tall with long monopodial branches sharply ascending. Leaf factor greater than 3; leaf wrinkled. Leaf and stem covered with short hairs. Bracteoles triangular with margin dentate. Flowers yellow or white.

The commonest form of this group possesses the habit and shape of bracts of Type 3, with the wrinkled leaf and short hairs of Type 2. It comprises the *G. intermedium* of Gammie.

Sympodial.

Annuals with few or none of the lowest secondary branches monopodia, the remainder sympodia; monopodial branches ascending and sympodial spreading.

Plant tall, drooping later under the weight of fruit. Leaf large, factor less than 2; lobes 3 or with 2 small accessory basal lobes. Young stem and leaves sparsely hairy. Bracteoles small, entire or with few small apical teeth, closely enveloping bud and fruit. Corolla yellow with deep red "eye". Petals large, semi-transparent. Stigma eglandular or with few glands only. Capsule 3-celled ovate.

G. indicum (Lamk.) Gammie, and *G. Nanking* var. *bani* Watt. Type 4.

Plant erect, drooping later. Leaf factor less than 2; lobes 5-7. Young stem and leaves hairy. Bracteoles large, entire or with a few small apical teeth, loosely enveloping bud and in fruit sometimes reflexed. Corolla yellow with deep red "eye"; petals opaque. Stigma eglandular, or few glands only. Capsule 3-4 celled, ovate. . . . . Type 5.

Plant erect, differing from Type 4 in greater rigidity of main stem and greater angle at which secondary monopodia arise (about 45°), and in the white corolla. Petals small, scarcely projecting beyond the bracteoles . . . . . Type 6.

Plant erect, secondary branching monopodial, when developed, sharply ascending. Leaf factor less than 2; flower white. The plant is strongly asymmetrical and the vegetative period very brief, the first flowers developing while the plant is quite small. Growth continues throughout the season, the plant maintaining a marvellous fertility. . . . . Type 7.

Plant tall, drooping later. Leaf factor greater than 3; lobes 5-7 with an extra tooth on one or both sides of the central lobe frequently developed. Young stem and leaves hairy. Bracteoles entire or with few apical teeth. Corolla yellow with deep red "eye". Stigma eglandular or with few glands only. Capsule 3-4 celled, ovate. . . . . Type 8.

Plant differing from above only in the colour of corolla which is white and scarcely protrudes beyond the bracteoles . . . . . Type 9.

Types 4-9 belong to the *G. neglectum* and *G. roseum* of Todaro, the *G. neglectum* (Tod.) of Gammie and the *G. arboreum* vars. *neglecta* and *rosea* of Watt.

Plant tall with main stem weak and early drooping. Leaf factor greater than 3 ; lobes 5-7. Bracteoles entire or with few apical teeth, large and continuing to grow with the developing boll. Corolla pale yellow with deep " eye ". Stigma eglandular. Capsule ovate, very large with numerous seeds. *G. cernuum* of Todaro and Gammie and *G. arboreum* var. *assamica* Watt. . . . . Type 10.

Plant tall. Leaf factor greater than 3 ; lobes 5-7 ; stem and leaves of a deep red or purple colour ; bracteoles entire or with few apical teeth. Corolla with deep red " eye "; petals white, tinged with pink along margin and the portions exposed in the bud.

G. sanguineum Hassk. var. *minor* Gammie . . . . . Type 11.

Plant small, with monopodial secondary branches few or none. Leaf factor less than 2 ; lobes 3-5. Flower yellow. Boll large. Includes types from China.

Corolla yellow-eyed; seed with fuzz . . . . . Type 12.
» » » » naked . . . . . Type 13.
» without eye; seed naked . . . . . Type 14.

Plant differing from Type 2 in the character of the secondary branches. This group includes a complex series of forms from Persia. The simplest form is the true *G. herbaceum*, Todaro.

G. hirsutum Linn. This plant, which yields the bulk of the American cotton crop, has formed the basis of numerous experiments in India.

G. Stocksii Max. Mast. A wild form of *Gossypium* found on the limestone hills around Karachi.

Pollination. — The cotton flower is hermaphrodite and self-fertilisation is effective in almost every case. Experiments in cross-fertilisation show that the different forms of *Gossypium* fall into two marked groups, the members of which are fertile *inter se* but completely sterile between the two groups. These groups are characteristic of the Old and the New World and are respectively characterised by united and free bracts.

The colour of the corolla. — The colour of the petals may be yellow, white or red. The latter colour is only found in Types 3 and 11 and extends to the sap. Two forms of yellow are readily distinguished, *viz.* ' yellow ' and ' pale-yellow '.

Breeding experiments show that yellow is dominant both to pale-yellow and to white. The inheritance of the pale-yellow factor is under further investigation.

The ' eye ' of the petal. — All true Indian cottons possess an eye situated at the base of the petal. In some Chinese forms the petal is self-coloured

yellow, and crosses between these forms appear to show that the 'eye' - factor is dominant, though in one case an intermediate form of eye appeared and has bred true to this condition. This constitutes; therefore, a further type.

The red colouring matter in the sap. — The presence of red colouring matter in the sap entirely masks the true petal colour. The true petal colour can only be directly determined in cases of diseased flowers or such as open out of season. The factor for red-coloured sap appears to be dominant over its absence, though the intensity of the colour is diminished and the petals attain a condition known as ' red on yellow ' when the cross is made with a yellow-flowered plant.

The type of branching and the length of the vegetative period. — The axil of the leaf of the cotton plant contains two buds, one main bud to which the second is accessory. Vegetative growth is effected by the development of a monopodium from either of these buds, reproductive growth only by the development of a sympodium from the former. Therefore according as the main bud develops into a sympodium or a monopodium, so will the appearance of the first flowers be accelerated or retarded ; in other words the length of the vegetative period is controlled by the form of the secondary branches. In pure monopodial types even the ultimate secondary branches are monopodial. In sympodial types generally a few of the lowest secondary branches are monopodial. In hybrids between these forms every gradation is found and the change from the sympodial secondary branching to the lower monopodial branching is so abrupt that the character can be conveniently expressed as the percentage of the stem bearing monopodial branches. In actual practice, however, growth does not continue sufficiently long to enable this character to be determined accurately. The length of the vegetative period is therefore made use of in this connection. Determination of the correlation coefficient between the type of branching and the vegetative period gave 0.6628 and 0.8589 for different series.

Crosses between sympodial and monopodial types give F_1 generations with a vegetative period intermediate between those of the two parental types and approximating in a greater or less degree to that of the sympodial parent. The F_2 generation form a continuous series showing every degree of length of vegetative period, but, though the full sympodial type appears comparatively frequently, the full monopodial type only rarely or never does so. In the F_3 generation the average length of the vegetative period of a family approximates to that of the F_2 parents.

Conclusions. — Up to the present these studies have been confined to factors of considerable, though only indirect, importance. The more intricate task of studying the commercially valuable portion of the crop is the subject of further investigations.

627 – **Oils in the Seeds of *Dumoria Heckeli* and *Baillonella toxisperma* Pierre.** — DE WILDEMANN, E. in *Bulletin de l'Association des Planteurs de Caoutchouc*, Vol. VI, No. 4, pp. 81-83. Antwerp, May 1914.

Dumoria Heckeli (1), found on the Ivory Coast by CHEVALIER is native of tropical virgin forests. Its seeds yield a semi-solid oil, snow white when fresh, with a pleasant sweet flavour and slightly aromatic, at the rate of 16.5 per cent. of the seeds or 33.25 per cent. of the kernels.

Baillonella toxisperma Pierre, or *Mimusops Djawa* Engler, has been recently found in the Mayumbe district of the Belgian Congo. It yields a white aromatic oil at the rate of 56.04 per cent. of the kernels or 40.60 per cent. of the seeds.

Both residual cakes are unfortunately toxic on account of the presence of a glucoside of the saponin group, but they may be employed as manure, for they contain a considerable amount of potash and nitrogen (2 and 3 per cent. respectively) though very little phosphoric acid (*Dumoria Heckeli* 0.76 per cent.).

628 – **The Improvement of Indigo in Bihar.** — HOWARD, A. and HOWARD, G. L. C. in *Bihar Planters' Association Bulletin*. Calcutta, 1914.

The cultivation of Java Indigo (*Indigofera arrecta* Hochst.) in Bihar has rapidly declined since 1910, owing to the increasing prevalence of a so-called disease which prevents seed formation. The disease appears towards the end of the monsoon and is characterised by a great reduction of leaf surface and a change in the colour of the remaining leaves to a yellowish green slaty colour. Cultivation experiments have shown that this diseased condition of the plant is due to long continued wetness of the soil, which leads to the destruction of the young feeding roots, followed by leaf-fall and more or less complete wilting of the plant.

This wilting can be checked for a time if the plants are only pruned at the first cut, leaving one branch, instead of being completely cut back. The process is more conducive to normal growth and results in an increase in the total crop.

After the second cut in an ordinary monsoon the crop ceases to be profitable and should be dug up to make room for *rabi* crops.

The growth of indigo for leaf and for seed should be regarded as separate things and seed should not be raised from the old plants which have been cut for leaf. The best method of obtaining good seed of Java indigo is to sow the crop in lines about 24 inches apart in the middle of August on high-lying. well drained fields which are in good heart. After gathering the seed the crop can be grown on for leaf during the next monsoon. Being thdeep rooting plant, the surface soil may be harrowed and the weeds a stroyed with great benefit to the plant. When wheat is grown as a oever crop an early maturing variety with little foliage and stout straw gives the best results.

Selection. — Owing to the frequency of cross-pollination the ordinary-

(1) See FOURNIER, J. *Etude pharmacologique des graines du Dumoria Heckeli et du Baillonella toxisperma Pierre.* Clermont Ferrand.

methods of single plant selection cannot be applied to this crop. Further, the method of estimating the indican-content is too difficult and expensive to be employed in selection experiments. Selection must therefore be confined to those individuals in the mixed crop which grow rapidly and strongly and which by their habit of growth and amount of leaf surface are likely to give the highest yields of leaf. A process of roguing will be necessary to remove all undesirable types and prevent their crossing with the better types. Similar methods require to be applied to the ordinary Bihar indigo (*I. sumatrana*), and a reliable system of seed distribution remains to be established.

RUBBER, GUM AND RESIN PLANTS

629. – **Hevea in Cochinchina.** — GIRARD, M. E. in *Bulletin Economique de l'Indochine*, Year XVII, No. 106, pp. 46-53. Hanoï, January-February 1914.

Effect of the dry season on Hevea plantations. — The dry season is in no way unfavourable to the growth of hevea in the deep soils of Cochinchina, more especially if the soil surface is kept stirred during the wet season so that the rainfall is absorbed. In one year in which the dry season extended over five or six months, the average circumference of trees increased 4 to 6 in. in certain groups, while individual increases amounted to as much as 7 in. The dry season is moreover eminently useful in checking the development of fungoid diseases, especially *Fomes semitostus*.

Contrary to results obtained elsewhere, the dry season apparently has a very favourable effect on the yield of latex. During November, December and January the highest yields are obtained, reaching in the latter month as much as 50 per cent. more than the average for the rainy season. When vegetation becomes active again the yield decreases rapidly and tapping is suspended.

Tapping lasts about 300 days, during 180 to 200 of which the yield is approximately equal to that obtained in the Malay States, whilst during the 100 to 120 days at the height of the dry season the yield is considerably higher.

Capacity of Annamite labour. — The skill and rate of working of the tappers gradually improved, so that the number of trees tapped per head rose from 125 to 400 per day. Further, each man, besides making three excisions on every tree, wetted the cuts, collected the latex and the scrap, carried the latex to the factory and cleaned all recipients employed. When the price of rubber went down, the process was simplified by suppressing the use of water on the cuts, with the result that each man was able to undertake 600 trees and each woman 450 trees per day; these figures represent averages for all the coolies over a period of several months and are important, as three-quarters of the expenses of production are represented by the cost of tapping. The writer considers that the suppression of watering will not only economise labour, but also prove beneficial by causing the latex to be less diluted and the rubber of better quality.

Advantages of smaller excisions. — After numerous experiments, the method of practising three excisions, 18 in. apart vertically, and only engaging one-fifth of the circumference of the tree, has been adopted, as the longer

rest gives the wound a better chance of healing, while the yield is increased or at any rate in no way decreased by limiting the tapping area.

630 – **Influence of the Partial Removal of the Bark on the Yield of Latex** in ***Manihot Glaziovii*** (1). — ZIMMERMANN, A. in *Der Pflanzer*, Year X, No. 4, pp. 180-188. Daressalam, April 1914.

Experiments carried out at Amani and Victoria have shown that the partial or total removal of the bark of *Manihot Glaziovii* increases the production of latex. Of the two methods, the partial removal is more to be recommended, not only because it has a better effect on the yield of latex, but also because it requires less labour and is less liable to damage the tree.

631 – **The Industrial Uses of Maize when Cultivated for Sugar.** — BOYER, L. in *La Sucrerie Indigène et Coloniale*, Year 49, Nos. 10. 11, 13, 17, pp. 226, 252, 299, 343, 392. Paris, March 11 to April 29, 1914 (2). SUGAR CROPS

After a short account of the history of the subject, the influence of castration on the sugar content of maize juice is discussed. Of all known varieties the Giant Servian is the one which has the richest juice in sugars, but JU MELLE has also reported a variety from the Ivory Coast which yielded, with male castration alone, a juice containing 10.49 per cent. of saccharose and 1.23 per cent. of glucose, whilst the male castrated Servian variety only yielded 9.68 per cent. of saccharose and 1.32 per cent. of glucose.

The production of sugar from the juice has still to overcome certain practical difficulties. The ordinary process of extraction in use in sugar-beet factories only results in about half the saccharose being obtained in the form of crystallised sugar from a juice of 59 per cent. purity. The residual molasses contain a high percentage of glucose and are approximately of the same quality as molasses from refineries; they could be profitably used by working them up with the fibrous residues into stock food at the sugar factory itself, the food value of such a product being estimated on the basis of food values in straw. Or a still better use might be to reduce the stalks to a fine meal after a preliminary drying, and put the product on the market either in the pure condition or mixed with various other meals to increase its nitrogenous content and make it into a better balanced food. As the maize would be harvested during the warmest season of the year the stripped stalks could quite well be set up in sheaves to dry, so that their water content should be reduced to 15 to 20 per cent.

As raw material for the manufacture of denatured alcohol, maize is superior to beets both with regard to the produce obtained per ton of treated substance and to the possible profits. In comparing Giant Servian maize with beets of a corresponding sugar content, the value of the maize works out at 3*s* 9*d* per ton more than that of the beets; moreover the distillery residues of maize can be sold to paper works at 3*s* 6*d* per ton, while the beet pulp is only worth 2*s* 6*d* per ton.

(1) See ZIMMERMANN A., Der Manihot-Kautschuk, p. 176. (*Ed.*).
(2) See No. 512, *B.* May 1913. (*Ed.*).

632 – **Comparative Water Absorption of Sugar Cane Plants when Suffering from Sereh Disease** (1) — BREMEKAMP, C. E. B. (Pasoeroean Experimental Station) in *Archief voor Suikerindustrie in Nederlandsch-Indie*, No. 14, pp. 514-519. Sourabaya, April 1914.

The vascular system of sugar cane plants suffering from sereh is stopped up with gummy matter which influences the circulation of water in the plant so that healthy stems absorb 1.18 times more water than affected stems. Using a lithium salt as an indicator, the writer showed that the salt had risen to a height of 70 cm. in 3 ½ hours in a healthy plant, while in a diseased plant it had only reached 30 cm.

STIMULANT, AROMATIC, NARCOTIC AND MEDICINAL CROPS

633 – **Coffee in Tonking.** — BOREL, M. in *Bulletin Economique de l'Indochine*, Year XVII, No. 106, pp. 54-60. Hanoï, January-February 1914.

The coffee bush is little pruned in Tonking owing to the borer (*Xylotrechus quadrupes*), which causes so much damage on plantations that planters allow suckers to grow in order to furnish a substitute for the parent bush when the latter is attacked by the beetle. On the other hand the bushes are kept low by being topped as soon as they are one year old in order to develop the lower branches and expose the young plant less to the action of the wind. Usually the trunk is not allowed to grow above 5 ft. making with the uppermost branches a total height of 6 to 6 ½ ft., which could not be increased without letting some of the fruit get out of reach of the pickers.

Manurial requirements per bush are : 55 lbs. of dung every two years ; ¾ oz. of nitrogen, 1 oz. phosphoric acid and 2 ½ oz. of potash every year ; and every three years a dressing of lime varying in amount with the nature of the soil.

The yield per bush varies from ½ lb. to 2 lbs. of coffee, with an average of about 1 lb. Approximate estimates of expenses and returns on coffee plantations are as follows :

A. *Plantation of* 50 000 *bushes.*

	£
Total cost of establishing plantation spread over 4 years . .	4 310
Expenses during 5th year	1 188
Sales during 5th year :	
44 000 lbs. of coffee	1 804
live stock run on the plantation	225
Total sales . . .	£ 2 029
Total profit.	841
less 15 per cent. to manager.	126
net returns . . .	£ 715

or a return of 16.6 per cent. on a capital of £ 4 310 over and above a 5 per cent. interest on capital allowed for in estimated expenses.

(1) See No. 1541, *B.* May 1911. [*Ed.*]

B. *Plantation of* 160 000 *bushes.*

		£
Total cost of establishing plantation spread over 4 years . .		10 512
5th year:		
expenses . .	estimated to counterbalance	3 267
receipts . .	one another	3 310
6th year:		
expenses		3 375
receipts		6 505
total profits		£ 3 130
less 15 per cent. to manager.		470
	net returns . . .	£ 2 660

or a return of 25.3 per cent. on a capital of £10 512 over and above a 5 per cent. interest on capital allowed for in estimated expenses.

634 – **Mocha Coffee Culture.** — RIES, M. and BARDEY, P. in *The Tea and Coffee Trade Journal*, Vol. XXVI, No. 1, pp. 19-26. New York, January 1914.

Mocha coffee derives its name from the small ruined town on the South Arabian coast of the Red Sea from which it used to be exported. It is an absolutely unique product with a flavour and aroma quite distinct from the Abyssinian variety, though many writers consider them identical.

The tree is cultivated in the province of Yemen, South-western Arabia, on terraced slopes, a southern aspect being preferred. The seeds, after being separated from the pulp, are rolled in ashes and preserved in a dry place. Seedlings are raised in nurseries on a fertile and well manured soil; they are protected from the sun, watered frequently and transplanted once or twice before being finally planted out 2 to 3 yds. apart. Plantations are all in the immediate neighbourhood of wells, as irrigation is absolutely necessary; the soil has to be kept loose and permeable by repeated cultivations. The crop is harvested continously from August to March; the seed is hulled in a small stone mill, spread out to dry and packed in bags made of woven aloe fibre (« sanseviera ») and lined inside with the leaves of palm trees (« doum »), this packing being known in the trade as the Mocha bag and constituting a kind of certificate of origin.

The trees belong to three main types: 1) pyramidal with the biggest branches at the base; 2) umbrella shape with the lower part of the trunk bare; 3) bush shaped.

In the low regions where rain is abundant, the fruit is larger but of inferior quality; in the hot dry uplands, growth is slower and the grain is smaller and rounder, but of the finest quality.

The annual production of Mocha coffee is about 100 000 bags of 160 lbs. each, and the principal importing countries are the United States which takes 30 per cent., France which takes 20 per cent. and Egypt which takes 18 per cent., others being the Red Sea ports (7 per cent.), Germany (5 per cent.), England (5 per cent.), Spain (3 per cent.), and Austria (3 per cent.). About half the amount is exported from Aden, and half from Hodeidah.

635 – **Vanilla in Madagascar.** — FAUCHÈRE, A. in *Journal d'Agriculture Tropicale*, Year XIV, No. 154, pp. 105-109. Paris, April 30, 1914.

Vanilla is successfully cultivated on various kinds of soil in Madagascar, not only on granitic alluvial soils, but also on the sandy soils of the coast and on basaltic or volcanic soils, though the two latter kinds are perhaps the most suitable. From a series of analyses carried out by the writer it would seem that a soil with a high phosphoric acid content is specially good, the best at Nossy-Bé containing a minimum of 0.4 per cent. and that of the most productive plantation containing 0.75 per cent.

The most usual shade and support tree is *Jatropha Cureas*, but *Dracæna tesselata* is also frequently used. Vanilla cuttings should always be at least 5 ft. long; they cost 2*d* to 2 ½*d* each. Decomposed banana stems are frequently used as manure in vanilla plantations.

The production of vanilla in Madagascar has been increasing of recent years. The figures for 1903-1912 are as follows:

	Amount tons	Value £
1903	11.5	8 264
1904	9.1	6 892
1905	30.4	18 619
1906	40.0	19 029
1907	50.0	39 875
1908	56.4	41 748
1909	42.6	47 639
1910	42.2	50 846
1911	51.7	40 986
1912	112.0	142 217

Further increases are anticipated, but over-production will be checked by the growing practice of planting other crops in vanilla districts.

Plant bugs are destructive to vanilla in Madagascar, especially *Memia viccinia* which punctures the pods and young buds, causing them to fall. Preventive measures have not yet been thoroughly investigated, but it would seem that the only means of checking the parasite would be treatment with hydrocyanic acid.

An average yield of vanilla in the green condition would amount to 530 lbs. per acre, while expenses of establishing the plantation are estimated as follows:

	per acre £	s
1st year – clearing ground, planting shade and support trees, planting vanilla cuttings, 3 hoeings	14	7
2nd year – 3 hoeings, cutting shade trees, replacing cuttings	5	17
3rd year – as 2nd	5	17
4th year – as 2nd, pollination (22*s*) and harvest (14*s*)	7	13
	£33	14

636 – **The Cultivation of Poppies for Opium and Seed in Various Countries.** — *Enquiry made by the International Institute of Agriculture.*

The cultivation of poppies for opium in the Far East has been somewhat checked of recent years, but the crop remains an important one in many countries on account of the edible oil produced from its seeds. The replies to the circular letter on the subject sent by the Institute are abstracted below.

AUSTRALIA. — Victoria is the only State in the Commonwealth in which poppies are cultivated on a commercial scale, and even in that State, the area under the crop is very small, consisting of one or two acres during the years 1908-1912 with a total yield of 89 lbs. of opium in the whole period. The present price of opium is 30*s* a lb. and the product is used exclusively for pharmaceutical purposes.

CHINA. — According to the special convention of the Opium Agreement signed in 1911 between the English and Chinese Governments, the cultivation of the opium poppy in China and the importation of opium from India were to be proportionately and progressively reduced, starting from January 1st 1911, so that both local production and imports were to cease entirely by the end of 1913 and opium smoking to be prohibited after 1917.

EGYPT. — Poppies are cultivated in Upper Egypt chiefly for the sake of opium ; oil is also extracted from the seeds and used for cooking.

Three varieties are cultivated, having respectively red, yellow and dark brown seeds, and all belong to the same species. In 1912-1913, 516 feddans (1) were under the crop, which is partly raised as a pure crop and partly in mixed cultures with other crops, such as wheat, barley, onions, fenugreek, *Carthamus oxyacantha*. Seed is sown in October, after the flood, at the rate of 1 kadah (2 ¼ quarts) per feddan and mixed with fine soil to facilitate the operation ; no manure or irrigation water is applied. After a month the plants are singled 6 to 8 in. apart and 12 days later they are earthed up. When the plants are five months old, an incision is made in the capsules and the opium is collected the following day in the form of the solidified exudate, which is then kneaded into cakes and dried in the sun for four days. Each capsule is tapped three times.

A considerable amount of labour is required for the crop, making the cost of cultivation rather high :

	Cost per feddan, piastres (2)
Ploughing	50
Sowing	4
Singling	4
Earthing up	9
Making incisions	45
Collecting opium	120
Kneading »	9
Transport and storage	9
Hand threshing the seed with flails	10
Cleaning the seed	10
	270 (£2 15*s* 7*d*)

(1) 1 feddan = 1.038 acre.
(2) 1 piastre = 2.46*d*.

The total production per feddan amounts to 1½ ardebs (8 bushels) of seed, worth 112 piastres (£ 1 3*s*), 8 rotl (1) of opium, worth 960 piastres (£ 9 17*s*) and 120 rotl of oil. The stalks are sold for fuel and fetch 5*s* per feddan. An ardeb of seed yields about 80 rotl of oil, and the opium contains an average of 8 to 12 per cent. of morphine. Prices are very stable.

The only parasite dangerous to poppies is *Agrotis ypsilon*, which is kept in check by hand-picking the larvae.

No statistics exist on the consumption and exportation of opium, but imports for the years 1909-1912 were as follows :

	Amount lbs.	Value £	*s*	*d*
1909.	11 030	7	10	9
1910.	12 961	11	5	6
1911.	10 815	8	0	2
1912.	4 309	5	7	6

FRANCE. — Poppies are cultivated in various districts. more especially in the departments of Somme and Pas de Calais, but also in those of Ain, Aisne, Aube, Cher, Doubs, Maine-et-Loire, Nièvre, Nord, Seine-et-Marne, Deux Sèvres, Vienne and Yonne. The crop is raised for the sake of the oil obtained from the seeds, which is used as an edible oil in the north and also for the manufacture of paints. The two varieties of *Papaver somniferum* known as Pavot Gris Ordinaire and Pavot Œillette Aveugle are grown. The area under this crop, which was between 12 000 and 15 000 acres in 1900, was reduced to between 6450 and 6650 acres in 1910 and 1911.

Poppies replace beets or flax in the rotation. The land is prepared by autumn and spring cultivations, and seed is sown at the beginning of April at the rate of 2 to 3 lbs. per acre. Farmyard manure is applied, or cake residues, with 4 to 5 cwt. of superphosphate per acre. After-cultivation consists in hoeing and singling to a distance of 8 in. apart. Eighteen to twenty-seven bushels of seed are obtained per acre, yielding 45 to 50 per cent. of oil. Mean annual values for the period 1902-1911 are as follows :

Total area under the crop	acres	10 295
Total production	tons	5 100
Production per acre	lbs.	1 108
Total value of crop	£	77 048
Value of 1 cwt. of seed	*s*	15

CHALLAMEL has also recently (1913) published a book on opium.

JAPAN. — Poppies are only cultivated on a very small scale for the sake of the flowers and seeds, which are used in perfumery.

BRITISH INDIA. — Poppies are cultivated in the United Provinces of Agra and Oudh, in certain States of Rajputana, and in Central India, but they are no longer grown in Bihar. Opium production both for home consumption and for export is the main object, but the seed production is also considerable, as shown by the following figures :

Exports of poppy seeds.

	Amount cwt.	Value £
1910	814 871	559 890
1911	770 741	545 871
1912	497 862	391 899

The alkaloids morphine and codeïne are manufactured from the opium and are mostly disposed of on the London market.

Owing to the restriction in the export of opium to China the area devoted to poppies in India has decreased from 564 585 acres in 1906-1907 to 182 558 in 1912-1913 and to 156 250 in 1913-1914.

The white variety is commonly cultivated, and grown from October to March after maize or millet. Usually it is grown alone, but occasionally the preceding maize crop is left standing to attract the insects which would otherwise injure the poppies. Heavy black cotton soils are preferrred, and fields are selected in the highly manured circles round the villages, which receive 150 to 200 maunds (1) of cattle dung per acre per annum ; in Fatehpur the land is often manured by herding sheep and goats on it, the dung of which is supposed to be of peculiar value. The plants benefit greatly if they are irrigated with well-water impregnated with nitrates (Khari), and manured with earth impregnated with saltpetre (Nonamati) or well rotted cow dung ; ashes are also extensively used as top dressings. A finely powdered tilth is absolutely essential and the land is ploughed as

(1) maund = 28 lb.

many times as the cultivator has leisure for. Seed is sown from the middle of October to the end of December at the rate of about 3 lbs. per acre, having been previously mixed with earth. The ground is almost always prepared for sowing by a watering and in the drier portions of the United Provinces the plants are irrigated once a fortnight or three weeks between germination and harvest time, while in the Benares division four or five waterings are usually sufficient. The field is kept scrupulously clean, being weeded and thinned at frequent intervals.

The crop is ripe in February or March and the opium is extracted by means of incisions made in the pods in the afternoon, the exuded juice been collected the next morning. Each pod is lanced three or four times at intervals of two to four days. Linseed oil is freely used to remove opium that has hardened on the pod and as a medium in which to store the opium to prevent its drying out.

The process of manufacture is not ordinarily undertaken by the cultivator, but is in the hands of firms by whom the produce is bought and by whom the cultivator is often partly financed. The process is a very simple one : the opium is kneaded into balls and stored in racks covered with the dry leaves and stalks of the poppy plant. As it dries, the balls are apt to lose their shape and are periodically examined and reshaped, considerable importance being attached to the balls being spherical in shape and free from cracks, especially by the Chinese connoisseur.

Cultivation expenses amount to roughly 40 rupees (£ 3 6*s* 8*d*) per acre.

The specific diseases to which the poppy is subject in India are : *a*) root canker ; *b*) sun burning ; *c*) sclerosis, the symptoms of which are a gradual drying and hardening of all the plant tissues ; *d*) *patechia*, in which the cuticle of the leaves becomes more or less densely covered with specks or spots somewhat resembling those caused by the bite of insects ; and *e*) gangrene, which mostly affects the soft, herbaceous parts of the plant. Injuries are also caused by broomrape, various fungi, insects and birds.

The output of opium during 1912-1913 was approximately 19 854 cwt., excluding that grown in the Native States for which no reliable details can be given. The average content of morphia in opium ranges from 6 to 10.26 per cent. The whole of the opium produced is sold to Government by the cultivators at a fixed price and is then manufactured for export and for internal consumption. The quantity intended for export is put up to public auction in Calcutta every month in chests containing 140 lbs. each.

Imports and exports of opium during the period 1908-1912 are given below ; imports consist mostly of Persian and Turkish opium required for pharmaceutical purposes ; exports go to China and other countries.

	Imports lbs.	Exports cwt.
1908.	213	68 210
1909.	260	81 329
1910.	431	68 392
1911.	422	62 575
1912.	554	42 787

During 1913 the quantity to be exported was fixed at 32 125 cwt., the systematic reduction being due to the policy of restricting exports to China. The estimated annual consumption of opium in British India is 10 982 cwt.

For further reference see :

Watt's Dictionary of the Economic Products of India, Vol. VI, Part I. London, W. H. Allen and Co.

NETHERLANDS. — Poppies are cultivated in districts possessing a heavy soil, more especially in the provinces of Groningen, North Holland, South Holland and Zealand. A variety of *Papaver somniferum* L. with blue flowers, indehiscent capsules and grey or grey-blue seeds is in common use, and the plant is cultivated for the sake of its seeds from which oil is extracted. The average area under this crop during the period 1901-1911 was 808 acres, but increased to 1623 acres in 1912 owing to the rise in price of the seeds.

Poppies follow red clover, oats or barley in the rotation: cultivation consists in ploughing deeply and applying dung or superphosphate according as the preceding crop was a cereal or a leguminous crop. Seed is sown in April or May in drills 24 to 26 in. apart and the plants are singled to a distance of 3 to 5 in. apart in the rows. The crop is kept hoed and ripens in August, being harvested in a very dry condition so that the capsules may be threshed immediately ; if threshing has to be delayed the plants are tied in bundles and placed in small heaps.

The average production per acre amounts to 18 to 22 bushels of seed, yielding 50 to 60 per cent. of oil, and 12 to 16 cwt. of straw. Poppy cake makes a useful cattle food, but the poppy straw is of very little value.

Prices for poppy seed ranged very high in 1910, causing an increase in the area under the crop in 1912. As a result, before the harvest the seed fetched £1 9*s* 4*d* a cwt., but after it fell to about £1.

Poppies are a hardy crop and have few enemies in the Netherlands.

There exists no special publication on the cultivation of poppies in the Netherlands, but a chapter is devoted to the subject in *Byzondere Plantenteelt*, J. Z. TEN RODENGATE MARISSEN. Groningen, J. B. Wolters.

PERSIA. — Poppies are cultivated in all the provinces except Kazvine, Zindjan, Guilan, Mazenderan, Astrabad and parts of Azerbaydjan. The white flowered variety is commonest and the red and purple flowered varieties are also grown, the production of opium being the chief object. The harvest is very early, especially in the south, so that the crop is usually followed by melons, sesame, lentils, beets, millet, etc., and then the land is again put to poppies, or the poppy crop may be followed by two years' fallow. Cultivations consist of a single ploughing (or spading in the South) and dung or nightsoil is used as manure. Seed is broadcasted at the rate of 1.4 to 1.8 quarts per acre. The crop is hoed for the first time as soon as the seedlings have four leaves and they are then singled to a distance of 6 to 8 in. apart ; a second singling takes place after 20 to 30 days, further thinning out the plants to 10 to 12 in. apart. Irrigation is applied as required with a maximum of three waterings.

Opium collecting from incisions begins when the two lowest leaves have turned yellow, when the three upper leaves begin to lose their colour and the operculum of the capsule blackens. Incisions are made at midday and the exudate is collected at sunrise the next morning. A second incision is made a few days later, but the yield in this case is much smaller.

Expenses for raising the crop amount to about £5 per acre, average returns being 200 lbs. of seed and 32 lbs. of opium per acre, fetching 13*s* 4*d* per cwt. and 14*s* 4*d* to £1 5*s* 2*d* per lb. respectively. Imports and exports of opium are as follows :

		Amount lbs.	Value £
Imports . . .	1908	997	354
	1909	543	174
	1910	610	232
	1911	7 915	7 636
	1912	2 421	2 834
Exports . . .	1908	580 737	250 112
	1909	663 345	306 034
	1910	494 434	229 042
	1911	528 959	391 317
	1912	719 162	607 238

The home consumption is considerable, though its actual amount is unknown.

SERVIA. — Poppies are cultivated on a large scale only in those parts annexed during the late war, and no data on the subject are at present available.

637 – ***Cymbopogon coloratus* Oil from Fiji.** — *Bulletin of the Imperial Institute*, Vol. XII, No. 1, pp. 48-51. London, January-March 1914.

Recent investigations have been carried out at the Imperial Institute on the composition of the essential oil of *Cymbopogon coloratus*. The principal constituents are citral (40 per cent.) and geraniol (23 per cent. in the free state and 10 per cent. in the form of geranyl acetate); the oil is therefore intermediate in composition between citronella and lemon-grass oils and was assigned a value intermediate between those of the two above products by commercial experts.

FRUIT GROWING

638 – **Winter Spraying of Fruit Trees with Nitrate of Soda.** — BALLARD, W. S. and VOLCK, W. H. in *Journal of Agricultural Research*, Vol. I, No. 5, pp. 437-444, + 2 plates. Washington, D. C., February 1914.

These experiments on the effect of winter spraying with various solutions on the time of blooming and yield of fruit were begun in February 1912 and continued during 1913. The orchards used consisted of the Yellow Bellflower variety of apples, which bloom abundantly but only set a poor crop of fruit.

Seven 12-year-old trees were sprayed on February 2, 1912, with a solution of : nitrate of soda 50 lbs., caustic potash 7 lbs. and water 50 gallons, at the rate of 7 gallons per tree. Adjoining this row was a check row

of seven trees which received no winter spraying and a selected vigorous tree which received 50 lbs. of nitrate of soda ploughed in and washed down by the rains. In April it was found that the nitrate spraying had advanced the blossoming period about two weeks ahead of the normal period. The foliage buds were not so much affected, their condition remaining similar to that of the check row. Later in the spring the effect on the foliage growth became more pronounced and the sprayed trees assumed a more vigorous green appearance than the check trees. The single tree that received 50 lbs. of nitrate of soda applied to the soil showed no greater vigour than the check trees. During the summer both rows received sprayings for the control of apple powdery mildew and codling moth, and the crop loss from these and other insect pests did not not exceed 1 per cent. on either plot.

In the autumn, the check row of trees yielded 8 loose boxes of fruit, while the nitrate-sprayed row produced a little over 40 boxes. The single tree which received 50 lbs. of nitrate as fertiliser showed no increased production. In the spring of 1913 this row of nitrate-sprayed trees showed large plump fruit buds and blossomed several days ahead of the control row, showing that the effect of the winter spraying continued to some extent in the second year.

Similar experiments were carried out in 1913, using different solutions ; it was found that:

1. A solution of nitrate of soda (1 lb. per gallon) stimulates the trees to blossom earlier, and the effect is increased by the addition of either caustic soda or caustic potash.

2. The effect is proportional to the strength of the solution within certain limits. The best results were obtained with a solution of the following strength:

Nitrate of soda	200 lbs.
Caustic soda	20 lbs.
Water	200 gallons

3. Oxalic acid at the rate of 50 lbs. per 125 gallons of solution can replace the caustic soda with equally good results.

4. Nitrate of lime (130 lbs. per 100 gallons) and calcium cyanamide (92 lbs. in 100 gallons) also caused the trees to bloom earlier.

5. Sulphate of ammonia is considerably less effective than nitrate of soda.

6. Sodium chloride produced a distinct effect, sulphate of potash a slight effect and double superphosphate none at all.

7. The results with stone fruits were not so striking as those with apples and pears, but it is possible that stronger solutions together with earlier and repeated spraying may bring about better results.

Rain immediately following the application will wash much of the material off the trees, and it appears that at least a week of clear weather should follow the spraying, in order to ensure good results. The greater

danger of injury from frost that might result from forcing trees into bloom earlier than normally would have to be taken into consideration in making practical use of nitrate spraying in winter.

639 – **The Effect of Dust from Cement Mills on the Setting of Fruits.** — ANDERSON, P. T. in *The Plant World*, Vol. 17, No. 3, pp. 57-68. Tucson, Arizona, March 1914.

The decrease in the productivity of fruit trees in the vicinity of cement mills is attributed to the solution of the dust in the stigmatic secretions, which prevents the germination of the pollen. The dust contains a large amount of alkaline soluble lime, and artificial tests show that pollen will not germinate even in a very weak solution of the dust.

640 – **Shallow Cultivations in Vineyards.** — COUDERC, in *Comptes-Rendus de l'Assemblée Générale de* 1914 *de la Société des Agriculteurs de France*, No. 3, pp. 525-526. Paris, May 19, 1914.

In order to avoid chlorosis in shallow soils overlying chalky subsoils, very shallow cultivations, less than 1 in. deep, were adopted and gave good results. Not only were the vines less affected with chlorosis, but they also suffered less from drought. A light spring-tine cultivator was used for the purpose, and cultivations had to be carried out before the weeds got any hold on the land in order to keep it clean. Such shallow tillage cannot be practised indefinitely, as after a certain number of years the soil must again be stirred to a greater depth and well manured in order to stimulate the growth and development of the roots, which would otherwise succumb to the attacks of phylloxera.

641 – **Influence of American Vine Stocks on the Quality of the Wine Produced in Champagne, France.** — MANCEAU, F. in *La Vie Agricole et Rurale*, Year III, No. 22, pp. 621-624. Paris, May 2, 1914.

The wine produced from grafted vines has been compared with that from ungrafted vines each year since 1897. A number of research stations exist for the purpose in Champagne and growers send in numerous samples to be examined, so that a large amount of data is accumulating and it will shortly be possible to publish a list of American vine stocks classified according to their influence on the resulting wine.

The quality of samples is determined partly by tasting and partly by chemical analysis. Testing is carried out at various times of year, in the January or February following the vintage, and again in subsequent years during the second fermentation in bottles for champagnisation; thus reliable results are obtained by following out the process of maturation in the wines. The investigations have shown that only a few stocks exercise an unfavourable influence on the wine; the majority when grafted with Meunier, Pinot noir and Chardonnay blanc, yield wines up to the general standard of the district; specially good stocks recommended by the writer are the following :

Chasselas × Berlandieri 41 B for calcareous soils.
Berlandieri × Riparia 420 A, 34 E. M. and 157-11.
Riparia × Rupestris 3309 and 101-14.

The stocks influence the ripening period: for instance Pinot noir on Riparia Gloire of Montpellier ripens 8 to 10 days sooner than on its own roots; on Chasselas Berlandieri 41 B it is 5 to 6 days earlier; Mourvèdre × Rupestris 1202 on the other hand retards its ripening 8 to 10 days, while Riparia × Rupestris 5306 and 3309 also have a slight retarding influence.

642 – **The Papaya in Hawaii** (1). — HIGGINS, J. E. and HOLT, V. S. in *Hawaii Agricultural Experiment Station, Bulletin*, No. 32, pp. 44. Washington, March 26, 1914.

The papaya (*Carica papaya*) flourishes in all drained and aerated soils in Hawaii. Though irrigation will increase the crop, an abundant water supply is not essential and papaya will give good results on a soil just too dry for oranges. Suckers should be removed at first, but after the plant has fruited two or three times, the main stem should be cut down and replaced by one of the suckers left for the purpose. The whole plantation should be renewed after about four years' bearing.

The fruit will travel well if certain precautions be taken, *i.e.* the fruits, preferably those belonging to the long-fruited varieties, should be picked at the first sign of ripeness, wrapped in paper and packed in straw board

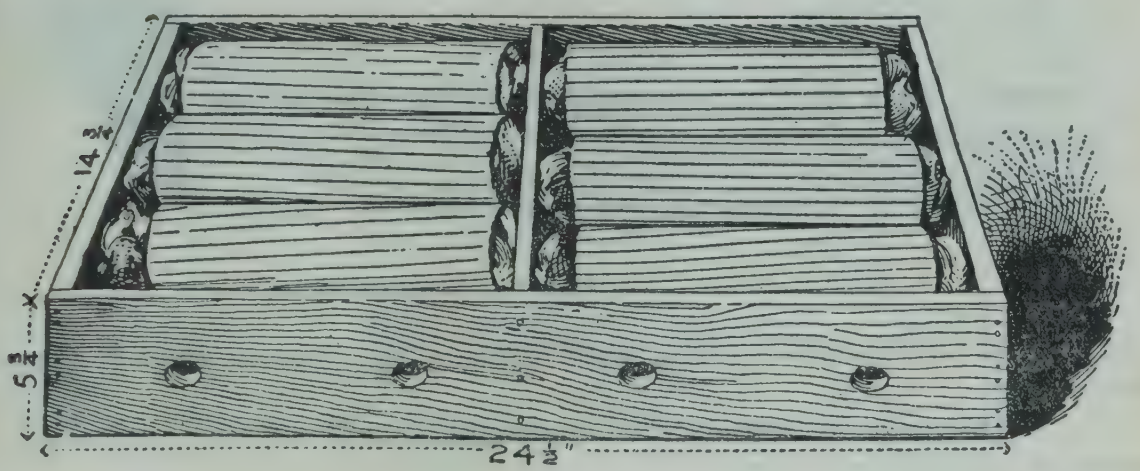

Fig. 1. — Crate for transport of papayas (open).

in well ventilated crates (the size of the latter is indicated in the accompanying figs. in inches).

Seed kept for propagation is washed and dried and preserved in glass bottles; it is sown in a well drained soil and germination takes place in from two to six weeks according to the temperature; when one month old the seedlings are transfered to a nursery, and at two months old are planted out about 10 feet apart. Experiments on vegetative propagation carried out at the Experiment Station have given promising results, making it probable that the fruiting season will eventually be made several months earlier. In breeding papayas, the following points should be borne in mind:

(1) See No. 813 *B.* July 1913. (*Ed.*).

1. Trees bearing their fruit high (more than 6 ft. from the soil level) are preferable to those bearing their fruits close to the soil.

2. Numerous lateral branches requiring frequent pruning are a disadvantage.

3. Hermaphrodite or elongata varieties are better than round dioecious varieties, as males represent 75 to 85 per cent. of the latter and cannot be distinguished before flowering.

4. The most desirable size of the fruit depends on the use to which it is to be put. Table fruit should not be too large, while fruits for the production of papain should, other things being equal, be as large as possible ;

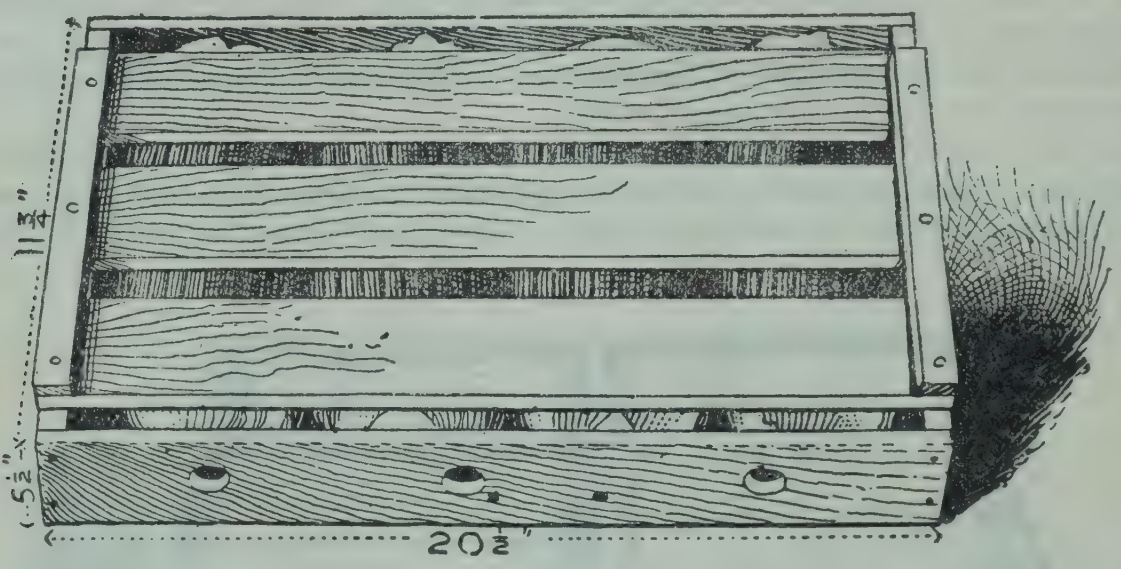

Fig. 2. — Crate for transport of papayas (closed).

and for this latter purpose too, fruit with a high papain content should be selected.

5. The long and round varieties should be kept separate and bred as constant and distinct types.

6. At present there is a tendency to unequal ripening of the opposite ends of the fruit which should be corrected. The ripe fruit should be of a fine yellow gold colour ; the flesh should be firm and of a yellow, red or pink colour, easily detached from the seeds and placenta and possessing a good flavour.

The papaya tree is subject to attacks from *Tetranychus* sp. on the lower surface of the leaves and on the fruits, and from the larva of the fly *Cryptoblabes aliena*, neither of which are serious enemies.

The harvest and preparation of papain are described in this bulletin.

643 – **Propagation of the Seedless Breadfruit.** — WESTER, P. J. in *The Philippine Agricultural Review*, Vol. VII, No. 3, pp. 97-99. Manila, March 1914.

The seedless breadfruit is one of the best and most nutritious fruits in the Philippines, but it is also one of the rarest owing chiefly to the difficulty of propagating it. The ability of the roots to sprout under certain conditions led to a series of experiments being carried out in 1913 at the

Lamas Experiment Station with the object of finding a simple and practical method of propagation. The following method gave good results: Root cuttings 20 to 25 cm. (8 to 10 in.) long and 1.5 to 6 cm. (½ to 2 ½ in.) thick are struck in a bed consisting of a layer of clean sand 18 cm. (7 ½ in.) thick situated in a sheltered and well drained position. The cuttings are inclined at an angle of 45° and buried three-quarters of their length, being set 20 to 30 cm. (8 to 12 in.) apart in rows 30 to 50 cm. (12 to 20 in.) apart . If planted in the rainy season, the cuttings require no further care; if not they must be watered. When 20 to 25 cm. (8 to 10 in.) high the cuttings are transplanted to a rich shaded soil, and when the plants are 60 cm. (24 in.) high they are ready for transplantation to the orchard. The roots should be disturbed as little as possible during the operation and a large ball of earth be moved with the plant. In replanting it is important not so set the plant deeper in the soil than it was in the nursery and a plentiful use of water should be made both before and after the operation.

LIVE STOCK AND BREEDING.

644 – **Results of Preventive Inoculation against Foot-and-Mouth Disease in Hungary, 1913.** — MEZAY, BÉLA in *Allatorvosi Lapok*, 1914, p. 238. HYGIENE

From observations made by the writer during the last campaign against foot - and - mouth disease in Hungary, it appears that, after undergoing preventive inoculation against this disease (aphtisation), a large number of animals became seriously ill. In many cases recourse had to be had to operations, while in others further complications caused by other diseases were set up, and some cases resulted in death.

In one district, the disease reappeared two or three months after the inoculation in a form more dangerous than the first.

645 – **Utilization of Potato and Jerusalem Artichoke Haulms.** — VÖLTZ, WILHELM; BAUDREXEL, AUGUST; and DEUTSCHLAND, ARNOLD in *Landwirtschaftliche Jahrbücher*, Vol. 46, Part 1, pp. 105-160. Berlin, March 11, 1914. FEEDS AND FEEDING

The writers carried out at the Berlin Agricultural College exhaustive experiments on the utilization of dried and ensilaged potato haulms and dried leaves and stalks of Jerusalem artichokes. The animals used for the experiments were three sheep and four milch-cows ; they were fed good meadow hay besides the experimental fodder. The haulm was from Silesia potatoes, and was dried in a hot-air apparatus ; some was fresh when cut, while some had been frosted. For the utilizationtr ials, two sheep were fed each ¾ lb. of hay with 1 lb. of haulm, the fresh haulm period preceding the frosted haulm one.

From these trials, as well as from a previous one (1) made with haulm from Wohltmann potatoes dried on the field, it appears that the percentage digestibility of dried potato haulm is about as follows:

(1) Cf. W. VÖLTZ and A. BAUDREXEL: Ueber die Verwertung des Kartoffelkrautes und der Kartoffelbeeren durch Wiederkäuer. *Landw. Jahrbücher*, Vol. 43, pp. 177-210. Berlin, 1912.

Organic matter	Crude protein	Crude fat	Crude fibre	N-free extract	Calories
64	57	53	66	68	63

There was very little difference between the three types, and none of them upset the health of the animals.

The amount of digestible nutritive matter contained in dried potato haulm appears from hese experiments to be about the same as that of good meadow hay; this is confirmed by a later experiment on four milch-cows, carried out wi h the object of ascertaining the effect of potato haulm on the quantity of milk and milk-fat and the total dry matter in the milk.

Ensilaged potato haulm was also prepared from the green haulm kept two months in a silo under strong pressure; after this, part was dried and the other part preserved in tin boxes. The loss of crude nutritive matter in the silo was 33 per cent. on the organic matter and 25 per cent. on the crude protein, while the digestible nutritive matter lost 35 per cent. on the organic matter and 13 per cent on the crude protein. The first utilization trial was made with the moist ensilage; two sheep were fed daily 4.4 lbs. ensilage with 0.77 lb. hay and 3.72 lbs. ensilage with 0.65 lb. hay respectively. Then followed an experiment with dried ensilage, during which one sheep was fed daily 0.78 lb. ensilage and 0.62 lb. hay.

Of the nutritive matter contained in the ensilaged potato haulm the following percentages were digested:

	Organic matter	Crude protein	Crude fat	Crude fibre	N-free extract	Calories
Fresh ensilage	62	62	66	60	63	58
Dried ensilage	65	56	77	65	67	66

The leaves and stalks of Jerusalem artichokes were dried by hot air and 1 lb. of them fed daily with $^3/_4$ lb. of hay to two sheep. As percentages of digestibility the following figures were found:

Organic matter	Crude protein	Crude fat	Crude fibre	N-free extract	Calories
65	55	70	54	72	66

According to its content of crude nutritive matter and digestibility, the Jerusalem artichoke haulm is about equal in value to good meadow hay. When fed alone, however, it causes strong fermentation in the alimentary canal, so that not more than half the bulky food should be replaced by it.

646 – **Feeding Experiments with Rice Gluten Food.** — HANSEN, REISCH, E. and SCHWEIGER, M. in *Deutsche Landwirtschaftlche Tierzucht*, Year 18, No. 21, pp. 245-248. Hanover, May 22, 1914.

Under the name of " Reiskleberfutter ", a food for milch cows is sold in Germany; it consists of a mixture of rice gluten and rice meal. The first is a by-product of the rice starch factories and is rich in protein, while the latter is a residue of rice milling. The writers have conducted a feeding experiment with the mixture which has the following composition :

Dry matter	93.30	per cent.
Crude protein	36.94	» »
Pure protein	31.25	» »
Fat	11.86	» »
N-free extract	36.87	» »
Crude fibre	1.32	» »
Ash	5.31	» »

The amount of nutritive matter contained in the food is so high that it places the mixture on a level with oil cakes countaining an average amount of protein. Its starch value is, according to the authors, about 71.77 per cent. and its protein content 22 per cent.

The food was fed with meadow hay, dry beet slices and brewer's grains mixed with molasses as basal ration, and compared with earthnut cake and wheat bran. The animals experimented upon were 18 Lowland cows in full milking. The quantity of rice gluten food was 6.6 lbs. during one period and 11 lbs. during the next. During the 75 days that the experiment lasted, record was kept of the daily milk yield, of its quality and of the changes in the live-weight of the animals.

The results of the experiment are that the rice gluten food under examination has the same value as a mixture of earthnut cake, dry beet slices and wheat bran ; consequently the writer recommends it for the feeding of milch cattle when it can be bought at a suitable price.

HORSES, ASSES AND MULES

647 – **Colt-breeding in Pennsylvania.** — COCHEL, W. A. and SEVERSON, B. O. *Pennsylvania State College, Agricultural Experiment Station, Bulletin* No. 122, 14 pp. Centre County, Pa., July 1913.

The writers carried out, in the State of Pennsylvania, where all the farmers buy their draught horses, a breeding experiment with 10 weaned Belgian and Percheron colts, with a view to ascertaining whether it is profitable for the farmer to breed his own draught horses.

The colts were divided into two groups of 4 and 6, and were fed, during the 532 days covered by the experiment, in the manner shown in Table I.

TABLE I. — *Daily Ration of each Colt.*

1. *Winter Period* (168 days).

1st Half.	Group I.	5 lbs. mixed grain (1); 8.2 lbs. maize ensilage; 7.4 lbs. hay.
	Group II.	5 lbs. mixed grain (1); 10.6 lbs. hay.
2nd. Half	Group I.	7.5 lbs. mixed grain; 13.1 lbs. hay.
	Group II.	Same as Group I.

2. *Summer Period* (106 days).

Both Groups: For the first 28 days: 5.5 lbs. mixed grain; 10.6 lbs. hay.
Afterwards: pasture, with mixed grain as supplementary food.

3. *Winter Period* (168 days).

1st Half: Both Groups: 8.4 lbs. of a different mixture of grain (2); 16.6 lbs. hay.
2nd Half: Both Groups: 10 lbs. mixture (2); 17.5 lbs. hay.

Note. Mixture (1) was composed of: 5 parts maize.
3 parts oats.
2 parts wheat bran.
1 part linseed meal.

Mixture (2) was composed of: 6 parts maize.
2 parts oats.
1 part wheat bran.
1 part linseed meal.

The animals, which were then two years old, were broken to work after the third period of the experiment.

The experiment was carried out without mishap and gave the results shown in Table II.

TABLE II. — *Results of the Experiment.*

Average weight per colt at the beginning	589.87	lbs.
» » » » after the 1st. Period	834.14	lbs.
» » » » » » 2nd. »	1 097.71	lbs.
» » » » » » 3rd. »	1 318.96	lbs.
Average increase in live weight per colt in the 1st. Period	244.27	lbs.
» » » » » » » » » 2nd. »	263.57	lbs.
» » » » » » » » » 3rd. »	219.25	lbs.
Average daily increase in live weight per colt in the 1st. Period	1.45	lbs.
» » » » » » » » » » 2nd. »	1.34	lbs.
» » » » » » » » » » 3rd. »	1.30	lbs.
Total increase in live weight per colt	727.09	lbs.
Average daily increase in live weight per colt	1.36	lbs.
Total cost of food and labour	$ 980.893	
Total cost of the ten colts by the end of the experiment	$ 1 893.390	
Value of the ten colts	$ 2.350	
Profit on the ten colts	$ 456.610	
Profit per colt	$ 45.661	

CATTLE

648 – **Crossing Bison and Cattle.** — 1. BOYD, MOSSOM M. (Bobcaygeon, Ont., Canada) in *The Journal of Heredity*, Vol. V, No. 5, pp. 191-197. — 2. GOODNIGHT, CHARLES (Goodnight, Texas) *Ibid.*, pp. 197-199. Washington, May 1914.

1. — Mr. Mossom M. Boyd publishes the first results obtained from his four years' experiments in the crossing of bison with domestic cattle.

He obtained about 30 hybrids. As to colour, the offspring of Hereford dams had white faces, but apart from these, the animals were practically whole-coloured, and were either brindled or a rich brown-black. The brindled varied between a tawny red and brown. The hybrids were, as a rule, larger and better proportioned than the bison; they stood more upright, had a less shaggy coat, and were altogether of better appearance.

The $^3/_4$ bisons, the product of a bison bull and hybrid females, did not differ one from another more widely than do different specimens of hornless Aberdeen-Angus. Their characteristics were midway between those of their parents. The $^1/_4$ bisons (Aberdeen-Angus or Hereford sire, hybrid dam) all exhibited the same build, but varied in colour. They resembled one parent as much as the other. The same is true in the case of the $^1/_8$ bison, obtained by a second cross with a pure domestic bovine animal. To the ordinary observer, the $^3/_4$ bison is easily confused with the bison, while the fine texture of the coat will alone serve to distinguish the $^1/_4$ bison from pure-bred domestic cattle. Taken altogether, the type of each class was homogeneous, and the proportion of bison blood regulated the likeness to that animal. As was expected, the proportion of bison blood did not regulate the appearance of the cattaloes (offspring of two crossbred animals). A number of these animals exhibited a greater similarity to the bison than did the hybrids.

On the whole, the results obtained are encouraging. Two especially interesting points immediately emerge, namely:

1. Crossing with bison is capable of improving the coat of the animals. Cattaloes with even less than $^1/_{10}$ bison blood may, with proper selection, have as good a coat as $^1/_2$ or $^3/_4$ bisons.

2. There is hope of being able to effect a great improvement in the capacity for beef-production. The bison's hump does not, as most people imagine, consist of a lump of fat, but of masses of muscle attached to neural spines double the length of those of domestic cattle. If it is borne in mind that the beef from the backs of cattle is the most valuable, it will be easily understood that the development of this characteristic is of first-rate importance. The writer obtained hybrids with humps 9 inches thick.

It is noteworthy that the experiments of the first class are not unattended with some danger. In this case, the principal effect of the first crosses was, in every cow without exception, an abnormal secretion of the amniotic fluid, which proved fatal in a large proportion of cases. Fortunately, considering that nothing of this kind had been in the least expected, the experiment had been made on a very large scale.

It should be observed that the writer was unable to raise a single fertile male hybrid. Of six born, only two survived the first 24 hours, and of these one was killed at an early age, without having been tested, and the other was barren. This agrees with the experiments made by Col. Ch. Goodnight, who states that he was unable to raise hybrid bulls. Ten male $^1/_4$ bisons were obtained, of which four were tried; only one proved fertile. Of five $^3/_4$ bisons only one was a bull, and he died as the result of an accident. The only $^1/_8$ bison tried proved fertile. In 1905 a $^5/_8$ bison was successfully reared, the offspring of a cross between a bison and a $^1/_4$ bison cow. This cross was interesting from the fact that difficulties of the same kind as those mentioned above in connection with the first cross were met with. This bull sired one calf in 1911 and four in 1912.

He is of a more elegant build than the true bison, and has a very well-developed back.

The results given by the crossbred cows are as follows: of 24 hybrids, 15 were barren, and only three were regular breeders. Up to 18 years of age they had respectively 9, 10 and 12 calves. Of the twelve ¼ bison cows only one was barren. Of four ³/₄ bison cows only one proved barren, but it must be admitted that the bull was not a good breeder. Of five ⅛ bison cows, one was spayed at 5 ½ years, without having had a calf up to that time. The other four were fertile.

The writer has not yet been able to obtain any results from the cattaloes, the experiments with which are still going on at the present time.

2. — Col. Goodnight has carried out crossing experiments in Texas between bison and domestic cattle. By putting domestic cows to a bison bull, he has only been able to rear successfully one bull-calf. The ³/₄ bison bulls proved barren, though the cows were perfectly good breeders.

Cattaloes shew a certain number of advantages over domestic cattle. They have a much higher disease-resisting power, especially as regards "Texas Black Leg" and Texas fever. Secondly, their weight is higher, as well as their beef yield (fully 70 per cent.). The beef is of good quality and never becomes leathery as it does in the bullock. The great development of the dorsal region enables them to produce about 150 lbs. more than any domestic animal. They are not subject to cattle panic and do not flee before storms, but face them as bison do. They can stand privation of water much longer than other animals; they are docile and never fight, and can do well under conditions which would be fatal to other animals.

649 – **Observations on the Origin and Distribution of Breeds of Cattle in French West Africa.** — Jacob de Cordemoy, H. in *L'Agriculture Pratique des Pays Chauds* Year 14, No. 130, pp. 24-36. Paris, January 1914.

The cattle of French West Africa may be traced to two definite types: 1) the zebu, or humped ox; 2) the humpless (taurine) type.

These two types have different areas of distribution, but at the borders of the two areas occur numerous races of a mixed or abnormal character, making the distinction more difficult. What is the primary origin of these types? The zebu is certainly an imported type, of Hindu origin, and its line of advance can easily be traced from the East to the West coast of Africa. The origin of the taurine type is a more disputable matter. Many writers admit the Asiatic origin of the taurine stock in Guinea, but Pécaud, who has long made a study of the cattle of Dahomey, thinks that the taurine type is indigenous to Central and West Africa.

The writer does not share this opinion, for two reasons: 1) many Central and West African tribes were cannibals, a practice not observed where meat is obtainable, as is the case when cattle are raised; 2) it is difficult to reconcile the existence of indigenous breeds of cattle with the fact that no aboriginal race practises stock raising; the only tribes which practise it are the Peuhlish peoples and the descendants of Peuhlish mixed marriages, and the Peuhls are foreign immigrants.

The zebu type may always be recognized by the hump, more or less highly developed, above the withers.

The other type is the Asiatic taurine type, which may be recognized by its height and more especially by the horns, which are strongly developed and lyre-shaped, a characteristic which persists in all breeds derived from this stock. A further confirmation of the Asiatic origin lies in the fact that these two types of cattle are found in all the countries right across the continent.

Dr. Decorse has described a third type, which he calls the Lake Tchad breed, but from the description he gives of it it appears to be merely an Asiatic breed. The writers opinion it shared by the Belgian verterinary surgeon Willaert, who only recognizes the zebu and taurine types.

The zebus were introduced by the Peuhlish invasion; they advanced westward along the 14th parallel, and from there some must have gone up and some down the Niger, but they followed rather a north-westerly route, on account of the trypanosomiasis in the south. Nowadays, the distribution of the zebu is limited to the south by the 13th parallel, and to the north by Upper Guinea. The two chief centres of the breed are, on the one hand, Senegal, and on the other, the countries round the mouth of the Niger.

The taurine type, also introduced by the Peuhls, seems to have been given up by them at a fairly early period to the natives of Upper Dahomey. It now forms the only bovine population in Dahomey and Guinea. There are three distinct breeds or varieties :

1. The Borgu breed, in Upper Dahomey.

2. The small Somba breed, found in the neighbourhood of Jugu Kwande and the Atacora Range.

3. The Wemé or Lagoon breed, in Lower Dahomey ; this breed is of small stature and appears to be degenerating in consequence of unfavourable conditions of soil and climate.

Variations due to climate are very noticeable in Guinea. The characteristic breed of Guinea is the N' Dama, which has produced two varieties, one small (43 in. high) and another taller (55 in.), which Ghebbard and the writer believe to be two modifications, produced by the climate, of one and the same breed.

650 – **Connection between Growth of Bone, Horn Development and Performance in Cattle.** — MÜLLER, MAX and NARABE, K. in *Landwirtschaftliche Jahrbücher*, Vol. 46, Part 1, pp. 1-40. Berlin, March 11, 1914.

After a short summary of Laurer's studies on the connection between growth of bone and horn development in Kehlheim (1), Simmental, and Lowland cows, the writers discuss the results of similar work on 59 Dutch, 59 Ayrshire and 18 Simmental cows. These investigations were carried out in Japan on pedigree animals, partly imported and partly bred at Hokkaido.

As in Laurer's investigations, the circumference of the cannon bone,

(1) A local brachycephalous draught breed, chiefly bred in the Upper Bavarian Palatinate.

and the length and circumference of the horns were taken as test measurements. Besides these, ten other measurements were taken with the object of throwing light on other points. After being measured, the animals were divided into groups and studied as to the connection between horn development and size of bones, between horn development and age, and between size of bones and age. The measurements of the Hokkaido-bred cows were compared with those of the imported ones. Besides the above, the relation between bone and horn development on the one hand and milk yield on the other was also studied in Ayrshire cows and at the same time the milk yields and live weights were compared with the horn and bone measurements.

The investigations led to the following conclusions :

1. In the breeds examined, increase in the size of the bones is correlated with decrease in the thickness and length of the horns, as Laurer had already found. This correlation seems to be more marked in Ayrshires than in Simmentals or Dutch cows.

2. The imported and Hokkaido-bred Ayrshire and Dutch cows did not show any appreciable difference in the circumference of the cannon-bone. The absolute circumference of the horns seems to diminish from generation to generation in Ayrshires and Dutch cows bred in Japan. The absolute horn length of the Ayrshire cows born in Japan is greater than in the original Ayrshires, while in the Dutch cows the opposite takes place. The different growth of the horns in the original breeds and in the animals raised in Japan is to be attributed only to the difference of environment.

3. The small-boned Ayrshire cows are in general, notwithstanding their relatively smaller live-weight, better milkers than the large-boned ones weighing about 110 lbs. more. Also the fine-horned Ayrshires under experiment proved better milkers than the thick-horned ones, while length of horn was not correlated with any difference in this respect.

It appears that well developed bone and slightly developed horns in young animals point to a continuation of growth of body, while moderately developed bones together with highly developed horns are signs that body growth will stop early.

651 – **Raising and Fattening Beef Calves in Alabama.** — GRAY, D. T. and WARD, W. F. — *Bulletin of the U. S. Department of Agriculture*, No. 73, 11 pp. Washington, March 30, 1914.

Experiments were carried out to determine the cost of raising calves to the age of 9 ½ months or the profits to be obtained, if any, by carrying them on and fattening them out at 12 months. Sixty-four calves from an Aberdeen Angus herd were selected for the purpose. The calves were born in the spring, ran with their mothers on the pastures till late autumn, were then weaned and prepared for fattening from December 21 to January 17, receiving broom-sedge hay (consisting chiefly of *Andropogon scoparius*), maize silage and cottonseed meal. On January 17, 49 of the calves were put on to fattening rations and kept on this diet until April 1st.

The average weight at 9 ½ months was 460 lbs. and the average cost of raising the calves to that age was $ 14.36. During the fattening period

the average daily increase was 1.37 lbs. on a ration of 4.4 lbs. of cottonseed meal, 23.9 lbs. of maize silage and 2.76 lbs. of broom-sedge hay, so that 100 lbs. of live weight increase required 323 lbs. of cottonseed meal, 1 741 lbs. of maize silage and 201 lbs. of hay, costing $ 7.3. The fat calves were sold at $ 5.87½ per 100 lbs., while the cost of raising and fattening them only amounted to $ 3.61 per 100 lbs. A profit of $ 436.19 was obtained on the whole herd, or an average of $ 6.81 per calf.

652 – **Cattle-Breeding and Dealing in Senegal.** — ADAM, J. in *L'Agriculture Pratique des Pays Chauds*, Year 14, Nos. 131, 132 and 133, pp. 65-80, 149-157 and 193-210. Paris, February, March and April 1914.

The physical conditions of the colony of Senegal make it favourable for cattle-rearing. The nearness to European ports points to beef production as the most suitable branch of the industry and from this standpoint Senegalese cattle may be divided into three groups.

1. The pure-bred Senegal zebu, humped ox, or Gobra, a Peuhlish variety of the zebu type. This is a heavy-framed breed, with a moderate beef-producing capacity, an average live weight of 750 to 900 lbs. yielding 40 to 42 per cent. dead weight of medium quality meat, not very spotted. The beef-producing capacity of the Moorish or Gabarougé variety is still smaller.

2. The N' Dama or humpless ox, which is of smaller size, but has a better-knit frame and better developed hind-quarters. The beef is of better quality than that of the zebu, and the average weight is 350 to 450 lbs. There are two varieties, the Gaboon and the Niokdo, the latter being the smaller of the two.

3. The mixed type (jakoré, warlé, n'dama-match), resulting from a cross between the two preceding breeds. This type is by no means uniform, as in native cattle-raising the crossing is promiscuous, but on the whole it is a good animal for the butcher, a full-grown bullock weighing on an average 650 lbs.

The distribution of Senegalese cattle is governed by natural conditions and by the zone where trypanosomiasis is endemic. Generally speaking, the N' dama breed is by far the hardiest and the most disease-resisting, and predominates in districts where water is scarce or where trypanosomiasis is prevalent, *i. e.* in the districts round Bakel and Matam, while about Saldé and Podor one meets with zebus as well, and crossbreds most of all. The zebu predominates in the neighbourhood of Dagana, where, on account of adverse local conditions, it remains without much size or muscle, and also in Djoloff and Baol, where the best beef-producing zebu are found. There are crossbreds there also, while in the Mjayes, where Gobras cannot live, only crossbreds and N'damas are to be seen.

Pure bred N'damas are predominant in the Serère Provinces, along with crossbreds, and produce good butchers' beasts, and the same applies to Sine Salum. At Niani-Ule, in Upper Gambia, and in Casamanca, they constitute the whole of the cattle. In Lower Casamanca, stock breeding is difficult, on account of the damp climate.

Senegal does not afford any well-defined stock breeding districts. Stock-breeding is distinct from crop growing, and there is a violent hostility between the two occupations. The negro races of Senegal must be classified into two divisions: first the Peuhls, who are nomadic and pastoral, and secondly the " Toucouleurs ", Serères, Mandingues, Ouoloffs, etc., who have a fixed abode and till the land. Usually, Senegalese herds are subjected to a system of migration.

The centre of Senegal consists of a huge plain, called the Ierlo, intersected in various directions by sort of gulleys. Here are to be found pools and also wells or " seïanes ", dug by hand at those points in the valleys where water is held up in the wet season. It is on this plain that the cattle are pastured during the wet season. As water becomes scarcer, the Peuhls return to the dry-season feeding-grounds ; those from the North, North-East and East reach the banks of the Senegal, those from the West go to Djoloff, and those from Baol, to the Serère Provinces. The young stock do not take part in the migration, but remain in the encampment together with a few milch-cows.

In some regions, as for instance in parts of the Luga district and on the coast in the neighbourhood of Saloum, the herds are stationary. As a rule, the cattle of the Toucouleurs, Ouoloffs, Sérères and the various tribes of Casamanca migrate short distances. The total number of cattle in Senegal may be reckoned at 800 000 head, and there are about 150 000 butcher's beasts.

The methods of cattle-breeding in vogue among the Peuhls, as well as those practised by other natives, are crude to the last degree. They make no provision of forage to feed their stock during the dry season, so when the latter arrives they are in a very bad way, and often lose their beasts, which die of starvation. The only care the native stockbreeders do take is to water their cattle, and even then they do not get as far as selecting suitable pools, so that only too often the stock drink foul, muddy water, swarming with the larvae of parasites. The repeated privations to which they are exposed have at length rendered the Senegalese cattle adapted, so to speak, to enduring thirst. They can go two months with only one drink every two days, or even every three days, according as they may chance to come across a watering-place, and it is no small wonder that with no more care than this the Senegalese cattle give so good a return as they do.

The calves are deprived from birth of part of their mothers' milk, weaned as soon as they can graze, and fed on a bare maintenance diet all their growing period, appreciably retarding their development. It is true that they share the supplementary ration sometimes given to their mothers, but that does not make up for the lack of sufficient milk.

653 – **Karakul Sheep in the Argentine.** — Direccion General de Ganaderia, Buenos Aires, in *Boletin del Ministerio de Agricultura*, Vol. XVII, No. 1, pp. 122-130. Buenos Aires, 1914. SHEEP

The small herd of Karakul sheep established in the mountainous district of Azul was presented to the Argentine Government by the Emperor of Austria in 1911.

They are being bred for the purpose of obtaining a number of acclimatised pedigree rams to be used for crossing with the local or Criolla ewes. By October 1912, 25 dark-fleeced native ewes from Entre Rios had given birth to 13 crossbred lambs, of which 9 were males ; all the lambs inherited the characters of their male parent with regard to colour and curliness of the wool. The experiment was then extended to include 250 ewes brought from different parts of the Argentine, and consisting almost entirely of Criollas with the exception of a few Merinos and Lincolns. The work is being carried out on the San Nicanor estancia belonging to Dr. M. M. Torino, and has resulted in the production of 76 first generation lambs all exhibiting the Karakul fleece ; the crossbred ewes will now be repeatedly crossed with the pure Karakul rams until a herd of pure Karakul sheep is obtained.

Wet, damp soil has proved very disastrous to the pure Karakul sheep, which contracted serious parasitic diseases (strongyles, sclerostomi, tricocephali). Of the total number imported in 1911, consisting of 4 rams and 16 ewes, only 5 ewes were alive in 1913. In the course of these two years 23 pure bred lambs were born, of which 8 died ; both the first and second generation remained true to type without showing any signs of degeneration.

654 – **Fattening Pigs on Cassava.** — Gouin, A. and Andouard, P. in *Bulletin des séances de la Société Nationale d'Agriculture de France*, Vol. LXXIV, No. 4, pp. 481-483. Paris, April 1914. PIGS

The writers, continuing Professor Frateur's experiments in feeding pigs on cassava, made some trials, and found that the method recommended by Professor Frateur might be profitable in Belgium, where cassava is obtainable for 12 or 13 francs per 100 kg. (4*s* 10*d* to 5*s* 3*d* per cwt.), but that it could not be followed in France, where cassava costs 18 fr. the 100 kg. (7*s* 3*d* per cwt.).

With a view to finding a more economic use for cassava, the writers made some experiments of their own, with the following results.

1. In the case of pigs fed with milk as well, it only took 3 lbs. of cassava to produce a gain in live weight of 1 lb., instead of the 4.18 lbs. of cassava required at Louvain.

2. By substituting for the milk ration 1.1 lb. of rice gluten and 2 ½ oz. bone meal, which costs 1*d* and is equivalent to 1 gallon of separated milk, there is required, to produce a gain of 1 lb. live weight, only 2.9 lbs. of cassava.

In practice, the profit exceeded 40 per cent.

Professor Frateur fed the cassava to the pigs in slices, cooked and then crushed. The writers fed it raw. It had been previously chopped fine in the colony itself.

655 – **The Influence of the Male Parent on the Character of the Egg-shells in Fowls.** — WALTHER, A. R. in *Landwirtschaftliche Jahrbücher*, Vol. 46, No. 1, pp. 89-104. Berlin, March 11, 1914.

In an investigation on the heredity of certain characteristics in fowls, it was sought to determine to what extent the breed of the cock influences the weight, shape, gloss and colour of the hens' eggs.

More than 130 eggs were laid by 13 hens, mated, some with cocks of their own breed, and some with cocks of 4 different breeds.

The breeds employed were the following :

I. *Dwarf fowls.*

1. Japanese: 1 cock, 2 hens.
2. Millefleur: 1 hen.
3. Silver-Sebright-Bantam: 1 hen.

II. *Medium-sized fowls.*

1. Huringian "Pausbäckchen": 1 cock, 3 hens.
2. Westphalian "Kruper": 1 cock, 3 hens.
3. "Nackthälse": 1 cock, 3 hens.

All the dwarf hens were reckoned as belonging to the same race, in view of the difference in weight between them and those of medium size. All the hens were first mated with cocks of their own breed; then the cock was removed and an interval of 8 or 10 days was allowed to elapse before he was replaced by a cock of another breed.

All eggs laid during the first mating period and subsequent isolation are reckoned as pure, while crossed eggs are those laid after the 10th day of the presence of the cock of another breed. Between the removal of the first cock and the time when the second cock's influence began to be felt, a space of time elapsed which the experiment shewed to be long enough to make sure that the influence of the first cock had entirely disappeared. The eggs were weighed and measured, and their colour and gloss noted as soon as possible after they were laid, and particulars were only kept of those eggs which proved fertile on incubation.

The results may be summarised as follows : The fact of the cock belonging to a different breed had no influence upon either the weight, shape, colour or gloss of the eggs. The writer therefore casts some doubt on the recent assertions of Holdefliess and Tschermak, in which those writers allege that they have observed in eggs phenomena indicating telegony.

POULTRY

656 – **Seaweed for Packing Birds.** — DEKOBRA, M., in *La Nature*, No. 2134, pp. 339-340. Paris, April 18 1914.

In speaking of the utilization of a species of "mutton-bird", the writer describes a new method of packing; this consists in placing the body in a natural bag formed by the lamina of a certain seaweed occurring in islands off New Zeland. Birds can be kept in good condition for several years in this way.

657 – **Ostrich-farming in New Caledonia** — FRAYSE, A. in *Revue de la Chambre d'Agriculture de la Nouvelle-Calédonie*, No. 39. pp. 26-30 Nouméa, March 1914.

A colonist in New Caledonia has started ostrich farming with nine imported birds. The price of the birds was £ 32 a piece, and the total cost of importation was £ 1000. Ostriches could be had in Austrialia at a price of £ 40 to £ 48 the pair.

658 – **Poultry-Farming in Canada.** — FORTIER, V. in *La Vie Agricole et Rurale*, Year 3, No. 16, pp. 434-435. Paris, March 21, 1914.

The writer describes the excellent results achieved for some years now in Canada with the system of unwarmed fowlhouses. Both from the point of view of preventing disease and from that of maintaining the birds in good condition, experience shews that it is better not to heat fowlhouses in winter. Among other good effects this system increases vitality and laying-power. It is sufficient that fowlhouses should be built well protected from damp, and that, at the beginning of the cold season, the fronts should have sacking or coarse cotton drawn over them, so as to keep out draughts. The fowlhouse should be built facing south, which greatly raises the temperature inside (when the thermometer outside shews 23° below zero Centigrade, the temperature inside will be 3° or 4° C. on a sunny day or 0° to 2° C. on a dull day). The house should be fitted with flat perches, to admit of the fowls covering their feet completely with their feathers. For laying purposes trap-door nests should be used, and should be visited often enough to prevent the eggs having time to freeze. This system has contributed largely to the recent great progress of Canadian poultry farming, the receipts from which have increased, under the encouragement of the Government, from £3 385 000 in 1901 to £7 842 000 in 1911.

FARM ENGINEERING.

659 – **Automatic Lifter for Balance Ploughs.** — DE CONDÉ, FERNAND in *Bulletin de la Société d'Encouragement pour l'Industrie Nationale*, Year 113, Vol. 121, No. 1. Paris, January 1914.

AGRICULTURAL MACHINERY AND IMPLEMENTS

In working with heavy balance ploughs, lifting the shares out of the ground at the end of the furrow is often very laborious. In Bajac's plough the work is done automatically. In fig. 1 the balance plough is shown travelling in the direction of the arrow. To the landside of the frame a sector shaped piece *S* is attached by means of a horizontal axis *x* round which it can revolve. While the plough is proceeding, the sector *S* is kept in the position shown in fig. 1 by a catch. On nearing the end of the furrow the ploughman, without leaving his seat, releases the catch by pressing his foot on a pedal, and at the same time he steers the plough so as to bring the wheel *A* on to the unploughed land. The sector then falls into the position *S*, fig. 2, touching the unploughed land with the point *a* ; the radius of the curve *ab* of the sector increasing from *a* to *b* causes the point *x* to rise as the machine advances and this, combined with the

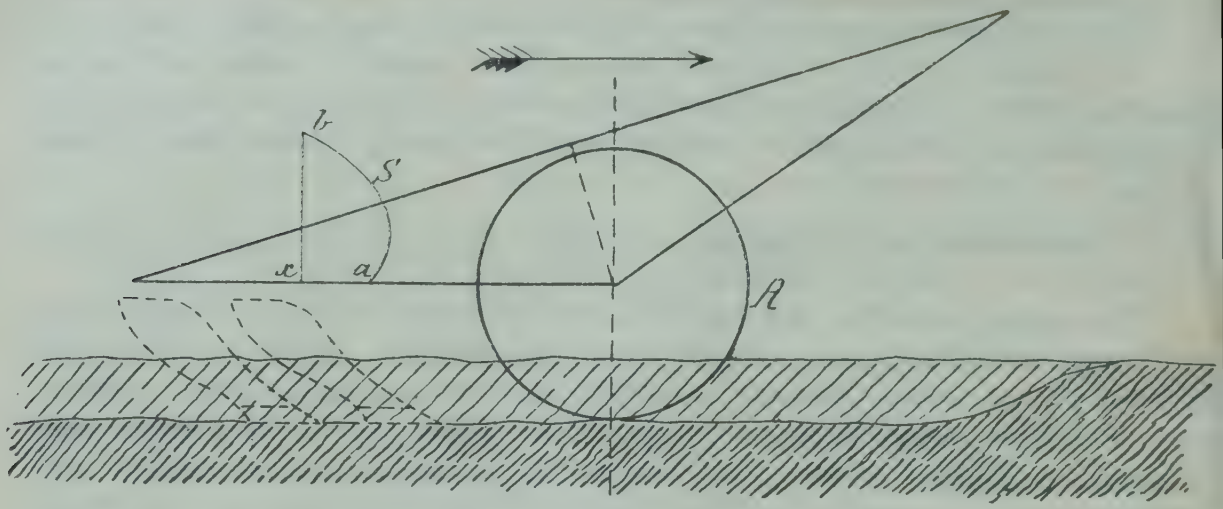

Fig. 1.

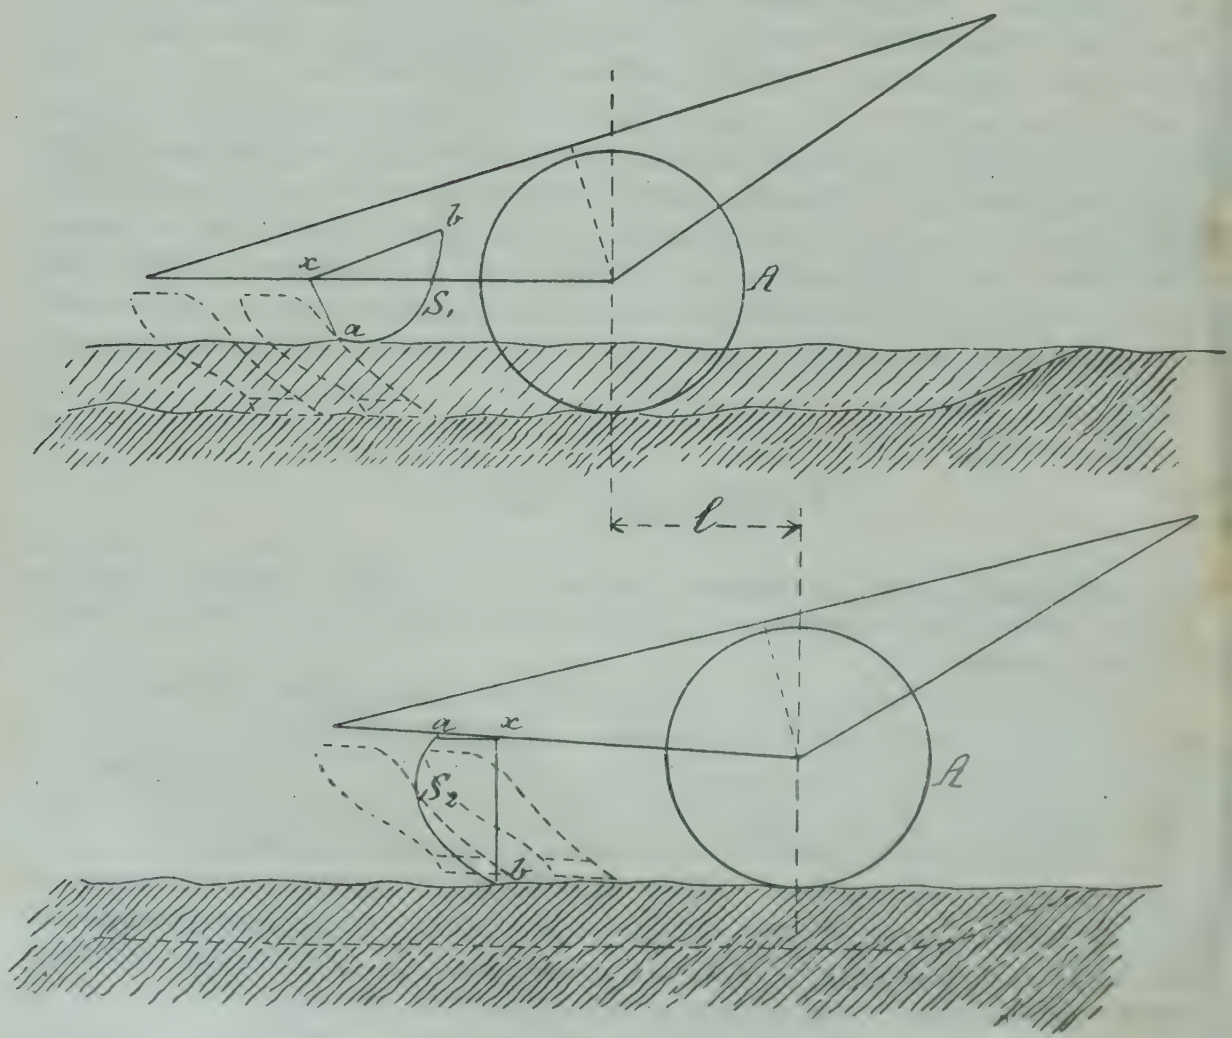

Fig. 2.

rising of the wheel *A* on the land lifts all the shares out of the ground within a length *l* equal to the development of the curve *ab*, fig. 2.

In order to prevent the sector slipping or dragging it is provided with strong projecting cleats.

When the plough is tilted for the return journey the sector is lifted by hand into its original position in which it is caught and fixed by the catch.

660 – **Team-hauled and Self-propelling Motor Binders.** — RINGELMANN, MAX, in *Journal d'Agriculture Pratique*, Year 78, Vol. 1, No. 2, pp. 55-57. Paris, Jannary 8, 1914.

In order to determine independently the power required by motors for working reaping and binding machines, *a*) when self propelled and *b*) when hauled by a team, the writer gives the following data drawn from a number of experiments carried out with various binders working in level fields.

A. The total amount of work done by a binder in travelling, reaping, binding and overcoming the friction of its mechanism ranges on average

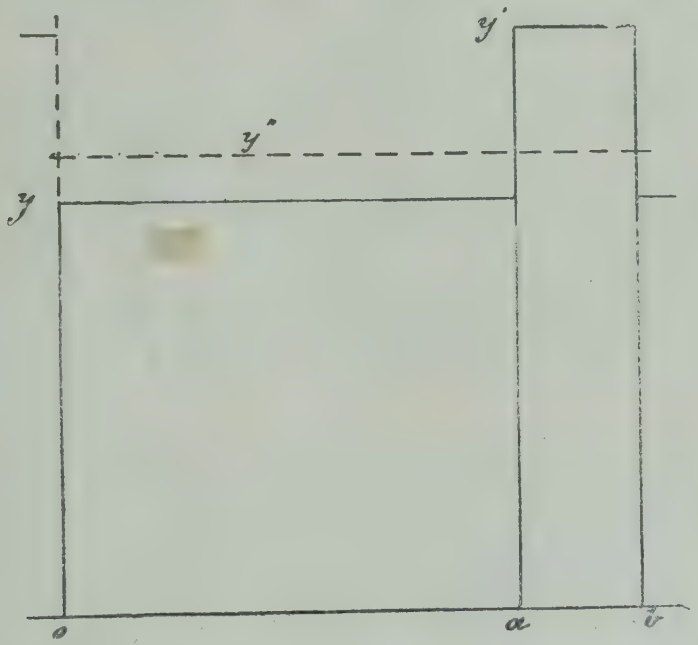

Fig. 1. — Diagram of a cycle of work done by a reaper and binder.

between 656 and 755 foot-pounds per pound of sheaves of wheat, and between 525 and 623 foot-pounds per pound of sheaves of oats.

B. The work of binding a sheaf of wheat weighing 11 lbs. requires an average expenditure of from 330 to 240 foot-pounds, which includes driving the mechanism, packing the cereal, knotting and cutting the twine and discharging the bound sheaf.

C. In machines having a five-foot cutter-bar, working in practice a swath of 4ft. to 4ft. 4in. on the level, and with a crop of about 44 cwt. of sheaves to the acre, the average power varies according to the various phases of the work and may be represented by the diagram, fig. 1, in which the distance travelled by the machine is shown by *oa* and *ab* and the power employed by *oi* and *ay*.

1) For a certain space *oa* the machine works as a simple reaper with elevator; the average traction *oy* is then 343 lbs.

2) At the end of this period there are 11 lbs. of cereals on the binder deck. The binder gets thrown automatically into gear and works while the machine travels from *a* to *b* and requires a power *ay'*, about 495 lbs.

3) The mean for the whole cycle, *i. e.* for the whole distance *ob*, is 380 lbs.

But the power required during the two periods is not constant throughout each period. Its variations are shown in fig. 2.

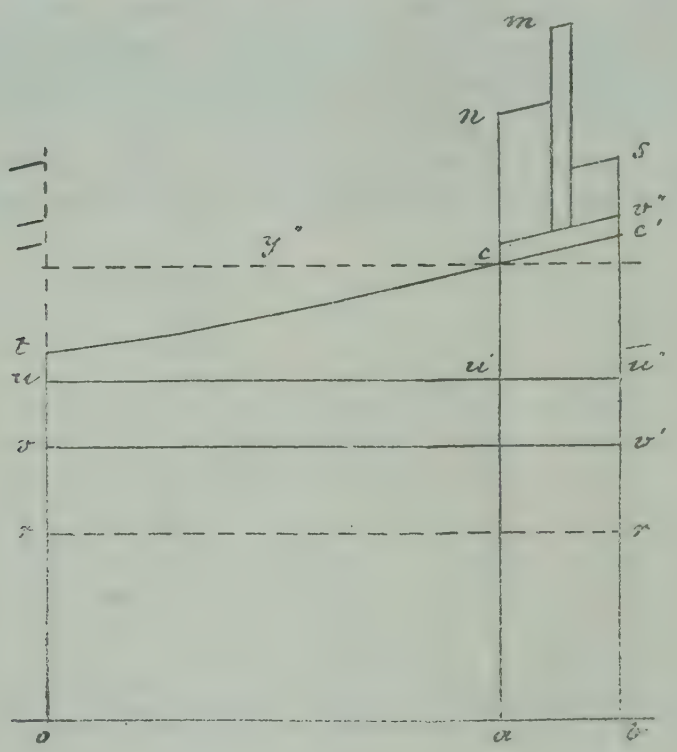

Fig. 2. — Diagram of the variations of power required by a reaper and binder during a cycle of work.

During the first period *oa* (when the binder is not working) the following work is done :

or haulage of the machine.

rv power consumed by the various parts of the machine itself minus the binder running empty. Everything above the line *vv'* represents the work done in passing the cereal through the various parts of the machine; thus *vu* is the work of bending down the grain to the cutter-bar, cutting it and carrying it by the platform and elevator canvasses.

utcu' is the work of the packers up to the moment *ac* when there is enough grain on the deck to throw the binder into gear.

In the second period *ab* there are besides these demands, all those above *cc'* required by the binder proper, to which must be added *u''c'*, or the power which presses the cereal, continually supplied by the elevator canvas, against the back of the needle and the sheaf which is being tied.

cc'v'' the working of the binder proper running empty.

n the average work of the needle and twine going through the compressed sheaf.

m the knotting.

s cutting the twine after the knot has been tied, the descent of the needle and the discharge of the sheaf by the carriers.

The team or the motor have thus to supply during a short time a maximum amount of work shown in *m* in fig 2. In reality the dynamometer diagrams reveal that in some moments the power required is still greater.

D. Assuming however the average traction required to be represented by *y''* in figs. 1 and 2, it has been found that a binder weighing, with its driver, about 1700 lbs., cutting a swath of 4ft. 2in. and dealing with a crop of 44 cwt. per acre, requires an average traction power of :

For the haulage of the machine	169.4 lbs.
For working the machine running empty.	90.2 »
For reaping and binding	121.0 »
average total	380.6 lbs.

which, at a speed of 4 ft. per second, corresponds to about 1502 foot-pounds per second or about 2 $^3/_4$ HP.

Taking the above data as a basis and making due allowance for shocks, sudden strains and maximum efforts, the writer calculates that if the binder is drawn by a team, the motor required to work the reaping and binding mechanism must be capable of developing not less than 4 HP, while if it has also to propel the machine, the motor must be a 14 or 15 HP one, in order to be able to cope with the gradients and inequalities of the ground often met with in fields.

661 – **Rubber-testing Machinery at the Imperial Institute.** — *Bulletin of the Imperial Institute*, Vol. XII, No. 1, pp. 76-79, 4 plates. London, January-March 1914.

It has been felt for some time that the present methods of judging the quality of rubber in the sale room are exceedingly crude and unsatisfactory and that accurate data for comparison can only be obtained by careful scientific investigations.

The best and most trustworthy method of judging rubber is to vulcanise a portion and to submit the vulcanised product to mechanical tests. Some work has been done in this direction, but much further investigation is required before the question of the best method for the preparation of rubber can be solved. Recognizing this fact, the Rubber Research Committee of Ceylon, in cooperation with the Department of Agriculture in the Colony, has arranged with the Imperial Institute to conduct a complete investigation of the effect of different methods of preparation on the quality of the rubber.

For this purpose there has been installed at the Imperial Institute a complete experimental vulcanising and testing plant, consisting of a washing machine, a mixing machine, a three-bowl calender, a vulcanising press, a vulcanising pan, a vacuum drier and a gas-fired boiler, and embodying all the most recent improvements which have been suggested by experience.

For the determination of the mechanical properties of vulcanised rubber one of Schopper's testing machines, which are considered to be among the most efficient, has been obtained. It can be used to determine the breaking strain, the elongation with fixed load, the load required for fixed elongation, etc. The machine is also fitted with an automatic apparatus for drawing diagrams. Other testing machines will be added during the progress of the investigations.

It is anticipated that by these means much light will be thrown on the effect of different methods of preparation on the quality of the rubber, and will enable a method to be selected on the plantations which will produce rubber of the highest possible quality.

662 – **The Motor Plough Trials at Litowitz and at Komotau Hagensdorf.** — WIRTH, HEINRICH in *Mitteilungen des Verbandes landwirtschaftl. Maschinen-Prüfungs-Anstalten*, Year 8, Part 2, pp. 67-79. Berlin, 1914.

In Austria, where the scarcity of agricultural labour is as keenly felt as in Germany, the question of efficient motor ploughs raises a good deal of interest. Two trials of these machines were held in the autumn of 1913, at Litowitz and at Komotau-Hagensdorf in Bohemia, and their results are given at some length in the above paper, from which the following data are taken :

I. *Trial of motor ploughs at Litowitz on medium heavy soil.* — The following firms took part in the trial carried out on September 9 and 10, 1913.

1. JOHN DEERE, with the " Twin City ", 45 HP, 4-cylinder direct tractor, 500 to 650 revolutions, and eight-furrow gang plough. Width of land worked 9 ft. 4 in. Price £1250, including eight-furrow plough.

2. I. H. C., with " Mogul ", 60 HP, 2-cylinder direct tractor, 350 revolutions, with 1 HP auxiliary motor. Eight-furrow Moline gang plough. Width of work 9 ft. 4 in. Price £1167, including plough.

3. HOFHERR-SCHRANTZ-CLAYTON SHUTTLEWORTH, with " Hart Parr ", 60 HP, 2-cylinder direct tractor, 300 revolutions, benzol, oil-cooling, Deere eight-furrow gang plough. Width of work 9 ft. 4 in. Price £1458.

4. ANTON DOBRY, with a 25 to 28 HP, 4-cylinder direct tractor on Saunderson's system, 550 revolutions ; three-furrow Sack plough. Width of work 3 ft. 4 in. Price, £833.

5. ERSTE BOEHMISCH-MAEHRISCHE MASCHINENFABRIK, with the self-contained 32 HP, 4-cylinder motor plough " Praga ", 1200 revolutions, five-furrow Joh. Cervinka ploughs. Width of work 4 ft. 8 in. Price £788 with two sets of ploughs.

6. MÜNCHENER MOTORENFABRIK (Munich-Sendling), with a 30-35 HP 2-cylinder direct tractor, 480-500 revolutions, five-furrow Eberhardt plough. Width of work 4 ft 10 in. Price £646.

7. STOCK-MOTORPFLUG-GESELLSCHAFT, with self-contained 42-50 HP, 4-cylinder motor plough, 720 revolutions, six-furrow Stock plough. Width of work 6 ft. 8 in. Price £1104.

8. CASE THRESHING MACHINE CO., with a 40 HP, 2-cylinder direct

(1) At each stoppage some water was lost.

tractor, 450 revolutions, Deere six-furrow plough (Inlands type). Width of work 7 ft. 6 in. Price £925, including 6-furrow plough.

All the above machines are provided with differential gear to enable the wheels to revolve independently of each other in turning, and with reversible motion. To prevent skidding most of the engines are fitted with fixed or removeable projecting cleats, besides fixed or removeable fly wheels to enable them to drive other machines. They are all easy to steer.

The object of the competition was to ascertain the amount and quality of the work done, and to this end a large field was divided into eight adjoining plots of the same shape and size, one for each machine. The first day the ploughing was done on the level, in the morning to a depth of a 6 inches, in the afternoon to about 10 inches. The next day (September 10) the ploughing was done on an inclined field. September 9 was a fine sunny day but in the night 0.16 in. of rain fell.

On the first day a wheat and barley stubble was ploughed ; the soil was a medium loam, dry on the surface. Each of the ploughs was given 5.2 acres to plough. The data obtained are given in Table I, and from these the work done per hour and the consumption per acre of fuel and of water for cooling were calculated. In consulting these figures, however, it must be borne in mind that the conditions were not all invariably the same throughout the tests. Thus in the morning the tractors on reaching the end of the furrow lifted the shares out of the ground and returned running empty, while in the afternoon they ploughed all round. Further, in the afternoon several of the outfits reduced the number of ploughs in the gang. The depth of furrow was not the same in all cases. There may also be some errors in the observations, which tell all the more as the duration of the trials was short. As for the quality of the work, the turning over of the soil was good throughout, with the exception of the " Praga " plough, which in shallow ploughing was not satisfactory. Uniformity of depth was attained better by the direct traction ploughs than by the self-contained ones. The loosening and crumbling of the soil was sufficient in all cases, with the exception of the " Praga " in shallow ploughing. Observations were also taken of the appearance of the ploughed land one week after the tests and after a rainfall of 2.2 in.

On the second day, September 10, the field to be ploughed was a wheat stubble, medium loam and sloping towards the south, the gradient being about 9 in 100. To each outfit 2.47 acres of land were assigned. The work done was similar to the deep ploughing of the preceding day. The ploughing in of the stubble was not quite satisfactory, nor was the loosening of the soil, especially in the case of the heavy tractors, which compressed the soil. " Praga ", " Stock " and " München-Sendling " crumbled the soil very well. The traction ploughs required two men each. the self-contained ploughs only one.

II. *Trials at Komotau-Hagensdorf* (*on very heavy soil*). — On September 14 and 15, motor plough trials took place on Herr E. Harsch's estate at Hagensdorf near Komotau. The machines entered were the following ; International Harvester Co's " Mogul " (60 HP) ; Hofherr-Schrantz-Clay-

ton Shuttleworth's "Hart Parr" (60 HP); Case Threshing Machine Co's 40 HP tractor plough; John Deere's "Twin City"; and Stock's motor plough.

On both days barley stubble was ploughed; the heavy humous clay was in good condition with regard to moisture. On September 14 the soil was not quite the same for all the machines, the I. H. C. plough getting the heaviest, the Stock the lightest and the others occupying the same intermediate positions as in Table II. On September 14, each machine was given a plot 3.7 acres in extent, on the 15th 2.47 acres. The resistance of the soil on the second day was very nearly the same for all plots.

The competing machines were to have ploughed to a depth of 6 inches on the first day and 10 inches on the second. On both days the ploughing in of the stubble and turning over of the soil, as well as the loosening of the soil, was satisfactory. The data concerning the performance of the machines are given in Table II (p. 925).

663 - **A Self-Steering Farm Motor.** — WASHBURN, H. J. in *The Scientific American*, Year 70, Vol. CX, No. 15, p. 313. New York, April 11, 1914.

A great need of the country is an efficient helper for the owner of the one-man farm, a machine that will work effectively and make him less dependent upon hired help, while saving him a considerable outlay in wages. Such a system has been devised on a practical basis. It requires compliance with certain conditions which cannot be fulfilled on all farms, but which are an easy matter in some existing ones and in many new localities.

The farm must contain one or more circular areas of any size up to about 10 acres each, reasonably level.

Thus a 10-acre farm would have a 7-acre circle in its centre, the remaining corners, 3 acres in extent, being occupied by fruit trees, buildings, etc. In the centre of the circle the post shown in the figure (facing p. 928) would be permanently erected. At the top of this post, which is strongly guyed, is seen an iron drum. This drum is set and locked by the handle on the side of the standard. Attached to the drum is a slender galvanized steel wire; it passes through a guide pulley and then to the steering lever of the motor-driven implement at some distance away. At each revolution of the implement round the field the wire wraps once roundthe drum, hence the circumference of the drum determines the width of work done. Between the frame and the steering lever of the implement a strong spring is attached, tending to steer the implement away from the centre post. The steering wheel has a deep flange in order to resist side pressure. About two pounds pressure at the end of the steering lever is sufficient to guide the implement. Since the tension of the spring and of the wire opposing it is about 50 lbs., the steering lever is obliged to follow an exact spiral path.

Repeated runs with the implement, starting at a radius of about 200 feet and finishing about 20ft. from the post, showed no visible variation from its course. The steering action was very dependable, requiring no attention whatever.

The framework of the implement is intended to be such as will facilitate the attachment of all the devices used in row-crop farming, such as ploughs, ridgers, cultivators, sprayers, etc.

An improved style of implement has been designed, having motive power applied to both rear and foreward wheels, both of them being pivoted so as to work between closely set rows of plants. The height under the beam is about 3 feet, permitting the cultivition of tobacco, cotton, etc., of that height. A safety device is provided to stop ignition in case of breakage of the steering spring or wire. With a dependable motor two six-hour runs per day *without an attendant* are possible.

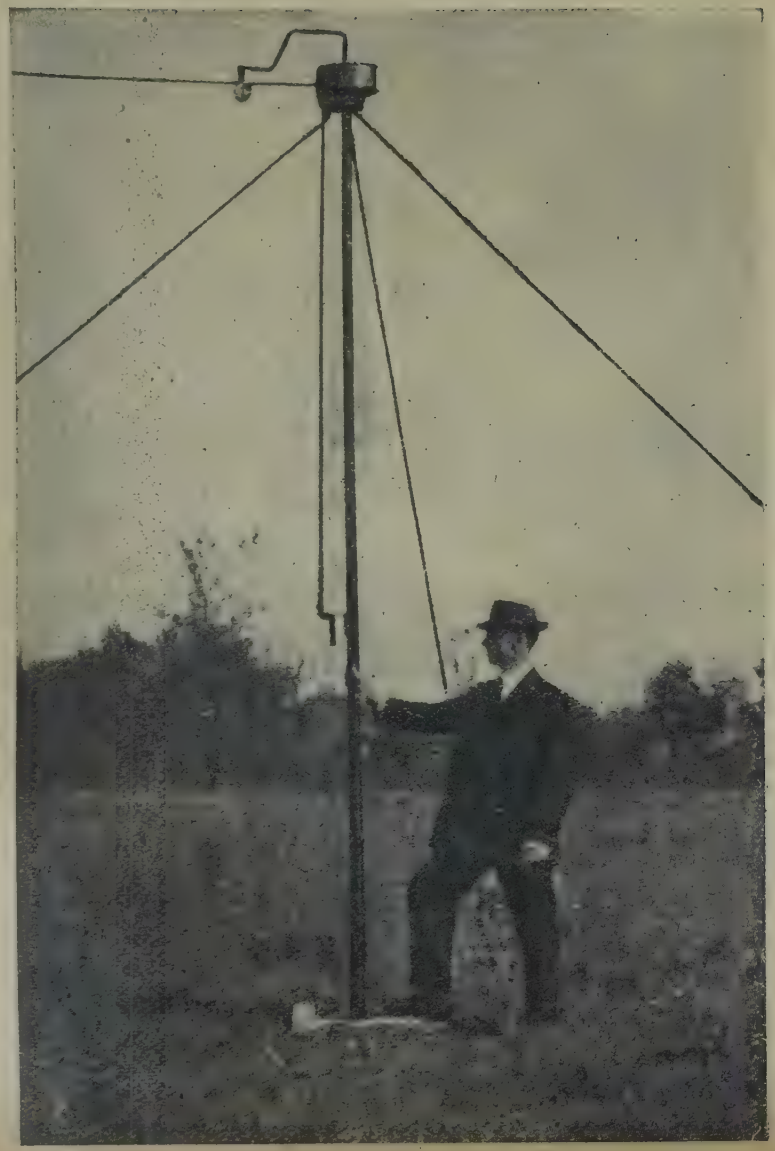
BUILDING CONSTRUCTION

664 – **Foundations on Explosion Piles in Compressible Soils.** — BEAUMONT, P. in *Revue Industrielle*, Year 45, No. 12, pp. 155-158. Paris, March 21, 1914.

Compact and resistant soils allow the foundations of buildings to be laid directly upon them, but such soils are rarely found at the surface; they are generally situated at varying depths and frequently so low down as to be practically beyond reach. In these cases recourse is had to: 1) a continuous simple or reinforced concrete foundation; 2) timber or concrete piles rammed by a pile driver; 3) concrete piles built on the spot.

The first system can be adopted only where the load to be borne is moderate and uniformly distributed and where there is no danger that the ground will be disturbed or undermined; it is, besides, expensive. Timber piles, among other drawbacks have that of being conical in shape and provided with a pointed iron shoe, both of which conditions cause them to tend to sink deeper into the ground under the weight of the building; if, on the other hand, they reach a sufficiently resistant layer they are liable to break under the blows of the ram and thus to become useless. The same defects are met with in the concrete piles driven in by ramming, and these are still more apt to break than the timber ones. Furthermore they require at least three months to set before being used and they are expensive.

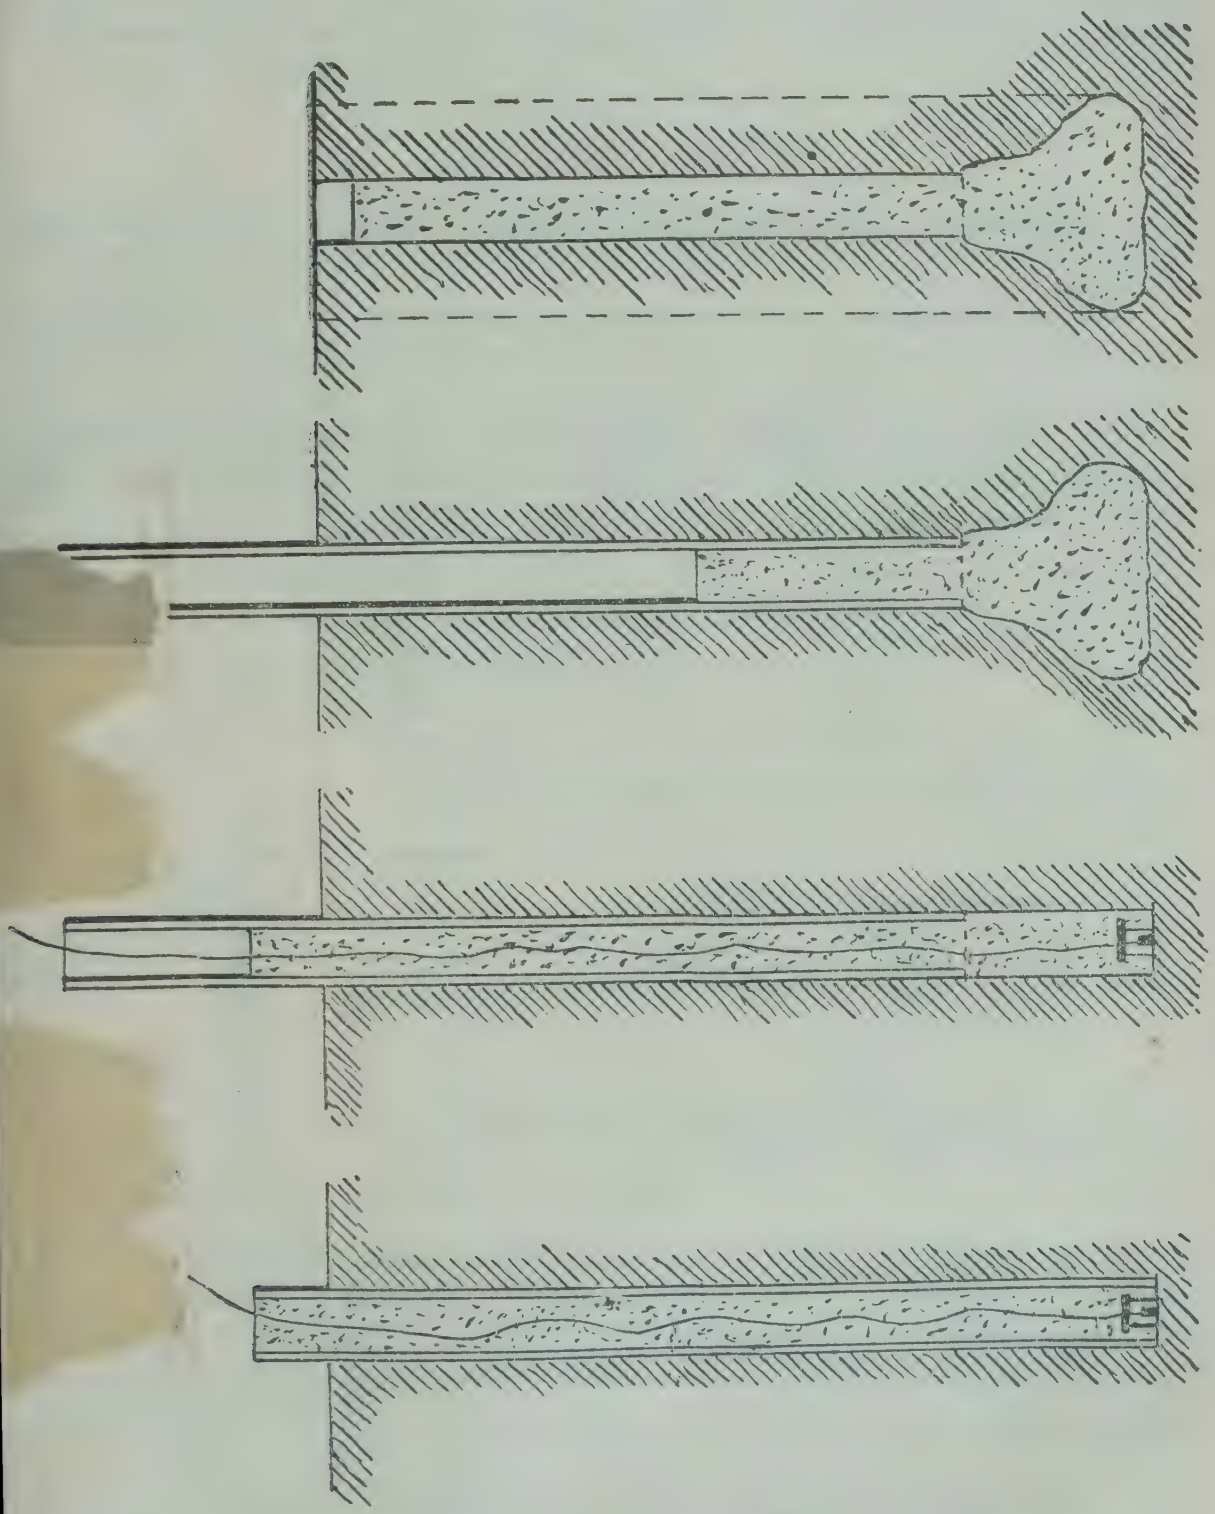
Wherever possible it is therefore an advantage to use concrete piles built where they are to stand, and to replace their pointed extremity by a base much larger than the rest of the pile. With the explosion pile a base having a large bearing surface is obtained together with an artificial compression of the surrounding soil which greatly increases its resistance. These piles are made as follows: a special steel tube encasing a timber pile is driven into the ground to the required depth by means of a pile driver. The timber pile is then withdrawn and the explosive cartridge is let down to the bottom of the hole in a special patented apparatus which has the object of protecting it and of directing the force of the explosion in a horizontal direction. The steel tube is then filled with fresh ce ment concrete (fig. 1) and lifted about 3 ft. 3 in. from the bottom (fig. 2), after which the charge is fired. The concrete sinks instantly and fills the chamber formed by the explosion (fig. 3). All that then remains to be done is to pour concrete into the tube, raising the latter gradually, and at last to remove it altogether, and the result is an explosion pile with a large and resistant base surrounded by, and resting on, strongly compressed ground (fig. 4).



Centre post for self-steering farm motor.
(See No. 663).

Explosion pile taken out of the ground.
(See No. 664, fig. 5).

There is no difficulty in regulating at will the size of the foot of the pile and the compression of the ground around it. The cubic contents of the chamber caused by the explosion are easy to calculate, being equal to the



difference of volume of the concrete in the steel tube before and after the explosion. Thus after a few trials the most suitable charge can be determined. It should be noted that with these piles the foundation is not repre-

sented only by the cross section of the pile, but by the section of the whole heterogeneous cylinder of earth and concrete shown by the dotted lines in fig. 4. If the soil is very bad and the load considerable, several of these piles can be grouped together, in which case the soil around their bases gets so compressed as to approach the hardness of concrete. Fig. 5 (facing p. 928) taken from a photograph of one of these explosion piles.

RURAL ECONOMICS.

665 – **The Economic Limit of Sugar-Beet Growing.** — BERNARD, P. in *Le Progrès agricole*, Year 28, No. 1392, pp. 229-230 and No. 1393, pp. 249-250. Amiens, March 22 and 29, 1914.

One of the most important factors influencing the profitableness of sugar-beet growing is the cost of transport, which depends principally upon the distance the beet has to travel on its way to the factory.

The writer determines the outside limit of this distance at the prices now ruling in France. He endeavours first to ascertain the cost of the "mile ton" of beets. In a farm of 494 acres consisting of:

Wheat	118.5 acres
Other cereals	59.0 »
Beets	118.5 »
Clover	59.0 »
Meadows	99 »
Lucerne	40 »

on a 6-year rotation, the carting is as follows:

	Horse-days	Weight carted
Farmyard manure for beets	432	1 417 tons
Lime and artificials	25	83 »
Liquid manure to the meadows	64	165 »
Cereal harvest	114	566 »
Haymaking, clover	33	165 »
» meadow	20	98 »
» lucerne	150	492 »
Carting sugar beets, mangolds and their leaves	792	5 197 »
Carting cereals to railway	30	110 »
Total	1 660	8 293 tons

If the average distance of this carting be taken at 2 kilometers (1.24 miles) this farm has to provide for 10 283 mile-tons in 1660 horse-days. The farm requires 4690 horse-days for all the agricultural work of the farm, and as the total cost of the upkeep of the necessary teams amounts to £1011, the cost of carting 10 283 mile-tons is $\frac{1011 \times 1660}{4690} = £357\ 16s$, and for one mile-ton $\frac{357\text{-}16\text{-}0}{10\,283} = 8.35\ d.$ If instead of 2 kilometers, 1.5 kilometer (0.9 mile) be taken as the average distance of the carting, other conditions being equal, the cost of transport per mile-ton amounts to 11*d*. The writer therefore considers that he is not far wrong when he assumes

the average cost of transport for a beet farm at 0.60 fr. per kilom.-tonne (9.81*d* per mile-ton).

The average cost of production of sugar-beets per acre is calculated as follows:

	£	*s*	*d*
Rent	1	5	8½
Interest on capital invested, at 4 %	—	9	0
Farmyard manure, 40 tons, of which $^{2}/_{5}$ are debited to the beets	2	11	2
Artificials	2	14	7½
Preparing the soil before sowing	1	0	10½
Value of seed and sowing	—	14	5½
Hoeing and singling	1	2	6
Lifting and loading	—	19	3½
Sundries	—	8	0
Total	£11	5	7½

To this cost of production the cost of carriage has to be added. If the beet crop be estimated at 11.94 tons per acre (30 tonnes per ha.), it means that a weight of 15.13 tons has to be carted to the factory on account of the earth adhering to the beets. At a cost of 9.81*d* per mile-ton, the cost of transport amounts to 9.81*d* × 15.13 = 12*s* 4*d* per mile. Thus the following table has been drawn up, showing the profit or loss per acre of beets grown, according to the distance between the fields and the factory, when the sale price of the beets is 22*s* 3¼*d* per ton.

Distance from fields to factory	Cost of carriage			Total outlay per acre			Profit (+) or loss (—) with an income of 22*s* 3¼ *d* × 11.94 = £13 6*s* p. acre		
Miles	£	*s*	*d*	£	*s*	*d*	£	*s*	*d*
1	—	12	4	11	17	11½	+ 1	8	0½
2	1	4	8	12	10	3½	+	15	8½
3	1	17	0	13	2	7½	+	3	4½
4	2	9	4	13	14	11½	—	8	11½
5	3	1	8	14	7	3½	— 1	1	3½
6	3	14	0	14	9	7½	— 1	13	7½

The point at which beet growing no longer pays lies at a distance between three and four miles from the factory. One means of extending this limit would be the granting of indemnities for carriage, proportional to the distance covered, as is already being done by the Meaux sugar factory. The substitution of mechanical for team haulage would also lower the cost of carriage; two 24-HP motor lorries, whose performance would amount to 48 132 mile-tons in 300 days, would work at a rate of 1.96*d* and 2.42*d* per mile-ton respectively. As the lorries would only have to deal with 10 302 mile-tons and would therefore be utilized during only a limited part of the year, these figures would have to be increased, but even if they were doubled a considerable saving over team haulage would be effected.

666 – **Work and Wages of Foreign Labourers in Prussia.** — GROSSMANN in *Georgine, Land- und Forstwirtschaftliche Zeitung*, Year 7, No. 28, p. 248. Königsberg, April 4, 1914.

The foreign labourers who come for the season are generally put on piece work at hoeing, harvesting, cutting green crops, pulling roots or lifting potatoes. The following are the most usual wages.

	I. With partial board: potatoes, milk and bread				II. With full board			
A. *Hoeing.*	Beets		Mangolds		Beets		Mangolds	
1. Per acre of roots:								
a) First hoeing	3*s*	2*d*	2*s*	4*d*	2*s*	4*d*	2*s*	0*d*
b) Hoeing between the rows	2	4	2	4	2	0	2	0
c) Singling	4	0	3	2	3	2	3	2
d) Second hoeing	4	0	3	2	3	2	3	2
e) Third hoeing	4	9	3	2	4	0	3	2
2. Per acre of potatoes	4*s*	0*d*			3*s*	2*d*		
3. Per acre of grain	4*s*	0*d*			3*s*	2*d*		
4. For work after the horse-hoe the above prices are diminished by 9*d* per acre								
B. *Cutting green crops and harvesting.*								
1. Reaping winter grain, per acre	4*s*	9*d*			2*s*	4*d*		
2. Binding, stooking and carrying winter grain, per acre	4	9			1	7		
3. Reaping spring grain, per acre	2	4			2	0		
4. Binding, stooking and carrying spring grain, per acre	2	0			1	7		
5. When working after a reaping machine the above prices are diminished by 4*d* per acre								
6. Mowing meadow grass, clover, lucerne, serradella or lupins, per acre	2	4			1	10		
C. *Pulling roots.*	Beets		Mangolds		Beets		Mangolds	
1. Roots: Pulling, topping, heaping, clamping, and covering clamps	22*s*	6*d*	14*s*	3*d*	19*s*	0*d*	12*s*	9*s*
The same afer a root-lifting machine	19	0	11	0	16	0	9	6
2. Roots: Pulling, topping, heaping, and either building small clamps for carting or loading on carts	19	0	9	6	16	0	8	0
The same after root-lifting machine	16	0	8	0	12	9	6	6
3. Covering the clamps with earth to a depth of 12 inches, according to the nature of of the soil; per running foot	$^{7}/_{8}d$ to $1^{1}/_{2}d$				$^{7}/_{8}d$ to $1^{1}/_{2}d$

667 – **Cost of Production of Milk and Beef.** — WATERSTRADT, F. in *Archiv für exakte Wirtschaftsforschung*, Vol. 6, Part 1, pp. 137-156. Jena, 1914.

The writer reports certain results of observations made on the cost of production of milk and of meat, and discusses the factors which influence these values in the various systems of farming. In one Table (see Table I) he collects the most important results from seven dairy farms where the farmers raised no stock of their own (Abmelkwirtschaften) and from seven others where they only raised a portion (Halbabmelkwirtschaften). These farms are placed in ascending order of cost of milk production.

TABLE I. — *Results from 7 Dairy Farms where none of the stock was raised and from 7 where some of it was raised.*

No. of Farm	Per Cow per Farm					
	Cost of feeding M.	Labour M.	Gain or loss of flesh M.	Total expenditure M.	Gross return M.	Cost of producing 1 gallon of milk pence
Farms where no stock was raised.						
1	531.2	60	— 1	702	718	6.2
2	512	60	+ 1	641	677	6.7
3	534	58	— 39	695	684	6.9
4	472	57	— 45	634	620	7.0
5	533	57	— 42	682	654	7.25
6	538	53	— 50	703	669	7.6
7	530	55	— 120	768	683	8.4
Average	521	57	— 42	689	673	7.2
Farms where some of the stock was raised.						
1	310	58	+ 16	427	475	5.3
2	316	58	+ 19	446	465	5.8
3	347	65	— 5	468	466	6.2
4	414	58	— 4	553	548	6.4
5	389	65	— 32	550	544	6.9
6	420	53	+ 13	548	468	7.3
7	437	68	— 32	593	507	8.0
Average	376	61	— 9	512	496	6.6

It is seen from Table I that on dairy farms where none of the stock is raised, in spite of the increased cost of milk-production, the cost of feeding and the labour bills are very little changed. On the other hand it is clearly shown that unfavourable results (*viz.* excessive cost of milk-production) are connected with the difference between the cost-price and the sale-price

of the cows. In the case of the dairy farms where a portion of the stock is raised, the chief factors influencing the cost of milk-production are the increasing cost of feeding and the milk-yield.

The results from nine dairy farms where the stock is raised on the farm are collected in Table II.

TABLE II. — *Results from 9 Dairy Farms where the stock is raised.*

Farm	Milk yield gallons	Gross return M.	Gain (+) or loss (—) M.	Cost of production, pence per gallon	Sale price, in pence per gallon	Cost of feeding M.
A	616	723	— 113	10.4	6.3	372
B	670	642	— 36	9.6	7.25	442
C	653	580	— 59	8.5	5.9	401
D	722	661	+ 3	6.9	7.0	438
E	724	672	+ 58	6.3	6.6	347
F	736	661	+ 58	5.4	5.7	303
G	788	891	+ 67	6.2	6.6	350
H	425	365	— 51	10.25	5.5	288
I	434	540	— 186	13.2	5.5	365

The three first farms shew a deficit, a result attributable to the high cost of milk-production. Whether a farm pays depends also on the milk-yield, as appears from a comparison of the figures for B with those for A and C. This interpretation is confirmed by the results from the other farms, of which four, having high milk-yields, realize a profit. The two last farms experience a loss, due to their poor milk-yield. The cost of feeding has also its significance with reference to cost of production. Thus for farms D and F, the gross returns are the same and yet the cost of milk production is very dissimilar. The writer lays stress on the fact that on the four farms where a profit was realized the feeding requirements had been very accurately calculated, the individual rations carefully compounded according to Kellner's tables, and their cost ascertained in each case.

In the second part of his work, the writer gives results from various pasture farms for 1909 and 1910. These results are given in ascending order of the number of head of stock carried per acre of pasture. It will be noticed that the number of head per acre has a marked influence on the gross yield of the pastures, as well as on the net yield and on the cost of production. The last farm, which in 1910 carried 1.6 head of cattle per acre, seems to have been overstocked. The gross yield was no higher, the net yield was lower, and the cost of production went up.

TABLE III. — *Results from Pasture Farms in* 1909-1910.

	Head of cattle carried per acre	Gross return per acre of pasture s.	Net return per acre of pasture s.	Cost of producing 1 lb. live weight d.	Net return per acre for the whole farm s.
1909	0.30	38	7	6.7	— 11
	0.72	86	66	2.7	+ 30
	0.74	88	20	5.0	21
	1.13	141	87	3.2	62
	1.41	152	109	2.5	29
1910	0.45	35	— 11	9.1	11
	0.62	88	43	3.2	35
	0.65	66	38	4.0	25
	0.66	54	39	3.5	39
	0.78	92	55	3.2	56
	0.83	96	55	—	25
	0.95	123	90	3.2	8
	1.62	120	59	3.7	62

According to Strebel's calculations, the cost of rearing a 2-year-old bullock is about £26 and the cost of producing 100 lbs. live-weight is about 54s, in raising young stock.

The writer's investigations on the cost of production in fattening cattle produced the results given in Table IV.

TABLE IV. — *Cost of Production of Fattening Cattle.*

	I 1908-11 Average	II 1908-11 Average	III 1909-12 Average	IV 1907-10 Average	V 1906-11 Average
	d	d	d	d	d
Per head per day:					
General expenses	1.55	1.55	1.52	1.56	1.65
Labour	1.2	0.7	1.1	1.0	0.9
	s d	s d	s d	s d	s d
Purchasing	2 8	2 5	1 5	2 10	2 6
Total outlay	4 0	3 7	2 7	4 11	3 11
Feeding	1 1	1 1	1 0	1 11	1 3
Cost of production per 100 lbs. live-weight	35 7	32 10	40 4	47 6	40 4

The great influence of the cost of feeding and of the difference between cost-price and sale-price in rendering the fattening of cattle profitable or unprofitable should be noted.

Finally, the writer gives the results of Howard and Lehmann's researches on the cost of fattening pigs. The average cost of production varies from 37*s* 6*d* to 40*s* 6*d* per 100 lbs. live-weight.

668 – **The German Imperial Commission of 1912-13 on the Cattle and Meat Trades.** — 1. *Verhandlungen der Gesamtkommission und Zusammenstellung der Sachverständigen Gutachten*, XVI + 468 pp. — 2. *Anlagenband I: Sachverständigen-Vernehmungen*, XII + 99 + 107 + 131 + 103 + 80 pp. — 3. *Anlagenband II: Materialien*, IV + 376 pp. + 11 tables. Berlin, 1913.

In 1912 the German Government set up a Commission of 30 members for the purpose of enquiring into the condition of the cattle and meat trade. The Commission held a preliminary sitting on the 22nd of November 1912, to discuss the scope of the enquiry, and subsequently, up to the 20th ot October 1913, sat on five occasions, each sitting occupying two days, to consider the evidence of 165 experts, including representatives of farmers, cattle-dealers, butchers, cattle valuation societies, and various towns in all parts of Germany. Representatives of the Imperial Government and of the Governments of the different Federated States also took part in the discussions.

The following questions in particular were considered at the various sittings: the determination of the price paid for beasts sold to the butcher; the question of dealers; the slaughter of immature calves; credit in relation to the cattle-trade; dealers' and slaughterers' commissions; the meat trade; meat-selling by stores, shops, and industrial enterprises; long-term contracts; experience with foreign meat, and municipal meat-buying; boards for fixing the price of meat; estimation of prices; organization of information and statistics.

The entire proceedings of the Commission, including the evidence of the experts and the material furnished by the investigations, were collected at the Imperial Ministry of the Interior and published in the three volumes under notice.

We here give only a few results of enquiries made by the Sub-Commission on the relative price of fat stock on the farm and in the market. After some endeavours to make a direct enquiry as to farm prices by general investigation in the country districts, the Sub-Commission soon came to the conclusion that the only way to obtain an accurate idea of the difference between the price on the farm and that in the market was to ascertain from a series of fat stock markets the sale prices of a large number of beasts in the country and the expenses entailed by them between then and their sale in the market. On these lines, therefore, thorough enquiries were made at the markets in Berlin, Dresden, Breslau, Hamburg, Munich, Frankfort-on-Main, Mannheim and Cologne. The whole of the material collected was then arranged in such a way that for each individual purchase the following particulars were ascertained:

1. The price in the country, *i. e.* the sum paid to the farmer.

2. The price in the market, *i. e.* the sum paid by the purchasing butcher.

3. The incidental expenses of the deal.

4. The gain or loss to the dealer.

From these it was discovered that a large majority of the transactions enquired into, at the markets mentioned, resulted in a loss to the dealer by reason of a fall in the price of fat stock. The average sale-price per 100 kg. (220 lbs.) live-weight for cattle (bulls, steers, cows and heifers) did not

usually exceed the purchase price in the country by more than about 5 to 7 marks (1), while in the case of smaller stock (especially pigs) this excess in some cases reached as much as 40 marks. The purchase-price of cattle per 100 kg. generally varied between 90 and 100 marks (45*s* to 50*s* per cwt.) and the sale price between 95 and 110 marks (47*s* to 54*s* 9*d* per cwt.). The purchase price of calves and pigs was mostly near 120 marks per 100 kg. (60*s* per cwt.) and the sale-price averaged about 140 marks (70*s* per cwt.) but here and there rose above 160 marks (80*s* per cwt). The incidental expenses may be seen from Tables I and II.

It was further found that the price on the farm is governed by the price in the market, and not vice versa, and that consequently the farm price may be reckoned by deducting the incidental expenses from the market price.

If this method of calculation does not always lead to exact results, the explanation is to be sought in the great distance often intervening between the purchase in the country and the sale in the fat-stock market, and in the fact that the irregular supply at the markets exercises a great influence on the prices. It has hitherto been impossible to regulate the supply to the markets, and thereby to eliminate its price-raising influence. If the prices have been sent down by a glut on any market, the farmers refuse, on the score of the low prices, to sell their stock to the dealers. The result is that the next markets are only feebly supplied and the prices go up again. Thus great oscillations are observable in the price of fat stock, and these exercise an unfavourable influence on the cattle-trade in general. This unfavourable influence on prices is not exercised by cooperative selling at the fat-stock markets, because in this case the fluctuations of the market recoil immediately upon the producer, who thus makes a smaller profit and cannot afterwards seek to recoup his direct losses, as the dealer does, from the next market.

669 – **Book-keeping Competition for Small and Medium-sized Farms in East Prussia.** — *Georgine*, Year VII, No. 40. Königsberg, May 16, 1914.

The East Prussian Chamber of Agriculture has organised its third book-keeping competition for holders of small and medium-sized farms. Competitors are limited to holders of not more than 100 hectares (247 acres), who either keep the books themselves or entrust them to a member of their household. The accounts must cover a whole year's operations and must include:

1. A cash account, *i. e.* a record of all incomings and outgoings, household and farm expenses being kept as distinct as possible.

2. A household account with a careful record of all goods furnished by the farm.

3. An inventory containing a valuation of buildings, and live and dead stock at the beginning and at the end of the period under consideration.

4. A balance sheet.

(1) The Mark is about 11 3/4*d*, or 23.86 cents.

The total value of the prizes amounts to 500 marks (£ 25). They will be awarded by a special committee made up of members of the Council of Rural Economics and Book-keeping of the Chamber of Agriculture. All data or figures communicated by competitors will be treated as strictly confidential.

AGRICULTURAL INDUSTRIES.

INDUSTRIES DEPENDING ON PLANT PRODUCTS

670 – **Results obtained by the Distribution of Pure Hungarian Yeast Cultures in 1912.** — REQUINYI, G. in *A. m. Kir. Ampelologiai Intézet Évkönyve* (*Yearbook of the Royal Hungarian Ampelological Institute*), Vol. V. pp. 36-39. Budapest, 1914.

One of the most important functions of the zymological section of the Royal Hungarian Ampelological Institute consists in collecting yeasts from the best wine-producing districts of Hungary, for the use of the vine-growers in wine making. This work was begun in 1901 ; the yeasts were taken from the lees of young wines and from the sediments of old wines (1). By 1906 it was possible to commence the selection of primary cultures, that is to say the founding of pure cultures of each kind, starting in every instance by inoculation with a single cell. This was a tedious process, having regard to the enormous number of species which exist (2), and more particularly because it was always essential to regard the matter from the practical standpoint, and to endeavour to obtain species which might exhibit qualities of value for wine making. The aim in studying individual species was to determine :

1. How far yeasts will ferment must of normal composition under conditions of varying temperature (24° to 25° and 6° to 12° C.), and must containing 35 per cent. of sugar.

2. Their power of resisting sulphur.

3. Their vitality, strength and power of forming sediment.

In fact, all the morphological and physiological characteristics which may serve toward the exact classification of the species. The number of primary cultures obtained from the material collected was 976. The study of these cultures produced 73 species, and after subsequent reduction, and elimination of species of no marked value, 54 species were successfully defined and are preserved in a dilute solution of saccharose, representing the Ampelological Institute's " Collection of Species " ; although all the species ferment must of normal composition, each one presents specific characteristics and advantages, suitable for use under special conditions, *e. g.* the production of sweet wines, champagne, membranous growth, etc.

(1) It is important that the yeasts should be collected from the lees, as this ensures obtaining those which have produced the fermentation of the wine, while those found in the wine itself are the yeasts which take part in the after-fermentation.

(2) From 1901 onwards, 341 divisions have been made, producing 73 species, from 20 yeasts collected in the Tokaj district (*Bulletin of the Royal Hungarian Ampelological Institute*, No. 1, p. 56. 1908).

After being carried through the experimental stage, the pure cultures were offered to vine-growers; 24 vine-growers asked for samples of yeasts in 1911, and this number increased to 152 in 1912 and 230 in 1913. The growers were supplied with application forms in which they stated certain working details, and the yeasts best corresponding to the growers' demands were sent to them, soaked on to cotton-wool, together with printed instructions for the use of the yeasts.

The following were the results of the experiments made in this way by vine-growers in 1912 (1):

1. In 65.6 per cent. of the fermentations carried out by the producers, the inoculation of the must was a complete success. The fermentation, clarification, and maturing of the musts treated in this way were effected more speedily and, in the majority of cases, the appreciation in value was estimated at an average of from 5 to 7 crowns a hectolitre (2 *d* to 3 *d* per gall.).

2. In 21.9 per cent. of the cases, the flavour of the wines showed no markedly increased development, but by reason of the quicker and purer fermentation, this development was also more speedy, and the draining-off easier.

3. In 12.5 per cent. of the cases only, no difference was noted between the produce of the inoculated must and that of the control.

Finally, the fact should be emphasized that in no case was an adverse result reported.

The smaller growers worked with from 1 to 20 hl. (22 to 440 galls.) of must, while the others carried out their experiments with 50 to 300 hl., (1 000 to 6 500 galls.) The total quantity of must inoculated during the 1912 experiments may be neckoned at 2300 hectolitres (50 600. galls.).

671 – **Hybrid Wines at the Toulouse Exhibition, 1914.** — PÉE-LABY in *La Vie Agricole et Rurale*, Year 3, No. 21, pp. 581-585. Paris, April 25, 1914.

Exhibitions of wines from direct-bearer hybrid vines have been held for some time now at Toulouse. Of the 60 white wines exhibited in 1914, the following proved the best: Cirere No. 157; Seibel Nos. 880, 4151, 3013 (liable to mildew), 2563, 3021, 2663. Seibel Nos. 2859 and 2677 produced fairly good rose wines. All the varieties mentioned above are entirely free from oidium (powdery mildew). Among the Malègue hybrids, the following were classed as " good ": 469-2, 1157-1, 1063-7, 1647-8, 1879-12, 2064-6, 2094-3, 2328-1 and 2401-4; their resistance to mildew (*Plasmopara*) and oidium is not yet sufficiently ascertained.

The quality of the wines exhibited in 1914 was on the whole better than in 1913. The writer comes to the conclusion that, at a comparatively small cost, white wines could be produced from the above hybrids, which might be consumed alone or blended with other wines or with each other. Many of them could quite well compete with the ordinary French white

(1) The results for the 1913 trials cannot yet be published, as the necessary data, the testing of the wines, etc., are not yet complete.

wines, and some, according to the verdict of the judges at the show, even with the better types.

Of the 120 red wines exhibited, the following deserve special mention: as general blending wines, the less delicate wines among the Seibel hybrids are noteworthy, namely 128, 156, 1020, 1077, 2003, 2007. The following newer hybrids produced quite good, but perhaps rather less full coloured wines: Seibel Nos. 1007, 2052 and 877, Couderc 4401, Le Madone and Couderc 286-68. The following wines were of a very fine red colour, with a good aroma, a delicious flavour, and plenty of fire: Malègue 2219-6, 2054-7, 2161-2, 2359, 1539-22, 2271-1, 2055-15, 1583-21, 391-6, 829-6, 2046-8 and 469-9. For the four last-named, two sprayings form a sufficient protection against mildew, while the others have not yet been sufficiently tested. The following wines, with a normal red colour, are also worth mentioning: Seibel Nos. 1000, 60, 4004, 3011, Bertylle-Seyve 413, Baco 1, Chenivesse 1-11. The exhibition of red wines shews: 1) that excellent blending wines can be obtained from red hybrids; 2) that many red wines, of normal colour, can be used for consumption just as they are. The hybrid blending wines are also very useful for improving the colour of poorly-coloured French wines grown from European vines, or for improving local wines by adding more body to them, on account of their higher content of alcohol and dry-extract. Some of the red wines could even compete, according to the show judges, with some of the better kinds of European wine.

A special section of the Exhibition was devoted to purely blending-wines, and the fact was observed that certain of the hybrid wines, which were unfit for use by themselves, gave quite good results when mixed with other better wines, or even with wines of no great worth in themselves. Some mixtures of good wines far surpassed either of the component wines taken individually. This group of blending wines gave rise to the following observations: to improve red hybrid wines no French white wines of European vintage are needed, because the white hybrid wines, which cost much less, answer the purpose perfectly. For this reason, according to the writer, every vine grower who only grows hybrids ought to cultivate, along with his red kinds, enough white hybrid wines to enable him to improve the quality of his red wines and give them a higher market valne. The mixing of certain red wines with one another produces in many cases also a good article, as was proved by various wines at the show. The greater the number of kinds of wine mixed (and this applies to red wines alone as well as to mixed red and white), the better the result tastes. Hybrid wines with a "foxy" or "grassy" taste (wines that come from hybrids of Lincecumii), should be mixed with hybrid wines which will mask this flavour, while wines having merely a raspberry flavour can, if required, be used alone.

672 – **Influence of Chloroform and of Oil of Mustard on the Alcoholic Fermentation of Grape-Must.** — KLOSS, in *Zeitschrift für Gärungsphysiologie*, Vol. IV, Part 3, pp. 185-193. Berlin, April 1914.

In order to preserve a sample of unfermented must for the purpose of submitting it subsequently to chemical analysis, chloroform or oil of mustard is sometimes added.

As a result of experiments on the action of these substances on ferments and on the fermentation of grape-must, the writer found that by adding 1 cc. of chloroform to 500 cc. of must, sterilized and inoculated with pure cultures of yeasts, the fermentation was arrested, but the multiplication of the yeasts was not entirely checked. Must inoculated with pure cultures of yeast 12 days old only fermented slightly and for a short time. With 6-day-old pure cultures the must did not ferment at all. This yeast thus showed itself less resistant than the older culture. At the end of the experiment the younges yeast cells had for the most part died out, while those of the 12-day-old yeast, though deprived of glycogen, survived for the most part, and, when introduced into ordinary non-sterilized must, fermented it, which was not the case with the former cells.

Oil of mustard has a much more vigorous action, seeing that even 3 drops in 500 cc. of must checked not only the fermentation, but also the reproduction of the yeast. All the yeast cells were dead at the end of the experiment.

A second series of experiments was undertaken with non-sterilized must in various stages (fresh-pressed, slightly fermented and highly fermented). In this case also, oil of mustard was the more effective, 10 drops in a litre of must being enough to arrest the fermentation completely, a result which was not achieved even on adding 2 cc. of chloroform. The addition of chloroform seems to have checked the multiplication of this yeast more in this experiment than in the preceding.

A further esperiment proved that the development of *Penicillium* was arrested by 5 cc. of chloroform or by 14 drops of oil of mustard per litre of must.

673 – **Co-operative Distilleries in the Pays de aux, France.** — BERTHAULT, PIERRE, in *Comptes-Rendus de l'Assemblée Générale de* 1914 *de la Societê des Agriculteurs de France*, pp. 653-656. Paris, May 15, 1914.

In the Pays de Caux, where the soil is remarkable for its fertility and carries wheat and sugar-beets well, the small size of the holdings places a considerable difficulty in the path of establishing industries requiring a large outlay of capital on the part of agricultursts.

It is due to the activity of the Director of Agriculture for the Seine Inférieure that co-operative distilleries have been formed. Of these there are at present four, situated at Raffetot, Anneville-sur-Scie, Fauville and Yvetot, all definitely co-operative in character. The distillery at Raffetot, which has the fewest members, comprises 16 producers and works 310 acres of beets. All these establishments employ exclusively the sugar-beets grown by their members. The latter, on the other hand, undertake to deliver to the distillery under the best possible conditions

all the sugar-beets they grow, and to put every year to beets a minimum area determined for each farm. The capital amounts to £2 660 at Raffetot, £3 560 at Anneville, £3 000 at Yvetot, and £3 200 at Fauville, each divided into £2 or £4 shares. The balance of funds required is advanced by the State, through the district Treasury of Upper Normandy, in the shape of a loan, as laid down by the Act of 29 December 1906.

The seed for the beet crops is distributed to members by the distillery, and deducted from their share of the profits at the annual settlement of accounts. The roots, when pulled, are sent to the factory, weighed and tared under the usual regulations, and the pulp is returned to the owners, in proportion to the weight of roots supplied. This pulp is taken back at half a crown per ton.

The administration of the Society is in the hands of a Board made up of at least 10 of the members, which superintends and controls all the commercial undertakings of the Society. At the end of each season, it divides the proceeds from the sale of the alcohol among the members, in proportion to the quantity and sugar-content of the beets contributed by each of them. Two deductions are first made to cover the repayment of the capital and the State loans.

The plant is, for the most part, on the Wauquier diffusion system, made to deal with from 60 to 70 tons of roots a day, at 6 degrees density, producing a very strong phlegm (92 at the least). The Anneville distillery is the only one fitted with Egrot machinery.

At the end of the first season at Yvetot, each member received an average of £41 10*s* per acre or £1 6*s* 5*d* per ton of beets.

674 – **Potato-drying Works in the German Empire in 1908-09, 1909-10, 1910-11.** — *Vierteljahrshefte zur Statistik des Deutschen Reiches, Ergänzungsheft zu* 1913, III: *Die Ergebnisse der deutschen Prnduktionserhebungen,* p. 76. Berlin, 1913.

In the following statistics the year commences on August 1 and ends on July 31.

During the three years 1908 to 1911 the potato-drying works in activity were respectively 170, 254 and 327. Of these 114, 167 and 216 were attached to farms or other agricultural undertakings ; 40, 65 and 94 were cooperative concerns (among which those having the form of joint stock and limited liability companies and the like are included) ; 7, 9 and 7 were independent undertakings and 9, 13 and 10 were attached to independent industrial concerns.

In the 170, 254 and 327 works, 170, 254 and 331 drying plants were at work. Among these, 140, 208 and 270 were cylinders ; 22, 36 and 54 were drums ; 7,9 and 6 were of the hurdle type and 1 was a press. As source of heat, 143, 209 and 273 used steam and 27, 45 and 58 the products of combustion. Some of the works, namely 82 in 1908-09, 143 in 1909-10 and 181 in 1910-11, worked with day and night shifts of 12 hours each.

The following table gives further details concerning the works and their produce.

	1908-09	1909-10	1910-11

675 – **The Value and Use of Millet Malt.** — HÉRICS-TÓTH, J. VON and OSZTRÓVSZKY, A. VON (Royal Hungarian Distillery Experiment Station, Gödöllö) in *Kisérletügyi Közlemények*, Vol. XVII., No. 1, pp. 35-44 + 2 plates. (Summary in German, p. 45). Budapest, January-February 1914.

Millet malt has the same value as barley malt. In malting the only difference is in the steeping: millet may stay in the vat until it has absorbed its full amount of moisture by alternate steepings and exposures to the air, or it may afterwards take up the moisture still required by being sprinkled. In the first case the grain is steeped for 5 to 7 days ; during the process it increases in weight by 35 to 50 per cent.

The disadvantages of millet are its extraordinarily high content of dirt, grass seeds and grains that do not germinate; also it is frequently covered with smut (*Ustilago destruens*). It is advisable to clean it before washing it. The really floating grains are not easy to recognize.

In order to prevent the formation of mildew, the steeped grain is daily ventilated once or twice. The temperature in the sweating heap should keep below 30° C. (86° F.). The best temperature for malting is from 18° to 23° C. (64° to 73°. F.). Lower temperatures lengthen the operation without other inconvenience. The sprouting grain is heaped at first to a depth of 8 to 12 inches and gradually reduced to 4 in. It is advantageous to wash the malt when ready.

In comparison with other grains, the production of the necessary enzymes takes place with loss of matter. The saccharification and liquefying capacity, according to Effront and Lintner, are smaller than in barley and rye malt, but greater than in maize or oat malt. In brewing, millet malt has some very valuable properties: it prevents frothy fermentation; the ratio between the maltose and dextrin formed, the final fermentation and the production of alcohol are good. Probably in the various grains the structure of the saccharification enzymes is the same, and the cause of the lower Effront and Lentner values does not lie so much in the greater or lesser capacity of producing enzymes as in the want of an agent (co-enzim, enzim, etc.) to increase the diastatic power of the various kinds of malt over pure and soluble starch. This agent is, however, contained in sufficient quantity in the various raw materials used in the mashes. With the analytical method, according to which less malt is taken than is required for the saccharification of the mash, the differences in the malts become apparent. The curve of the formation of diastase in millet resembles that of maize ; after attaining the highest value of diastatic power it sinks rapidly.

INDUSTRIES DEPENDING ON ANIMAL PRODUCTS

676 - **The Influence of the Fat Content of Milk upon the Rapidity of Coagulation.** — KREIDL, ALOIS and LENK, EMIL in *Biochemische Zeitschrift*, Vol. 63, Parts 2 and 3, pp. 151-155. Berlin, May 28, 1914.

In estimating the coagulating power of rennet, it is generally accepted as a law that the quantity of ferment used multiplied by the time required to obtain coagulation is a constant. This law is, however, modified by numerous factors, such as temperature, neutral salts, lime-precipitating bodies, alkaloids and more especially by the previous treatment of the

milk. The writers have shown that the rapidity of coagulation of a sterilized milk could be so diminished that often after 24 hours no coagulation had yet taken place. When, however, a non-sterile rennet or an incompletely sterilized milk was used, coagulation immediately set in. The writers observed also that when previously treated milks containing different amounts of fat received the same quantities of rennet, coagulation did not set in at the same time.

These experiments were recently repeated by the writers with five different milks containing respectively 1, 3, 10, 16 and 30 per cent. of fat. The milks were placed in test tubes kept at 40° C. (104° F.) in a water-bath. A fresh 1 per cent. neutral filtered solution of Grübler's rennet was used. Every five minutes the test tubes were taken out and examined for changes in the milk; all five were examined at the same time.

In the first experiment, in which 1 cc. of rennet solution was added to 10 cc. of each of the undiluted milks, no difference in the rapidity of coagulation was observed. In the next experiment, in which each of the milks was diluted with 50 per cent. of water, it was found that the lower the fat content of the milk, the more rapid and complete was the process of coagulation.

677 – **Purification and Disposal of Waste Water from Dairies**. — DORNIC, DAIER and VIGNEROT, in *Annales de la Science Agronomique*, Year 31, No. 4, pp. 150-170. Paris, April 1914.

The waste water from dairies cannot be allowed to flow into streams, rivers or the subsoil without first being purified. In France, the Act of 1902 imposes on local authorities the obligation to make bye-laws dealing with the question in their districts. Another Act, at present in course of preparation, is to deal with drainage into non-navigable rivers.

The process of purification employed varies naturally with the composition of the waste water, which in its turn depends on the type of work carried on in the dairy. From this point of view dairies may be divided, into four classes:

1. Dairies which receive milk from farms and forward it on to towns, with or without pasteurizing. These dairies produce a volume of waste water equal to half the milk dealt with, and proceeding chiefly from the washing of cans, machinery and receiving platforms.

2. Dairies where the milk is used for making cream, butter and cheese, but where the whey is returned to the farmers, after the casein has been extracted. Such dairies use a volume of water about equal to the amount of milk dealt with.

3. Dairies where pig-fattening is practised. These have to dispose of a volume of water about 2 to 2½ times that of their milk.

4. Dairies which extract the casein from the whey and discard the casein with the waste water. In these the outflow of water is double the volume of milk dealt with. This class is tending to disappear, as being economically unsound, seeing that pig-rearing pays 2*d* to 2½*d* per 10 galls. for whey with the casein removed, which is wasted in dairies

of this class. Besides, the waste water from them can only be purified by a biological process, which is exceedingly long and troublesome.

The composition of the waste water from a given dairy varies with the circumstances and the individual dairies. The range of possible variations is given in Table I.

TABLE I. — *Composition of waste water in mgm. per litre.*

	Water in which milk-cans have been washed (Kattein and Schoofs)	Bömmer	Calmette	Daire (water from butter factories)
Capacity for oxidation in mgm. of potassium permanganate per litre	754.7	126 to 4076.4	—	550 to 3050
Organic nitrogen	24.5	7 to 118	43.6 to 115	15 to 130
Organic substances	300.7	253 to 2733	1550 to 2135	215 to 1763
Fatty substances	from 159 to 290	—	628 to 1440	80 to 739
Milk-sugar	—	traces to 731	—	traces to 0.509

The waste water decomposes quickly, especially in summer, and gives off a foul smell due to the putrefaction of the casein and the albuminous matter. The milk-sugar is not present in a large enough quantity to be harmful, and besides, the acid fermentation which it undergoes would rather tend to delay proteolytic fermentation. Fatty matter decomposes very slowly. The chief object to aim at, therefore, is the reduction of the casein, and as this substance decomposes fairly rapidly, prompt action is required.

There are there different kinds of processes of purification: chemical processes, biological processes, and the filter-bed method. The last is the most suitable in the majority of cases. A chemical process recently invented by Daire seems to have a great future before it, and is described below in detail.

Chemical processes. — Considerable reduction of the nitrogenous matter in the waste water from cheese factories has been obtained with the use of the following substances (Table II):

TABLE II. — *Reduction by chemical means of the nitrogenous matter in the waste water from dairies.*

Reagents	Percentage of nitrogenous matter removed
Aluminium sulphate + lime	69.6
	67.5
Perchloride of iron + lime	25.8
Ferrous sulphate + lime	67.5
Ferric sulphate + aluminium sulphate + lime	75.3

Reduction in bacterial content was also obtained by adding 2.3 gm. of ferric sulphate per litre to water containing organic matter, but this process, in addition to being more expensive than the foregoing, gives a residuum which cannot be turned to account.

Hamilton's method, though extremely ingenious, unfortunately scarcely admits of application to commercial use. It is carried out by means of two masonry reservoirs. In the first of these the water is heated for 24 hours by means of a coil; a part of the albuminoids is precipitated by lactic, butyric and acetic fermentations. In the second, thick lime wash and sodium silicate is added; calcium silicate is formed, and carries off the albuminous matter in solution. The precipitate may be used as a manure, and the clean water can be drained into a river.

Daire's new chemical process, in use at the co-operative dairy at Courçon d'Aunis (Charente Inférieure) requires the following plant: *a*) a cylindrical decanting-basin, of about 350 cu. ft. content, in which decantation is effected by a system of outlet pipes flush with the level of the deposits inside the basin; *b*) a filter basin made of reinforced concrete, 6 ft. across and 31 in. deep, containing a bed of coarse slag, covered over with a layer of turf; and *c*) various accessories (a cement gutter, a pump and chute for waste water, a stirrer, etc.); the whole costing about £80.

The process is as follows: First, calcium superphosphate (6 ½ lbs. per 100 cu. ft. of water to be treated), is spread over the bottom of the basin; then the waste water is forced into the basin as fast as it is produced. When it is all in, milk of lime (which must not contain carbonate) is thrown into the basin, in just sufficient quantity to neutralize the phosphoric acid. In practice, it can be seen when this quantity has been reached by the liquid in the basin turning pink. An excess must not be given or albuninous matter will be dissolved. During the operation, stirring takes place by means of a stirrer consisting of a perforated iron disc on a long handle. When the mixing is complete, it is allowed to remain for 3 hours at least, after which the clear liquid is decanted and the deposit sent to the filter basin. It is convenient to arrange for the filtration to take place at night. The operation must be performed once in 24 hours.

This process, which has given complete satisfaction for a year at Courçon d'Aunis, is cheap, requires only a small amount of labour and makes use of easily obtained and inexpensive materials (superphosphate, lime and turf). The turf manure taken from the filter basin undergoes very active nitrification owing to the presence of the lime, and exhibits the composition shewn in Table III.

TABLE III.

Composition of turf manure from filter basins (average of 14 analyses).

Water	80.2 %
Organic nitrogen	0.38 »
Inorganic »	0.27 »
Mineral substances	5.85 »
Phosphoric acid (P_2O_5)	0.77 »

It will be noticed that this manure contains as much nitrogen and phosphoric acid as farmyard manure. Its value is therefore considerable, and in fact easily repays the cost of setting up the plant.

Biological processes. — Anaerobic fermentation in septic pits is suitable for dairies of the first three classes. For water rich in serum, the plant is complicated and costly, in addition to which the standard of intelligence obtaining among persons engaged in the dairy trade makes the method somewhat inapplicable. Oxidation in bacteria beds may be continuous or intermittent, the former being the more perfect. Water rich in serum requires previous neutralization and a more complex plant. Purification by irrigating growing crops is the most economical method and is the right one to employ wherever there is a large enough area and a sufficiently porous soil. Stagnation must be avoided, and too much water must not be allowed to soak into highly porous soil, for fear of polluting the underground water supply. Suitable crops for receiving such irrigation are forage crops, osier beds and vegetables.

678 – **The Activity of Cooperative Dairies in Hungary in 1911-12.** — Extract of Report in the Statistical Yearbook on the activity of the Hungarian Government in 1912, in *Volkswirtschaftliche Mitteilungen aus Ungarn*, Year IX, No. 2, pp. 194-196. Budapest, February 1914.

At the end of 1912, 528 cooperative dairies were working, or 26 less than at the end of 1911. Of these

335	or 63	per cent.	were	founded	in 1896-1905
121	» 23	»	»	»	in 1906-1910
40	» 8	»	»	»	1911
20	» 4	»	»	»	1912
12	» 2	»	»	»	before 1896

Comparative data for the years 1911 and 1912 are given in the adjoining table.

		1911	1912
No. of members		57 436	55 777
No. of cows registered		97 658	91 515
Total amount of milk received	million galls.	21.5	22.8
Av. annual yield per cow	galls.	220	250
Produce sold :			
Whole milk	million galls.	6.92	9.25
Cream	galls.	255 000	300 000
Butter	metric tons (1)	2 100	2 400
Cheese	» »	1 869	2 103
Other produce	» »	10 200	1 700

During 1912, 57 of the dairies received Government grants amounting to £3086, fourteen received grants from local authorities and four received grants from other sources.

(1) 1 metric ton = 0·9842 long ton.

679 – **A Review of Beef Production in the United States.** — MUMFORD, H. W. and HALL, L. D. — *University of Illinois Agricultural Experiment Station, Circular*, No. 169, pp. 1-28. Urbana, Ill., September 1913.

Cattle fattening was first practised in the United States at the beginning of last century. Starting in the State of Ohio it gradually extended westward over Kentucky, Indiana and Illinois, while at the same time the grazing industry spread northward from Texas over the great western plains. Then in the second half of the century, after the Civil War, an increased demand for beef in the East together with improved facilities for cattle transport stimulated the production, and the industry gradually extended westward with the building of the raliways and the introduction of the refrigerator car.

The cattle census per decade is given in Table I, together with the ratio of the cattle to the population.

TABLE I. — *Number of cattle per decade and ratio of cattle to population.*

Year	Total cattle	Cattle other than milch cows	Increase in total cattle, per cent.	Total cattle, per capita	Cattle other than milch cows, per capita
1870.	25 000 000	15 000 000	—	0.64	0.39
1880.	33 000 000	21 000 000	+ 32	0.66	0.42
1890.	53 000 000	37 000 000	+ 60	0.84	0.59
1900.	68 000 000	45 000 000	+ 28	0.89	0.66
1910.	62 000 000	41 000 000	— 10	0.67	0.45
1912.	58 000 000	37 000 000	— 7	—	—

The number of cattle increased up to 1900 and then decreased, but the decrease shown in 1910 is in reality less than would appear from the figures, as the census in that year was taken on April 15 instead of on June 1, which had been the customary date previously, and it is estimated that 5 to 6 million calves are born between those two dates. Even making allowance for this, the decrease is significant, especially when considered in relation to the increasing population. A natural consequence of the decline has been a diminution of the surplus available for export, as shown in Table II.

The numbers and percentages of the various classes of cattle in April 1910 are given in Table III together with the average value of the animals of the different classes.

Almost two-thirds of the cows of breeding age are designated as dairy cows, the remainder being kept mainly for raising beef calves, and the dairy cows are worth almost $12 a head more than the beef cows. The ratio of bulls and steers to cows and heifers is 1 : 1.46.

TABLE II. — *Surplus of cattle available for export.*

Year	Value of all cattle other than milch cows	Value of exports of beef cattle and beef	
		Absolute	Relative
	$	$	per cent
1870	290 491 000	2 693 000	0.9
1880	341 761 000	31 544 000	9.2
1890	560 620 000	53 170 000	10.0

Cows and heifers not kept for milk, born before 1909. . . .	12 023 682	19.5	22.39
Cows and heifers kept for milk, born before 1909	20 625 432	33.4	34.24
Unclassified	1 003 786	1.6	20.95
Total . . .	61 803 866	100	

The geographical distribution of the cattle other than milch cows i April, 1910 was as follows:

North Atlantic States		2 130 000
South » »		3 029 000
North Central »	west of the Mississipi . . .	12 320 000
» » »	east » » . . .	4 990 000
Southern and Gulf »		10 786 000
Far Western »		7 925 000
	Total . . .	41 180 000

The North Central States and the region including Oklahoma and Texas contain the largest number of cattle, the so-called "corn belt" States -- Ohio, Indiana, Illinois, Iowa, Missouri, Nebraska and Kansas -- accounting for almost one-third of the total number. Moreover, as large numbers of cattle are yearly brought into the "corn belt" to fatten, it is estimated that half the total beef produced in the United States comes from that district. As two-thirds of the cattle are west of the Mississipi, while two-thirds of the population are east of the Mississipi, there is an enormous movement of fat cattle from west to east to supply the demand for beef in the more densely populated districts, and this movement has brought about the establishment of the great cattle markets at Chicago, St. Louis, Kansas City, etc. These large central markets slaughter about half the total cattle in the United States. In 1903 the distribution of slaughtered cattle was estimated as follows:

	Head
At large central markets	6 570 000
In other cities of over 50 000 inhabitants . . .	930 000
In cities and villages of under 50 000 inhabitants	3 500 000
On farms and ranges	1 500 000
Total . . .	12 500 000

Further, in that same year, 520 000 head were exported alive, bringing the total number marketed for slaughter up to 13 020 000 head, of which 5 500 000 head or 45 per cent. were killed by six companies known as the "big packers".

AGRICULTURAL PRODUCTS: PRESERVING, PACKING, TRANSPORT. TRADE.

680 - **Arrangements for the Carriage of Agricultural Produce by Rail in France, especially on the Paris-Lyon-Méditerranée Co.'s System.** — BOUSIGUES in *Bulletin mensuel de l'Office des Renseignements agricoles*, Year 13, Nos. 2 and 3, pp. 194-212 and 300-329. Paris, February and March 1914.

The writer deals with the chief arrangements made by all the French railways for improving the carriage of agricultural produce. He describes the ice stores and the perfection of the rolling-stock on the State railway, the lowering of tariffs for milk by the Est Co., the fitting of vans for mushrooms, beer, bananas, beets and pulp on the Nord, and the various arrangements made by the Paris-Lyon-Méditerranée to encourage the trade in fruit, early vegetables and flowers. The last-named will be dealt with here.

From the agricultural point of view, the P. L. M. system is particularly rich; the natural resources of the districts it serves ensure a heavy traffic at all seasons: cereals in Brie, Beauce, Limagne and Lower Burgundy; wines in Burgundy, Franche-Comté, Auvergne, Languedoc and Provence; store cattle in the Charolais and the Nivernais; early vegetables and olives in Provence; oranges and flowers on the Riviera; fruit and vegetables in parts of the valleys of the Saône, Rhône and Durance. The Company also deals with the produce from Algeria, Tunis and Morocco.

Table I shows the progressive increase in the food-products carried by slow goods trains.

TABLE I.

Carriage by slow goods trains on the P. L. M. (metric tons).

Goods	1912	1911	1910	Difference 1912-1910
Wine	2 629 000	2 366 000	2 655 000	— 26 000
Flour	1 023 000	1 085 000	964 000	+ 59 000
Cereals	2 335 000	1 727 000	1 525 000	+ 810 000
Fruit, vegetables, milk, etc.	950 000	955 000	921 000	+ 29 000
Hay, straw	677 000	568 000	543 000	+ 134 000

The P. L. M. Co. has made special efforts to increase the traffic in fruit, early vegetables and flowers by express train ; for this purpose trains have been speeded up and the best possible conditions arranged. Table II shows the amounts of these goods carried by express service.

Besides the ordinary post-trains, the Co. runs eight or ten special trains for perishable goods daily ; their average speed is 40 m. p. h., so that the run from Marseilles to Paris (536 miles) is done in 22 to 24 hours and that from Avignon to Paris (458 miles) in 18 to 20 hours ; these times include unavoidable stoppages as well as the collecting at the various departure stations.

In 1911 this organization was completed by special arrangements at Chasse, a Station 13 miles south of Lyons on the left bank of the Rhône.

Arrangements at Chasse station. — The station is on the Paris-Ventimiglia line, and is the junction for three branches: Lyons-Nîmes by the right bank of the Rhône ; Roanne-Lyons, via St. Etienne; Paray-le-Monial-Givors. Goods can be sent to Paris and England by three routes: St. Etienne-Lozanne or Dijon ; to the Est Ry. via Dijon Is-sur-Tille ; to Germany via Bourg-Besançon - Belfort ; to Switzerland via Ambérieu-Geneva.

The vans passing through Chasse number 60 000 yearly ; the packages are rearranged so as to make up whole trains requiring no shunting other than the dividing up at junctions ; in this way 6000 vans are liberated. The Chasse station is informed by telegraph of the composition of the trains arriving, and has a practised staff who put right irregularities in packing and examine the labelling. The compensation for loss, delay and damage paid on the Paris markets, has been reduced to 156 000 fr., or 1.51 fr. (about 1*s* 3*d*) per ton.

The P. L. M. Co. has also arranged with the Nord and Est Cos. and the German State railways for through fast services ; these allow perishable goods to arrive in excellent condition on the markets in London, Berlin, Cologne, Frankfort-on-Main, etc. The times are as follows :

Avignon to London	37 hours
Avignon to Frankfort-on-Main	39 »
Avignon to Berlin (Anhalt sta.)	57 »

TABLE II.

Fruit and vegetables carried by express train on the P. L. M. *(metric tons)* (1).

	1912	1911	1910	Difference 1912-1910 %

(1) 1 metric ton = 0.9842 long ton.

The Company has 2847 fast vans (type H. P.) ; these are well ventil ated; the walls and roof are double, with an air-jacket, so that deli cate goods keep well.

The Company has sent commercial agents to study packing and outlet for produce on the spot. It has got into direct communication with foreign purchasers and the French producers. It has published notices on ex porting and distributed them free. At the Marseilles and other exhibi tions it arranged packing competitions ; it also defrays the expenses of exhi bits of the " United P. L. M. Producers ": these took 82 prizes a Turin in 1911. In Paris, in 1913, it arranged an exhibit covering 700 sq yds. and containing 5 000 dozen flowers from the Riviera. Educationa journeys to London, Scotland, Belgium and Holland have been arranged for producers.

On the Paris market the Company keeps an inspector to settle small dif ferences on the spot ; he also considers proposals for improving the service

In 1909 it distributed in the Carpentras district thousands of plants of a strawberry much in favour in Germany ; in 1911 and 1912 Mirabelle plum trees and greengage trees were distributed, as well as plum grafts. Grafts of very late table grapes were also distributed, and in 1912 and 1913 tomato seeds from Naples. It has experts to advise as to planting, and arranges lectures, field demonstrations and agricultural journeys in France and abroad. Further a series entitled " Publications of the P. L. M. Co. " has been printed.

Lastly, freights have been lowered on its own system, as well as for through carriage to other systems and foreign railways. In this connec tion a prize of 100 fr. (£ 4) has been aranged for prunes leaving France by the Nord and Ouest Cos.

Flower trade. — The principal lines for flowers from the Riviera are:

Paris.
England via Boulogne.
Germany via Petite Croix.
Belgium, Holland and Germany via Jeumont-Herbestal.

Almost all the Riviera flowers are sent in postal packages of 5 kg. (11 lbs.); they are packed in flat reed baskets, which are stacked in ordinary vans.

Table III shows the extent of the traffic in the last ten years.

TABLE III. — *Flowers carried by the P. L. M. (metric tons).*

Winters	Paris	England	Germany via Petit-Croix and via Paris	Geneva and Switzerland	Beyond Paris, various	Total

1911–1912	3 686	2 110	3 156	198	1 217	10 367
1912–1913 (1)	3 836	2 547	3 620	232	1 348	11 583

(1) From October 1912 to end of March 1913.

A collecting train arriving at Marseilles at 6.30 p.m. brings in the vans from the various stations, the most distant having started at 11 a. m. They are forwarded to Paris by two regular fast trains, one of which runs in two parts from November 15 to May I.

Flowers leaving Nice at 1 p. m. arrive:

Paris, next day at 10.30 a.m. (= 21 ½ hrs.) in the early season, or 8 a.m. (= 19 hrs.) in the height of the season.
Boulogne, next day at 6.30 p.m. (= 29 ½ hrs).
London, second day at 4 a.m. (= 39 hrs.).
Brussels, second day at 5 a.m. (= 40 hrs.).
Frankfort-on-Main, next day at 11 p.m. (= 33 hrs.).
Cologne, second day at 7 a.m. (= 41 hrs.).
Berlin, second day at 8 a.m. (= 42 hrs.).

Although the route from the Riviera to Berlin through France is 180 miles longer than the one through Italy (Chiasso-Bale), the time is the same and the French route costs less.

PLANT DISEASES.

GENERAL INFORMATION.

LEGISLATIVE AND ADMINISTRATIVE MEASURES

681 – **Decree of the President of the French Republic, April 18, 1914, relating to the Importation into Algeria of Plants other than Vines and Resin-yielding Trees** (1). — *Journal officiel de la République Française*, Year 46, No. 113, p. 3798. Paris, April 26, 1914.

Art. 1. — Woody plants (other than vines and resin-yielding trees), palms (rooted or not), and the fresh parts of these plants, coming from foreign countries and from the French departments of Alpes-Maritimes, Var, Bouches-du-Rhône, Gard, Hérault, Aude, Pyrénées Orientales and Corsica, may only be taken into Algeria through the ports to be designated by the Governor General of Algeria, or at the points on the Algero-Tunisian frontier to be determined by agreement between the Beylical Government and the Governor-General of Algeria.

On arrival at the ports or the points on the land-frontier, these products will be disinfected in buildings prepared for the purpose and under the direction of technical experts chosen by the Governor-General. Such disinfection will be carried out by means of a mixture containing gaseous hydrocyanic acid, the strength of which will be determined by the said technical agents.

The operation will be carried out at the expense of the interested parties. Exceptionally, when the consignments are accompanied by a phytopathological certificate granted by the Service of Phytopathological Inspection and are sent from establishments under State control, they will be exempted from disinfection, provided their freedom from all parasites is ascertained by the technical agents mentioned.

In case they are not passed, the importer may decide whether they are to be disinfected under the conditions laid down above or returned to their place of origin.

Art. 2. — Citrus fruits imported into Algeria will be disinfected under the conditions laid down in art. 1 for woody plants.

(1) See also No. 2026, *B.* June 1911 and No. 1347, *B.* Sept. 1912. (*Ed.*).

Art. 3. — Infringements of the regulations of the present decree and of the orders made for carrying it out will be punished by a fine of 50 to 500 fr. (£2 to £20).

Art. 4. — Persons convicted of having introduced any of the objects mentioned in arts. 1 and 2 without declaration or by means of a false declaration or by any other fraudulent device, will be punished by imprisonment for from 1 month to 15 months and by a fine of from 50 to 500 fr.

Art. 5. — The punishments laid down in the two preceding articles will be doubled for a second offence. A second offence is established when a first judgment under this decree has been given against the offender in the previous twelve months.

Art. 6. — Article 463 of the Penal Code is applicable to convictions under the present decree.

Art. 7. — Woody and herbaceous plants coming from France will be admitted into Algeria, with the earth surrounding them, provided they have been raised in pots at establishments listed by the Ministry of Agriculture under article 9, § 6, of the International Convention of Berne. For plants coming from foreign countries, this condition will be replaced by the obligation, on the part of the interested parties, to obtain a permit, supplied by the Governor-General of Algeria previous to the despatching of the goods, and after seeing a special declaration signed by the French consular authority of the place of origin.

All the regulations of the decree of March 10, 1894, not contrary to the present decree, are maintained.

Art. 8. — The decrees of January 25 and November 22, 1909, are abrogated.

Art. 9. — The Minister for the Interior, the Minister of Finance and the Minister of Agriculture are entrusted, within their respective spheres, with the carrying out of the present decree, which will be published in the *Journal Officiel* of the French Republic and inserted in the *Bulletin Officiel* of the Government of Algeria.

61 — **Act allotting 500 000 Francs to the Minister of Agriculture of France for the Control of Voles** (1). — *Journal Officiel de la République Française*, Year 46, No. 116, p. 3854. Paris, April 29, 1914.

The President of the French Republic has promulgated an Act, dated April 23, 1914, of which the following is the purport :

Sole clause. — A sum amounting to 500 000 francs is granted, from the 1914 budget, in addition to the provisional grants allocated by the Acts of December 29, 1913 and February 26, 1914. The sum will be inserted in a special article of the Ministry of Agriculture, bearing the No. 27 *bis*, and entitled " Grants to Communes, Syndicates and Agricultural Associations for the Destruction of Voles. Expenses of Organization of Control Measures ". The present Act, discussed and passed by the Senate and by the Chamber of Deputies, will be in force as the law of the Land.

(1) See also No. 385, *B.* April 1914. (*Ed.*).

DISEASES NOT DUE TO PARASITES AND OF UNKNOWN ORIGIN.

683 – **Leaf-Curl in Potatoes and its Connection with Necrosis of the Phloem.** — SCHANDER, R. and TIESENHAUSEN, M. in *Mitteilungen des Kaiser Wilhelms Instituts für Landwirtschaft in Bromberg*, Vol. IV, Part 2, pp. 115-124. Berlin, 1914.

The writers wished to control the investigations of Quanjer (1913), which led him to believe that leaf-curl of potatoes (Blattrollkrankheit) was due to necrosis of the phloem. Among the material examined was some of the same as was used by Quanjer.

It was ascertained that : 1) Necrosis may appear in plants not affected by leaf-curl (either in quite sound plants or in plants attacked by " Kräuselkrankheit ", etc.), and sometimes in a much worse form than in those affected by leaf-curl.

2) Such necrosis usually begins towards the apex of the stem, no doubt owing to the fact that the young tissues are more sensitive to assimilatory disturbances than the old ones. Further, it is more prevalent towards autumn in nearly all plants.

3) The phloem of the potato seems to be specially susceptible to this alteration, while in the tomato, which often suffers from strong leaf-curl, no important necrosis of the phloem has been observed. Thus, the phloem of the potato seems so susceptible that it may become necrosed without the plant appearing abnormal or losing its vigour.

4) General necrosis seems to be infrequent : the disease is generally limited to a portion of the phloem, so that complete interruption of the descending sap is very rare.

5) Lignification of the necrosed phloem has never been observed.

The writers believe this condition to be a secondary one, appearing in consequence of functional disturbances taking place in the leaves.

684 – **Observations on Bramble-leaf of Vines in Hungary** (1). — BERNATSKY, J. in *Zeitschrift für Pflanzenkrankheiten*, Vol. XXIV, Part 3, pp. 129-139, figs. 1–2. Stuttgart, 1914.

From observations in the vine districts of Hungary, the writer has ascertained the following facts with regard to the bramble-leaf disease (Krautern des Weinstockes).

1. It attacks old American stocks only on low ground, particularly depressions and valley-bottoms, on damp, rich and heavy soil. A rise of a few feet may quite prevent the appearance of the disease in such cases.

2. Young vines, one or two years old, may be attacked in situations favourable as regards height and soil.

(1) For previous work on this disease see the following Nos.: 1911—501 (Feb.), 1883 (June); 1912— 572 (March), 968 and 969 (June), 1097 (July), 1349 and 1350 (Sept.), 1570 (Nov.); 1913—67 (Jan.), 1207 (Oct.), 1302 and 1303 (Nov.), 1394 (Dec.); 1914—289 (March), 480 (May), 576 (June). (*Ed.*).

3. In many rather old vines examined (hybrids of Ripestris, Ruparia and Berlandieri) it was found that the swollen part at the top was dead; the dead tissue generally extended from the pith to the origin of the shoots. Further, there are streaks of brown wood reaching a good way down the stem, as often happens after frost damage.

4. The wood and bark of diseased vines, whether living or dead, is very incompletely differentiated, or in other words does not ripen off well.

5. It is interesting to note that diseased plants often come from grafts of poorly ripened wood; this is often the case in quite young vines in favourable situations, but yet diseased. For this reason, the writer considers the practice of using the ends or side shoots of the canes for grafts as unsound, for these parts are nearly always badly ripened.

6. The roots of vines affected by bramble-leaf were diseased, and sometimes even rotten. The writer considers this not as a result, but as the cause of the disease, and due to certain soil conditions.

7. In grafted vines (Vinifera on American stocks) the cause of the diseased condition is often to be found in an imperfect binding; this is particularly liable to occur with woody grafts on unrooted stocks. In good warm soils, with other conditions favourable, a complete closing of the tissues takes place later, but if the weather is unfavourable or the soil unsuitable (cool and damp), the wound tends to open wider instead of closing. Eventually it forms a cankerous growth, and the wood at the point of union is soft and hypertrophied, and finally dies. This disturbance of the relations between graft and stock shows itself later in the production of the bramble-leaf condition.

8. Even when the binding is perfect, the disease may appear. It is suggested that this may be due to damaging of the graft (*e. g.* by frost).

9. In grafted vines affected by the disease, the stock often throws out suckers, which also become diseased.

10. In making herbaceous grafts, the suckers are often not removed till the vine is planted out; they then leave open wounds, which may, under unfavourable conditions, spread and become cankerous, thus encouraging disease in the plant.

11. Parasites have sometimes been found to cause the disease, but only when present on the roots; of these cockchafer grubs (*Melolontha vulgaris*) are the most important, though *Phylloxera* may sometimes provoke it.

It thus appears that the cause of bramble-leaf is to be sought in conditions which act only indirectly on the canes, the trouble being deep-seated or the result of causes which have disturbed the whole plant.

BACTERIAL AND FUNGOID DISEASES.

GENERALITIES

685 – **On the Presence of Sori and Mycelium of Rusts in the Caryopses of Cereals.** — ERIKSSON, JACOB in *Comptes rendus hebdomadaires des Séances de l'Académie des Sciences*, 1914, 1st Half-year, Vol. 158, No. 17 (April 27, 1914), pp. 1194-1196. Paris, 1914.

Referring to Beauverie's observations (1) on the presence of the sori and mycelium of rusts in the caryopses of cereals and other Gramineæ, the writer remarks that he had already described and figured this in 1896; in 1901 he expressed the opinion that the presence of the sori and mycelium is to be considered as an abnormal and excessive growth, without practical importance in the life of the fungus. After the publication by F. J. Pritchard of similar observations in the United States, Eriksson made known in 1912 his own results on the wintering of cereal rusts. Results obtained since have confirmed the opinion that the presence of mycelium and clusters of spores on the surface of the caryopses is without importance.

RESISTANT PLANTS

686 – **Resistance of Hybrid Direct-Bearer Vines to Mildew.** — PÉE-LABY, E. in *La Vie agricole et rurale*, Year 3, No. 22, pp. 603-605. Paris, 1914.

One of the most important properties of hybrid direct-bearers is their resistance to mildew (*Plasmopara viticola*). The following among the older hybrids have been thoroughly tested in this respect in various parts of France: Seibel Nos. 1, 2, 63, 110, 138, 1000, 1007, 1014, 1015, 1070, 1077, 2003, 2007 and 2041; Couderc Nos. 503, 4401, 7103, 7120, 28-112 and 106-48. All these can do without copper-sulphate spraying in moderate mildew years. The following should under ordinary circumstances be sprayed twice: Seibel Nos. 47, 60, 128, 1020, 1200, 2042 and 2044.

Various newer hybrids appear to require only two sprayings, but have not yet been sufficiently tested; many of these yield better wines than the older ones, so that it is to be hoped that their mildew resistance will be confirmed. The following white hybrids may be recommended: Girerd No. 157; Seibel Nos. 880 (which might do without spraying), 793, 850, 2791, 3010, 3021 and 4681; several Malègue types, several Couderc and two Bertylle-Seyve.

Two new rose-coloured direct-bearers (Seibel Nos. 2859 and 2677) also appear to be sufficiently protected by two sprayings.

BACTERIAL AND FUNGOID DISEASES OF VARIOUS CROPS

687 – **Wilt Disease of Sweet Potato.** — HARTER, L. L. and FIELD, ETHEL C. in *Zeitschrift für Pflanzenkrankheiten*, Vol. XXIV, Part 4, pp. 204-207. Stuttgart, 1914.

The wilt disease of sweet potatoes is characterized by the wilting of the whole plant or parts of it; the diseased portions become discoloured and die; no wrinkling of the leaves takes place in such cases. The agent or agents of the disease occur in the vascular bundles of roots, stem and leaves.

(1) See No. 879, *B.* July 1913 and No. 73, *B* Jan. 1914. (*Ed.*).

Nectria Ipomoeae Hals. has generally been considered the cause of the disease, but a series of inoculations (1500) with various species of *Fusarium* isolated from the xylem of roots and stems and from tubers wholly or partly decayed, have shown that *F. hyperoxysporum* Wr. (isolated from the xylem of the stem) and *F. Batatatis* Wr. (from the vascular bundles of the root) are both parasites capable of producing the symptoms of wilt disease.

Inoculations of *Ipomoea Batatas* Poir. with *F. hyperoxysporum* produced 78 per cent. of infections, while with *F. Batatatis* 45 per cent. became diseased. The cultures of the latter were obtained from various parts of the United States (Maryland, New Jersey, Virginia and Delaware).

Inoculations with both species of *Fusarium* were tried on other plants : *Solanum tuberosum* L., *S. Melongena*, *Lycopersicum esculentum* Mill., *Ipomoea purpurea* Roth., *I. hederacea* Jacq., *I. coccinea* L., and *I. lacunosa* L. Only with *I. hederacea*, which grows wild in sweet-potato fields, were positive results obtained ; both species gave infection. It is probable that the disease is spread by means of this weed.

Inoculations with *Nectria Ipomœae* were entirely without result, so that this fungus appears not to be the cause of the disease. It appears that various species of *Fusarium*, in particular *F. oxysporum* Schlecht., *F. culmorum* W. Smith, *F. orthoceras* App. et Wr. and *F. caudatum* Wr., bring about the rotting of stored sweet potatoes.

688 – **Black Spots on Tomatoes caused by *Cladosporium herbarum*.** — PEROTTI, R. and CRISTOFOLETTI, U. in *Le Stazioni sperimentali agrarie italiane*, Vol. XLVII, Part 3, pp. 169-216, figs. 1-9, plates IX-XI. Modena, 1914.

Tomatoes of a variety with fruits in clusters have frequently been observed late in the season with olive-black spots on them ; these are nearly circular, and gradually increase in size : they are due to *Cladosporium herbarum*.

On naturally-occurring spots a bacterium has always been found with the *Cladosporium:* this is described as new under the name of *Pseudomonas polychromigena*. An undescribed form of *Oospora* (*Oidium*) *lactis*, var. *Solani*, is also frequently present.

The writers have investigated the morphology, physiology and pathogenic character of the *Cladosporium* and the *Pseudomonas*, as well as the relation of the *Oospora* and the *Pseudomonas* to the *Cladosporium* in the attack on the fruits.

The *Pseudomonas* is in no way parasitic, its development being permitted by the reduction of the acidity of the sap due to the attack of *Cladosporium*.

The *Oospora* is a true parasite of the tomato fruit, but takes no direct part in the formation of the spots. The *Pseudomonas* and the *Oospora* both tend to hinder the development of the *Cladosporium*, restricting and reducing the rapidity of its attack on the fruit.

The *Cladosporium* seems to infect the fruit through small breaks in the skin.

The proportion of fruits attacked in the variety in question is between 5 and 10 per cent. At present the disease does not seem serious, but

should it become so, the best course to pursue would be to grow varieties resisting it.

689 – **The Anatomical and Physiological Conditions of Chestnut Branches attacked by the Ink Disease.** — PETRI, L. in *Rendiconti della Reale Accademia dei Lincei, Classe di Scienze fisiche, matematiche e naturali*, Vol. XXIII, Series 5, 1st Half-year, No. 5, pp. 363-369. Rome, 1914.

The writer has already expressed the opinion that *Coryneum modonium* Griff. et Maubl. (which he considers identical with *C. perniciosum* Briosi et Farneti) should be regarded as one of the agents in the rapid withering of the branches of chestnuts attacked by ink disease (a black rot of the roots and the stool), and not as a cause of the disease.

In 1913 investigations were made on the physiological condition of the twigs in trees attacked by the disease.

Branches three to nine years old were collected from diseased and healthy trees in the chestnut-woods of Soriano nel Cimino (Latium) at the end of November 1913, when the trees had just lost their leaves. Various differences were found, chiefly by micro- and macrochemical means, between the branches from healthy and from diseased trees. The decreased content of certain minerals, such as lime, sulphur and potash, and the increased content of magnesia, are evidences of a diseased condition, due no doubt to disturbances in the functioning of the root-system. It is in the mineral food that the earliest and most serious irregularity takes place. The destruction of chlorophyll and the disorganization of the chloroplasts in the cortical parenchyma should be considered as the natural consequences of assimilatory disturbances and reduced vitality of the protoplasm, closely connected with the high acidity, absence or reduction of calcium oxalate, and increase of gallic acid.

These conditions no doubt allow the twigs to be attacked by weak parasites some time before any diseased condition is visible.

INSECT PESTS.

GENERALITIES

690 – **Insects injurious to Crops in the Nyasaland Protectorate.** — BALLARD, E. in *Bulletin of Entomological Research*, Vol. IV, Part 4, pp. 347-351. London, 1914.

The following insects have been collected on or bred from cultivated plants in 1911 to 1913 ; unless otherwise stated they are from the Upper Shiré district.

ORTHOPTERA. — *Acridiidae*. — *Maura bolivari* Kirby and *Chrotogonus* sp. are very destructive to seedling tobacco. The following also damage tobacco to some extent : *Acrida turrita* L. (Lower Shiré), *Zonocerus elegans* Thunb., *Catantops opulentus* Karsch, *C. solitarius* Karsch, *C. vittipes* Sauss., *C. melanostictus* Schaum, *Morphacris fasciatus* Thunb., *Oedaleus citrinus* Sauss., *Gastrimargus marmoratus* Thunb., *G. wahlbergi* Stål, *Acrotylus patruelis* H. S., *Oxyrrhepes procera* Burm. and *Acridium lineatum* Stål.

Gryllidae. — *Brachytrypes membranaceus* sometimes damages cotton by eating the roots.

LEPIDOPTERA. — *Noctuidae.* — The red bollworm (*Diparopsis castanea* Hmp.) is very injurious to cotton throughout the Protectorate; *Chloridea obsoleta* F. occurs everywhere with it, and besides destroying the bolls and flowers of cotton, attacks maize, tobacco capsules and chick-peas. *Earias insulana* is not as bad a pest of cotton as the previous two, possibly owing to its being severely parasitized by an Ichneumonid: it is generally distributed throughout the Protectorate and has been found on *Hibiscus*. *Euxoa segetum* Schiff. gnaws the stems of tobacco in January and February. *Prodenia litura* F. is worst in the tobacco seed-beds, but it also damages tobacco after planting out, and has been found on cotton and maize, and even once on tea. The larvae of *Plusia orichalcea* F., *P. chalcites*, *Cosmophila erosa* H. B., *Gonitis sabulifera* Guén. and *Acontia graellsii* Feisth. are more or less injurious to cotton, eating the leaves up to the time of flowering; on the Upper Shiré they are about from December to the middle of March. *Busseola fusca* is one of the worst pests in the Protectorate, boring into the stalks of maize and millet. *Pteronycta fasciata* Hmp. (newly described) is uncommon, but would be very injurious if it were to increase in numbers, as the larva bores into cotton stems to pupate; the slightest wind is enough to break one of the bored stems, so that the plant then dies.

Limacodidae. — *Parasa vivida* Walk. occasionally appears on coffee, doing considerable damage.

Lymantriidae. — *Heteronygmia leucogyna* Hmp. is common on mahogany (*Khaya senegalensis*); plantations near Somba have been almost completely defoliated by it.

Pyralidae. — The cotton leaf-rolling caterpillar (*Sylepta derogata* F.) is rare on cotton in the Upper Shiré, at any rate about Somba; further north, on the banks of Lake Nyasa, it is much more frequent and injurious. The larvae are largely parasitized by a Chalcidid.

Tineidae. — *Phthorimaea heliopa* Lower bores into the stems of young tobacco plants, and is most injurious in the seed-beds. *Gracilaria* (sp. nov.) is common, but not much to be feared; the larvae mine cotton leaves, but seem to have little effect on vigorous plants.

Nymphalidae. — *Hypolimnas misippus* L. was once found in a cotton-field, some plants being defoliated by considerable numbers of the larvae.

COLEOPTERA. — *Lagriidæ.* — *Lagria villosa* F. devours the flowers and leaves of pulse crops.

Galerucidæ. — *Ootheca mutabilis* Sahl. occurs on cotton, Leguminosæ and Cucurbitaceæ, being especially destructive to the flowers of native melons. *Diacantha conifera* Fairm. attacks Cucurbitaceæ and Leguminosæ. The imago of *Asbecesta cyanipennis* Har. eats the leaves of Leguminosæ, but is not very harmful. *Pachytoma gigantea* was found damaging the leaders of young cypresses in plantations at Mlanje, on the top of Mount Somba.

Tenebrionidæ. — *Zophosis* sp. (adult) is sometimes injurious to cotton and tobacco, while *Gonocephalum simplex* F. does a little damage in tobacco plantations.

Dermestidæ. — *Dermestes vulpinus* F. is common in houses.

Meloidæ. — *Mylabris tricolor* Gerst., *M. amplectans* Gerst., *M. dicincita* Bert. and *Decatoma catenata* Gerst. destroy cotton flowers, while *Ceroctis trifurca* Gerst. eats the flowers of soy benas and velvet beans (*Mucuna pruriens* var. *edulis*).

Curculionidæ. — Tha larvæ of *Apion armipes* Wagn. bore into cotton stems ; a swelling is produced at the injured part, and the stem may break in a strong wind ; the insect is capable of doing considerable damage and appears to be generally common in the Upper Shiré. *Calandra oryzæ* is very injurious to stored maize and rice. A species of *Isaniris* is common ; the adult eats cotton leaves, but does not do much harm.

Coccinellidæ. — *Epilachna dregei* Muls., *E. hirta* Thunb. and *E. paykulli* Muls. are harmful in gardens. *Chilomenes lunata* F. is very useful in destroying *Aphis gossypii*.

Cassididæ. — *Cassida gibbipennis* is somewhat injurious to Leguminosæ.

Nitidulidæ. — *Epuraea* sp. eats the stamens of cotton flowers, but is of little importance.

Ptinidæ. — *Lasioderma serricorne* F. tunnels into cigars and cigarettes.

HYMENOPTERA. — *Tenthredinidæ.* — *Athalia* sp. is very injurious to turnips and cabbages.

RHYNCOTA. — *Aphididæ.* — The cotton aphis (*Aphis gossypii* Glover) is very harmul in some seasons, especially those with heavy rainfall. *A. brassicæ* L. is abundant on cabbages and difficult to destroy with washes owing to its waxy covering. Another species damages beans. *Ceratophis lataniæ* Newst. has occurred on *Raphia vinifera* in the Botanic Garden at Somba.

Coccidæ. — *Pulvinaria jacksoni* Newst. has been noted in small numbers on cotton.

Coreidæ. — *Anoplocnemis curvipes* F. does some damage to cotton by sucking the sap ; it has also been observed puncturing young shoots of mahogany.

Pentatomidæ. — *Antestia variegata* Thunb. damages coffee berries, while *Atelocera stictica* Westw. sucks the young shoots of mahogany.

Pyrrhocoridæ. — The cotton stainer (*Dysdercus nigrofasciatus* Stål.) occurs throughout the Protectorate and is very injurious ; *Odontopus confusus* Dist. has the same habits, but is restricted to the lower and hotter parts.

691 – **Contribution to the Biology of *Bibio hortulanus*, and its Control.** – MOLZ, E. and PIETSCH, W. in *Zeitschrift für wissenschaftliche Insektenbiologie*, Vol. X, 1914, Parts 3 and 4, pp. 98-105 and 121-125. Berlin-Schöneberg, 1914.

Bibio hortulanus appeared in the Province of Saxony (Prussia) in quite epidemic form in 1913 ; previously it had only been known to injure beets, but in this season it attacked spring crops of barley and wheat so severely that many fields had to be ploughed up and resown.

The damage is due to the larvae, which go on feeding up till the beginning of May, when they pupate at 2 to 4 in. below the surface of the soil.

The writers have carried out a long series of laboratory experiments with chemicals and other means for the destruction of the larvae, as well as observations on the life-history with a view to finding a point of attack. Steeping of the seed gave no results, and contact poisons (sulphate of iron, soft soap) had very little effect on the larvae.

The following measures seem to give good results :

1) In cases of severe damage in spring, the land should be ploughed deeply at the time of pupation (which begins in early May) and then well rolled ; in this way a large number of the insects are prevented from reaching the surface, while those which do so will be much weakened. If it is necessary to plough earlier in preparation for another crop (say the middle of April), thorough harrowing should follow, so as to injure the larvae ; in this case little damage is likely to be done to the second crop, though a number of insects will emerge.

2) The best means of destroying the adults is to place wisps of straw on sticks about a yard high, in the places where the larvae have been noticed, at the time of emergence of the gnats : this begins about the 20th of May, only isolated individuals being observed as early as the 10th. The gnats settle by preference on these wisps, and can be collected and killed on cool mornings : several hundred may be found on a single wisp.

3) Care should be taken that no dung, particularly stable dung, is lying about at the time of emergence of the gnats ; farmers believe that the insects are spread by means of stable dung.

The abundance of these gnats in the Saxon province is very likely connected with the prevalence of beet aphids (*Aphis papaveris*) in 1911 and 1912, as the honeydew produced by them is very attractive to the gnats.

MEANS OF PREVENTION AND CONTROL

692 – ***Anagrus ovijentatus*, a Hymenopterous Parasite of the Eggs of *Lygus pratensis*.** (1) — CROSBY, C. R. and LEONARD, M. D. in *The Canadian Entomologist*, Vol. XLVI, No. 5, pp. 181-182, figs. 19-20. London, 1914.

From an egg of *Lygus pratensis* on *Erigeron ramosus*, obtained at Ithaca (New York) in October 1913, a Hymenopterous parasite was reared ; others were also obtained by enclosing heads of the plant in breeding-cages. It appears to be a new species, and is described under the name of *Anagrus ovijentatus* ; it is near *A. saga* Girault, but differs from this in several particulars.

693 – **A Nematode Parasite of the Olive Weevil *(Rhynchites ruber)*.** — DEL GUERCIO, G. in *Redia, Giornale di Entomologia*, Vol. IX, Part. 2, pp. 233-234. Florence, 1914.

The great irregularity in the appearance of the olive weevil (*Rhynchites ruber* Fairm,) (2) and in the amount of damage it does is very likely due in part to the presence of a so far unrecorded parasite : this is a minute Nematode worm, apparently a *Rhabditis*, which the writer has noticed since 1911. The worms attack the larvae when they leave the olives and burrow into

(1) See also No. 1381, *B.* Sept. 1912. (*Ed.*).
(2) See No. 1240, *B.* Aug. 1912. (*Ed.*).

the ground. Once inside the larva, the worm grows and reproduces, so that the host becomes a centre of infection for other larvae. The infected larva eventually becomes motionless and dies. After death the body becomes covered with a whitish felt, consisting of numbers of the Nematodes ; they are very prolific, so that the number hatching from the eggs is enormous.

694 – **Control of the Second Generation of Vine Moths by means of Protecting Envelopes.** — MILANI, A. in *Zeitschrift für Pflanzenkrankheiten*, Vol. XXIV, Part 3, pp. 139-148. Stuttgart, 1914.

The writer has made trials of the protecting envelopes (German patent No. 250 053, July 1, 1911) for use against the second generation of the vine moths (*Conchylis ambiguella* and *Polychrosis botrana*) ; these were carried out in the three seasons 1911-1913, in conjunction with the Vine-growing College at Geisenheim (Germany). The envelopes in question are conical and open below, and the opening is gummed ; they are put over the flower clusters in June, and the moths coming to lay are caught by the gum.

It has been found that grapes so protected were hardly damaged at all, while the unprotected ones were sometimes severely damaged.

INSECTS INJURIOUS TO VARIOUS CROPS

695 – ***Lachnodius greeni*, a New Scale injurious to Coffee in Madagascar.** — VAYSSIÈRE, P. — *Bulletin de la Société entomologique de France*, 1914, No. 5, pp. 156-157. Paris, 1914. — *Journal d'Agriculture tropicale*, Year 14, No. 154, p. 125. Paris, 1914.

The writer describes under the name of *Lachnodius greeni* a new scale-insect sent to the Paris Entomological Station by M. Fauchère, inspector of colonial agriculture in Madagascar. This species occurs in clusters on the roots and stems of coffee, covered over by cells of earth and bark made by ants. It appears to be a serious pest of *Coffea robusta* and *C. liberica*.

Treatment should if possible be carried out before the scales are covered up by the ants. The bottom of the stem and the parts of the roots attacked should be laid bare and then washed with a petroleum insecticide strong enough to destroy the insects without damaging the plants. Proper attention to the plants will also help them to resist the scale and other enemies.

696 – **The Yellow-headed Coffee Borer *(Dirphya princeps)* in Uganda.** — GOWDEY, C. C. in *Bulletin of Entomological Research*, Vol. IV, Part 4, pp. 279-281, 2 figs. London, 1914.

Dirphya (*Nitocris*) *princeps* Jord. (Cerambicidae) was first recognized in Uganda as injurious to *Coffea robusta* in 1910 ; it has since been found on *C. arabica* also.

The bushes attacked can readily be recognized by the accumulations of excreta and gnawed wood below them. The branch through which the larva has made its way into the main stem can generally also be recognized either by the openings of the horizomtal tunnels in it or by its tip having turned black : the latter occurrence is, however, not to be relied upon.

If the larva is still in the side branch, the simplest way to destroy it is to cut off the branch and burn it. If it has gone into the main stem the best thing is to inject a few drops of carbon disulphide or carbon tetrachloride into the gallery ; the side branch through which it has entered should

be cut off close to the stem, so that the opening can be used for the injection; this and all other openings should then be closed with damp clay.

If the larvae are not killed, the tree soon dies or else gets broken by the wind. Coffee bushes less than two years old do not seem to be attacked.

697 – ***Pseudococcus filamentosus*, a Scale injurious to Tropical Trees.** — VAYSSIÈRE, P. in *Journal d'Agriculture tropicale*, Year 14, No. 154, pp. 109-111. Paris, 1914.

Pseudococcus filamentosus Ckll. (=*Dactylopius perniciosus*) was first recorded about twenty years ago in Hawaii ; it has since spread to various parts of the world.

In 1899 it occurred in Mauritius on Euphorbiaceae and citrus fruits ; later it was reported from Jamaica. In 1906 it was found in Cairo on cotton and *Albizzia Lebbek*, and by 1909 it had become a serious pest of the *Albizzia* trees along the avenues of the city. In 1912 the writer recorded it in French West Africa (Koulikoro, Upper Senegal-Niger) on *Ximenia americana*. In 1913, German East Africa was stated to be the original home of this scale ; it was observed there on native cotton in 1909, and in 1911 was found to be highly injurious to ornamental trees in Daressalam.

A tree infested by this insect has its branches and leaves covered by masses of white filamentous waxy matter, which sometimes form sheets joining one branch to another. Among these masses can be found adult females, eggs and larvae. The recently-hatched larvae migrate in quantities to the young branches and leaves ; thence they are easily carried by the wind, birds or insects to considerable distances.

Severely attacked tres may be killed in a few months. Infection almost always begins at the top ; first the leaves turn brown and fall off, then the branches also wither and die. Hundreds of trees were killed in this way in Cairo, and also in Honolulu at the time of the outbreak in Hawaii (1891).

Till lately the number of host-plants known was limited, but at Daressalam it has attacked a great variety of trees. The most favoured are the following : *Albizzia Lebbek, Pongamia glabra, Pithecolobium Saman, Eriodendron anfractuosum, Citrus, Acacia arabica* and *Loranthus ;* the latter, being a parasite of various trees, tends to weaken them and make them more susceptible to the scale. At the same time, the *Terminalia* trees at Daressalam, though parasitized by species of *Loranthus*, were hardly attacked.

Other trees resistant to this scale are : the species of *Eucalyptus, Pandanus, Plumeria, Bauhinia* and *Bougainvillea*, as well as *Pithecolobium dulce, Syzygium guineense, Barringtonia racemosa, Anacardium occidentale*, various species of *Sterculia*, etc. Occasional hosts are : *Sapindus Saponaria, Chrysophyllum Cainito, Landolphia* sp., various species of *Ficus* and *Bambusa, Khaya senegalensis*, cottons, palms, *Melia Azedarach*, various species of *Agave* and *Albizzia, Ximenia americana*, etc. *Mangifera indica*, which was badly attacked at Daressalam in 1912, should also be classed here.

Among natural enemies so far know should be mentioned two Chalcidids (Hymenoptera), as internal parasites in Egypt, a predatory Hemerobid

larva (Neuroptera) in Cairo, and three Coccinellids: *Exochomus nigromaculatus*, *Scymnus includens* and *Cryptolaemus montrouzieri*. The last named ladybird, coming from the Cape, was found very efficient against this scale in Hawaii, and should be acclimatized in various parts of Africa to keep scales in check.

In new centres of infection cultural methods and insecticides should be given preference over introduction of natural enemies. In particular resistant species of trees should be chosen for parks and avenues, and infested trees of no economic value should be destroyed; *Loranthus* should also be removed. The best insecticide seems to be petroleum emulsion (6 to 15 per cent.) applied as a winter wash; mixtures of petroleum, soap and lime are also good.

ALFREDO RUGGERI, gerente responsabile.

Agricultural Education in the Netherlands

by

Dr. K. H. M. VAN DER ZANDE.

Inspector of Agricultural Education.

HIGHER AGRICULTURAL EDUCATION.

The seat of higher agricultural education is the National College of Agriculture, Horticulture and Forestry at Wageningen. Previous to 1906 this college was connected with the National Agricultural School at Groningen, the National Horticultural School and the Municipal College, all four being under the management of the same board. Since its separation from these other institutions the Wageningen College has undergone considerable development both as regards attendance and equipment. Teaching is now conducted on academical lines ; the courses are open to all, but only students who have been through the secondary schools (modern or classical) are admitted to the examinations. It already possesses good laboratories, a library, buildings for feeding experiments, etc., about 100 acres of land and a special hothouse for tropical plants. The following institutions are attached to the College : 1. Phytopathological Institute, which is also the headquarters of the Government Service for the protection of plants. 2. The Institute for Agricultural Machinery and Construction. 3. The Institute for the Sugar Industry, which undertakes more especially the training of young men for the East Indian sugar plantations. 4. The recently founded Plant Breeding Institute.

The staff of the College consists of 28 lecturers and a number of assistants. Instruction is given in all branches of agriculture, horticulture and forestry, both Dutch and tropical. At present 247 students are in attendance; of these, 34 have specialised in Dutch agriculture, 39 in tropical agriculture, 6 in horticulture, 5 in Dutch forestry and 44 in tropical forestry. The remaining 119 students are still following the preliminary unspecialised courses.

2. Secondary Agricultural Education.

The secondary agricultural schools comprise the National Agricultural School at Groningen and the Colonial School at Deventer. In 1896 a so-called "Indian class" was founded at the National Agricultural School to deal with tropical farming. In the colonial school the course lasts three years, at the Groningen school two and a half years. Both schools are well equipped as regards qualified masters for teaching natural science, agriculture and other technical subjects. (For curriculum, etc., see Tables I and II in appendix).

3. Special Schools and Special Courses.

(a) *National Dairy School at Bolsward.* — The course at this school extends over two years and is intended specially for managers of butter and cheese factories. Besides practical cheese and butter making the principles of commerce, book keeping and commercial correspondence in French, German and English are taught. Only students who have had at least eighteen months' practical work in a butter or cheese factory are admitted, and they must undertake to work in a dairy during their vacation, producing a certificate to that effect at the end of the vacation. Forty students were in attendance in the year 1912-1913.

(b) *Agricultural and Horticultural Winter Schools.* — The course at these schools lasts over two winter terms. There are at present in the Netherlands 9 agricultural and 5 horticultural winter schools, which are on the whole very well attended and much appreciated by the country people. They are especially adapted for lads whose presence at home is indispensable during the summer or whose means do not allow them to attend a secondary agricultural school. In order to be admitted, it is sufficient to have passed through the elementary schools, though the winter schools are also frequented by lads who have had a rather better education. The instruction given is purely theoretical, like that given in the National Agricultural College and in the secondary agricultural schools, and it is adapted to the special agricultural conditions of the districts in which the schools are situated. In the horticultural schools some facility for practical work is afforded by the school gardens. In the year 1912 the agricultural and horticultural schools were attended by 349 and 155 pupils respectively.

The directors of these schools are usually specially qualified in agriculture or horticulture and have under them one or two permanent teachers and some temporary elementary school teachers. Further details of the curriculum are given in Tables III and IV. Only pupils over 16 years of age are admitted, for in the Netherlands, as in other places, experience has shown that the older pupils profit most by the instruction. It is very desirable that the lads should attend continuation classes in the interval between leaving the elementary schools and joining the winter schools. Such classes exist in the country, but hitherto too little has been done for their development.

The fees at the winter schools are low, at most 16*s* per term, while books etc. amount to about £2 per head. As most of the pupils live in the immediate neighbourhood of the schools their total expenses are very moderate. If the pupil cannot afford it, the payment of the fees is not insisted upon and in such cases the books are also frequently supplied free of charge by the school. Scholarships are available besides, and allowances are made by associations and by the local authorities.

All winter schools are national institutions; this year, however, the Catholic Association for Agricultural Education will open a private winter school which will also receive a State grant. There is further a school of horticulture, which is not a winter school proper but resembles it in character. It was founded by the Frederiksoord Beneficent Association with funds given by General van Swieten.

(c) *Winter courses in agriculture and horticulture.* — This form of education is especially intended for those young farmers and gardeners whose presence at home cannot be dispensed with for any length of time even in winter. The courses generally extend over two winters and include from 300 to 400 hours of instruction. The lecturers are elementary school teachers who have undergone special training in agriculture and horticulture.

The courses in agriculture and horticulture are organised privately by associations and occasionally by local authorities, but they are subventioned by the State, which generally pays the lecturers and provides the material. Such courses are in great request throughout the country, and their number is constantly increasing. Unfortunately suitable lecturers are often wanting, but it is hoped that their numbers will soon increase, as special provision is being made for their training. In the year 1912-13 a total of 405 courses on agriculture and 119 courses on horticulture was held, with an attendance of 6015 and 2203 pupils respectively.

(d) *Agricultural and horticultural courses for adults and special courses.* — These courses, as a rule, consist of twelve lectures lasting two hours each. The lecturers are usually teachers with much practical experience. In the winter 1912-1913, 131 agricultural courses and 78 horticultural courses were held and they were attended by 3729 and 1567 students respectively.

Special courses are given in poultry keeping, horse shoeing, and live stock management.

(e) *Agricultural instruction for soldiers.* — On request of the military authorities, instruction in agriculture has been given to the soldiers of some garrisons since 1905. This is especially intended for those men who have been brought up in the country. A whole course consists as a rule of 12 lectures of two hours each on questions connected with manuring and live stock management. The lectures are generally well attended. In the winter of 1912-1913 these courses were held in 16 localities and attended by 565 soldiers.

(f) *Agricultural education for women.* — During the last few years, a start has also been made with regard to instructing the female rural population. In this respect the Netherlands are perhaps behind several other countries.

Formerly when butter and cheese were made in almost every farmhouse, special courses were held in these subjects. At present except in a few districts in South Holland and in the province of Utrecht, butter and cheese are made exclusively in factories, and dairy courses are only held in the limited districts mentioned above. In districts with light sandy soils, where small holdings are very numerous, special courses on livestock management, feeding, etc., are held for women. Of still greater importance, however, are the courses on domestic subjects, such as cooking, housework, first aid, gardening. In general the tendency is to get women teachers for the purely domestic subjects and special agricultural or horticultural teachers and medical men for the others.

Hitherto domestic economy has only been taught in short courses. Only one permanent school exists in the country, that at Lierop, which was opened in 1911 ; it is chiefly a cookery school for peasant women conducted by Catholic sisters. This year a new National School of Domestic Economy will be opened; for the present, only teachers of domestic economy will be trained in it. The courses on domestic economy are usually organized by agricultural associations who have special grants from the Government. In the year 1912, 53 courses were held, and attended by 1100 women students. In some places courses have been held for the wives of agricultural labourers; they have awakened much interest and will be continued.

With regard to the amounts of money granted by the Government for agricultural education, it should be noted that out of the total population of 5 411 800 inhabitants, about 2 683 800 live in the towns and 2 728 000 in the country. In the budget for 1913 the following sums were voted :

For the National College of Agriculture, Horticulture and Forestry.	£	22 875
For the two Secondary Agricultural Schools	»	7 464
For the National Butter and Cheese-making School	»	1 136
For the Agricultural and Horticultural Winter Schools	»	9 183
For other courses	»	16 333

Besides the Government grants, contributions to agricultural education are also made by associations and local authorities, but as these vary greatly no reliable data can be given.

The Present Position of the Science of Manuring in Germany

by

Professor M. HOFFMANN, of Berlin,

Manager of the German Agricultural Society.

The discussion of this question is made easier by the publication of the symposium on " New Methods and Aims in Manuring ", in the March and April numbers of *Mitteilungen der D. L. G.* for this year. In this article the leading experts express their views, and consideration of these papers

leads to the regrettable conviction that we have not yet been able to solve the weightiest problem of the science of manuring, namely how to find out, rapidly and surely, the manurial requirements of a given piece of land before a crop is put into it.

Yet there is no doubt that we have got a good deal further in this direction in the last ten years, and for this we have especially to thank the efforts of KÖNIG (at Münster), MITSCHERLICH (at Königsberg) WAGNER (at Darmstadt) and PFEIFFER (at Breslau), who have done much to increase our knowledge of the analysis of soils and crops. It is true that water containing carbonic acid was known to the older agricultural chemists as a means of obtaining a soil extract suitable for analysis, but the finer type of experimental and critical observation work was not yet undertaken.

To Mitscherlich belongs the credit of having instituted researches regarding the temperature, concentration, and duration of influence of this agent, and of obtaining partially satisfactory results from them. He succeeded in finding out, with reference to the cultivation of spring sown cereals, a regular relation between the quantities found in the carbonic soil extract and those recovered in the harvested crop, although his experiments have not yet stood the test of independent investigation.

It will be interesting to see whether the methods suggested by König for determining the assimilable mineral plant foods of the soil prove reliable. König starts from the assumption, which has a good deal to be said for it, that the pioneer work of microorganisms, yeasts and catalases in bringing into solution the compounds of potash and phosphoric acid in the soil, is most readily investigated if the soil to be examined is previously steamed under pressure. For potash requirements, König believes in steaming for 5 hours under a pressure of 5 atmospheres : as a result of his latest experiments, he arrives at certain standards, as for example that soils of which the potash content rendered soluble by steaming only amounts to 5 mgms. per 100 gms. of soil, will benefit by a potash dressing, whereas if this figure reaches 8 mgms. the soil does not need potash ; in the same way a soil which after steaming, gives less than 4 mgms. of soluble phosphoric acid will profit by a dressing of phosphates. At the same time he does not wholly reject as an extracting agent the 2 per cent. citric acid solution recommended by GERLACH of Bromberg more than a decade ago. Unfortunately the indefatigable veteran experimenter has not hiherto, in the course of his comprehensive researches, been able to determine definite relations between the quantity of nitrogen and of lime taken up by plants and the absolute quantity of these substances existing in the soil. He is, however, of opinion that in this case the percentage content of the dry matter of plants provides a sufficient clue as to whether these substances are present in the soil in sufficient quantity.

Such an admission as this is a further stimulus toward plant analysis, the applicability of which has, in the last few years, been advocated by Wagner and Pfeiffer. Wagner's doctrine, according to which a meadow the more urgently needs manuring with the chief fertilizing agents, the more widely the content of its air-dried hay varies from the limit values " 2 per

cent. potash, 0.7 per cent. phosphoric acid, 1 per cent. lime", has already been many times confirmed, and steps are now being taken to establish similar standards for spring-sown cereals. In calculating an analysis of hay, the fact must be borne in mind that, as a rule (and my own investigations support this), the second cut is richer than the first in P_2O_5 and in CaO, as well as in protein, while on the other hand the potash content is lower. It may here be remarked that nitrogenous manuring for meadows and pastures has come more into fashion in Germany, in the last five years than could justifiably have been expected from the opinion hitherto prevailing on the subject.

Speaking generally, however, the pot and field experiments which Wagner has developed in so masterly a manner, continue to hold the first place in the determination of manurial requirements; Hiltner who also showed the possibility of applying potash and nitrogen to plants direct through the leaf-organs is now occupied in arranging water culture experiments with the same object.

Should the farmer not be in a position to make use of experiments, which, after all, only tell what happened on a given piece of land, he would do well to call to his assistance the so called "Soil Statics", and keep a soil account-book; though this might not be necessary for the whole farm or for the whole of the arable land, at any rate it would be of value for the individual "hungriest" fields. Soil Statics, that is, the science of balancing the intake and output of the plant foods in the soil in relation to its power of plant production, which was, before the introduction of artificial fertilizers, a much valued means of determining manurial requirements, has not achieved the success expected of it after the recent efforts to restore it to favour. All the same soil statics, as proved by my own comprehensive experiments, provide the critically minded arable farmer with a useful indicator, particularly as to whether a further application of potash and phosphoric acid is profitable; for fertizers like nitrogen and lime, which are easily modified or washed out of the soil, the method is less suitable. The subject is fully explained in Part 251 of *Arbeiten der D. L. G.*

A fact which is not without its significance in the practical application of statical calculations is the discovery, which has received repeated confirmation, that the ratio between the plant foods found in the composition of normal plants is something like 100 N : 50 P_2O_5 : 150 K_2O : 80 CaO, although many plants, the Leguminosae for example, show considerable divergences from these proportions. The farmer who reckons out his stock of the principle plant foods per acre for each piece of arable land on the basis of an up-to-date and complete soil analysis, and from this substracts the quantity of plant foods contained in the forthcoming crop at harvest (allowing about 1 per cent. for wastage) on the above ratio, will be able to measure approximately, before the annual crop sowing, the quantities of manure which he must still apply to his land. In doing this, however, he must take into consideration the average coefficients of utilization of the said plant foods and all the other factors which influence the productive

capacity of the soil. If he continues this calculation in the following years, he will, of course, not need a fresh soil analysis, the previous year's figures being used as a basis.

There exists at present no method at once rapid and entirely free from objection, of determining the manurial requirements — not the plant food requirements — of a soil, and there is not likely to be one until the biological and colloido-chemical actions taking place in the soil have been more clearly defined. The work of decomposition due to bacteria, the numerous sources of production of carbonic acid and the conditions affecting the coagulation of colloid substances which is important for growth, are matters too complex and varied, even on the smallest scale, to admit of being expressed in incontestable numerical terms, in the light of our present knowledge and with our present methods of investigation.

Apart from the revival of Statics, the Law of the Minimum has very recently formed the central point of numerous investigations. The endeavour to find a symbolical representation of this fundamental Law of Nature on the basis of Wollny's definition gave rise to a keen competition, as described in detail in my report on the prize competition on this subject in Part 245 of *Arbeiten der D. L. G.* In this connection it should be noted that Mitscherlich, on the proposal of P. Mazé, wants this law, which was already known to Karl Sprengel, to be designated "The Law of Physiological Relations", since the amount of plant-production depends on the collective effect of a number of growth factors, each of which individually exercises on that amount a retarding influence proportional to its own proximity to the minimum. This suggestion may contain a germ of truth, but at the same time the name "Law of the Mimimum", chosen by Liebig, will not so soon disappear from the vocabulary of practical scientists; and it may well be preserved for application in the case of plant foods, since these are factors over which man can exercise a vigorous control.

The present current of opinion in this sphere is strongly influenced by the fact that certain factors formerly regarded as bring present in excess, for example carbonic acid, are now suspected of being present only in the minimum quantity. Individual experiments with ornamental plants show that flowering in glass-houses is considerably improved by applications of carbon dioxide, made by means of a cylinder, or by the action of hydrochloric acid on marble, or by burning alcohol. Similar success was looked for with agricultural crops, from the application under the soil, of carbonic acid, either in the form of gas by means of pipes, or by means of rapidly decomposing organic substances. Unfortunately this success has hitherto been practically unattained, but all the same the problem, on which we possess a number of accurate studies by earlier investigators, will still be kept in view, just as for a considerable time the question of making a more productive use of the sun's energy, in combination with artificial watering and manuring, has been under discussion.

It is not without interest to recall, in this connection, that STRACKOSCH, of Vienna, who established the "Law of the Variation of Work done by Cultivated Plants", and who started the idea of the "Assimilative Effect"

(relation between the utilizable substances produced and the quantity of plant food consumed), succeeded in obtaining an increase of yield amounting to about 11 shillings an acre by altering the cropping scheme on his estate at Hohenau in accordance with this " Assimilative Effect "; these results he described in a lecture before the Royal and Imperial Agricultural Society in Vienna. (See *Österreich Agrar-Zeitung*, 1913, N° 18).

In this case " Energetics " may be said to play a part inasmuch as Strackosch avails himself, for the determination of the effective utilizable value, of Kellner's " Starch Equivalents " that is to say, of a conception based on " Energetics ", as Remy has already pointed out.

Even, however, if more arable land is eventually to be permanently cropped than is at present the case, the sun's energy will still remain no more than a powerful contributing factor in the development of private and national wealth. The quintessence of human art in agriculture lies, in my opinion, in the correct application of fertilizers to well prepared soil, and in sowing productive varieties.

As SCHULZE, of Breslau, has recently shown, the remains of the roots and stubble of grain and of root-crops do not by a long way leave in the soil the quantities of plant food required for the attainment of maximum harvests ; even if, in the case of Leguminosae, the whole of the aerial portion of the plants on a field were also applied as green manure, the utilization of them by the succeeding crop by means of bacterial and chemical processes, assisted by the return of plant foods from the body of the plants before they are ripe for harvest, would still, in the majority of cases, by no means come up to expectation. According to the pot experiments published by Professor VON SEELHORST in Part 241 of *Arbeiten der D. L. G.*, the losses by washing out of nitrogenous green manure are very considerable on light soils, so that the utilization during a three-course rotation may be taken at only about 30 per cent.

The same applies, in the long run, to the utilization of the nitrogen in farmyard manure, which can, however, be greatly improved by keeping the liquid and solid manure separate in the cowhouses ; the liquid manure should be kept from contact with the air in a tank with a lid, and should also be covered with a layer of petroleum or oil. Ortmann, who owns the manor of Schependorf, has been trying for some time to introduce a method of storage of this kind into general use in Germany, and such endeavours are worthy of support, for with nitrogenous manures at their present price, it makes a considerable difference whether one employs liquid manure containing 1 or 2 per thousand nitrogen or that containing 6 or 7 per thousand. Recent experiments have shewn that liquid manure treated in this manner produces excellent effects, equal to those of ammonia, but it must be thoroughly covered with earth, immediately after being applied, or at least be ploughed in shallow, as in the case of farmyard manure well soaked with urine (box or yard manure). If it can only be used as a top-dressing it is profitable to add crude sulphuric acid as a preservative.

A further series of experiments is now in progress in Germany, with the object of discovering within what limits home produced manures can

be replaced by commercial manures. The trials which have been carried on during the last 70 years on the home farm at Wingendorf near Freiberg, in Saxony, seem to show that this method of farming cannot be continued through several decades without fundamentally impairing the yield, except on good soils containing plenty of humus, and even then, only when the remains of the roots and stubble are allowed to accumulate for the enrichment of the soil.

The majority of the German farms carrying no live stock work principally with green manure or, in some parts, also with night-soil combined with heavy dressings of artificial fertilizers, while here and there manure is purchased from neighbouring towns, or straw is handed over to neighbouring farmers to be used for making manure and returned. Farms using only commercial fertilizers only exist in isolated cases, or this system is confined to the outlying portions of the farm. In any case, it has been found again and again that profitable root crops can, as a rule, only be obtained by an intelligent combination of home produced and commercial manures, while cereals following a previous crop dressed with farm-yard manure or green manure usually pay well for a complete dressing of artificial fertilizers suited to the previous crop and to the strenght of the soil. It is a universal rule in all the better managed farms, to keep the replacing of plant foods at a minimum, or, having regard to the kind of manure, crops, and soil, and to the rotation practised and the general circumstances of the farm, to approach the line of soil enrichment, taking into account the time occupied by the various farm crops in absorbing plant food.

Agricultural chemists in Germany are busily engaged in determining the utilization coefficients and the best adapted forms in which to apply both home-produced and commercial manures under the most widely varying conditions ; numerous articles have been published on the agricultural value of all these fertilizing materials, especially the different forms of phosphates, potash, and above all nitrogen, such as that contained in nitrate of soda, nitrate of lime, nitrate of potash, ammonia, and organic and cyanic nitrogen. Nitrogen is the plant food most often present in the minimum quantity, and unfortunately it is also the dearest. It is therefore not surprising that it is this element which is the subject of the most extensive study, a fact which is also manifested in the numerous applications for patents having for their object the utilization, for fertilizing purposes, of the nitrogen of the air. But technical science is also endeavouring to make use of crude phosphates, minerals containing potash, and the less pure limes, and to make them available to agriculture as fertilizing materials — with what success, Pfeiffer and Lemmermann have reported in this journal. (1)

Potash salts are at present being worked at more than 150 mines, and, like amber, represent up till now a natural monopoly of Germany. The fu-

(1) See " The Possibility of Using Crude Phosphates and Limes containing Silica as Manures ", by Prof. TH. PFEIFFER, *B.* Sept. 1913, pp. 1316-1321 ; also " The Possibility of Replacing Stassfurt Salts by Finely Ground Phonolite, Leucite, etc. ", by Prof. LEMMERMANN, *B.* Oct. 1913. pp. 1483-1495. (*Ed.*).

ture will shew whether this will continue to be the case, and whether the deposits discovered in recent years in the north of Spain and elsewhere give promise of profitable working. For the present, they can only be regarded as of historical interest, in the same way as the working of certain quartzrocks for platinum recently undertaken in Westphalia.

A special interest has become attached in the last few years to the three substances magnesia, silicic acid and sodium. Since Professor Willstätter ascertained that the colouring matter of chlorophyll contains about 4 per cent. of magnesia, but no iron, this base has received the attention it deserves, and this not only for the sake of proving Loewe's theory of the so-called " Lime Factor ". Similarly, sodium and silica, which have come into prominence on account of the discussions on phonolite and the researches into the chemistry of colloids, have become the subject of recent investigations ; Schulze, among others, has been able to prove a direct nutritive effect of sodium. It is true that the preparation named " Natramon ", an artificial product composed of 75 parts of sulphate of ammonia to 25 parts of common salt, has not been able to establish itself in practice but on the other hand an addition of rock salt to nitrogenous manures containing no sodium was accompanied by the most successful results especially for plants requiring sodium, *e. g.* mangels and beets, barley and certain vegetables. As regards silica, German agricultural chemists maintain their previous opinions.

It would take too long, here, to go into the experiments which have for their object the investigation of what are called catalytic fertilizers or stimulants, such as the salts of sulphur, manganese, boron, aluminium lithium, rubidium. As we cannot deal with questions having at present no practical significance, we must leave out of consideration the question of drilling in fertilizers and using the rotatory spreader, as opposed to the broadcasting method prevalent in this country, also the question of the applicability of powerful, high percentage preparations of urea, and the new composite manures, known as nitrate of ammonia and nitrate-phosphate and, in general, all the latest — and unfortunately also in most cases short-lived articles which appear on the manure market. The said market seems likely soon to be brought under Government control in Germany as already elsewhere.

It is certain that the great increase in the consumption of artificial fertilizers (see Table II, p. 984), and the corresponding increase in our crop yields (see Table I, p. 983), which represent an expenditure of some 600 million marks by the German farming industry, are due not to the superstitions of ministers nor to unsound or misleading theories, but to systematic and representative researches, clear sighted regulation of the means of communication, and distribution, on the widest scale and in the shortest time, of accurate reports of the results of experiments. In this work apart from the advertisement departments of the great manure manufacturing houses, the chambers of agriculture and agricultural societies (notably among them the German Agricultural Society) each have their meritorious part, as have also, in particular, the schools of agriculture with

their travelling instructors, the agricultural colleges, and, of course, the experiment stations. It should here be observed that it was also the German Agricultural Society which extended its researches from field, meadow and pasture, to orchard, vineyard, forest and lake. At the same time this Society afforded financial assistance for the training of young students in methods of research and exerted itself to bring to a satisfactory solution the interpretation of the results obtained from manurial experiments. Since the foundation of the Imperial Fund for Advertizing Potash, it has fortunately been also possible to introduce the employment of artificial fertilizers into the tropical agriculture of the German colonies in a clear-sighted and comprehensive manner, and even to establish there, for that purpose, trained agricultural chemists.

There is no doubt that, in spite of being heavily overburdened with the work of analytical control of agricultural goods, the representatives of German manurial science have made good use of their time, and that many gaps have been filled up in the sphere of knowledge entrusted to them within the last ten years through their accurate and methodical researches.

It is a matter for congratulation that the Government and other competent authorities recognize the activity and success of these experiment stations, and assist in promoting the development of all institutions of this kind. Another step to be hailed with satisfaction is that the experiment stations themselves are seeking to form separate departments for research and control — indeed many are going still further and resolving themselves into separately located and separately administered research stations and control stations. Finally, it is to be hoped that the State may gradually assume control of all experiment stations, just as in the same way the question should be considered of a uniformly regulated training for the rising generation of agricultural chemists. Then the far-reaching conceptions and the numerous details introduced in the above-mentioned symposium would more speedily attain a satisfactory solution, to the great benefit of agriculture and of political economy.

Appendix.

TABLE I. — *Average yields of the chief crops in Germany*, 1890-1912 (*lbs. per acre*).

	Rye	Wheat	Barley	Oats	Potatoes	Meadow hay
1890–91 — 1894–95	1 170	1 460	1 480	1 290	9 390	2 960
1895–96 — 1899–00	1 280	1 580	1 480	1 410	10 380	3 620
1900–01 — 1904–05	1 380	1 700	1 650	1 530	11 500	3 590
1905–06 — 1909–10	1 490	1 780	1 740	1 720	12 400	3 870
1911	1 590	1 850	1 780	1 590	9 230	(1) 2 910
1912	1 660	2 010	1 950	930	13 410	(1) 4 100

(1) Irrigated meadows : 1911 — 4 000 lbs.; 1912 — 4 940 lbs.

TABLE II. — *Consumption of commercial fertilizers in German agriculture*, 1890-1912.

	1890 — metric tons	1900 — metric tons	1910 — metric tons	1912 — metric tons	Value in million of Marks
1. Bone meal	99 001	63 462	81 063	75 500	c. 6 3/4
2. Guano (artificial and natural)	45 888	37 450	40 200	40 200	» 5 ½
3. Superphosphate (incl. misures)	500 000	754 944	1 267 060	1 640 600	» 98
4. Basic slag	400 000	878 917	1 428 633	1 800 000	» 81 ½
5. Nitrate of soda	247 815	352 785	542 137	630 250	» 130
6. Sulphate of ammonia	60 000	117 638	268 330	356 150	» 100
7. Various (cyanamide, nitrate of lime, dried blood, horn meal, etc.)	50 000	50 000	60 000	100 000	» 18
8. Potash salts (total)	219 553	833 472	2 219 037	2 700 000	» 71
(As crude potash salts)	—	(774 916)	(1 953 964)	(2 320 000)	—
Total (1)	1 622 257	3 088 669	5 906 530	7 352 700	c. 512

(1) Owing to lack of precise data, these figures are only approximate, except for potash

Lime may be estimated at 800 000 to 1 000 000 metric tons, worth 12 to 14 million Marks ; this sum may be set against the mixed manures (ammonia-super, etc.) included with superphosphate, so that the final total will not be materially altered.

The prices of the chief artificial manures have diminished considerably since 1870 ; this fall is to no small degree due to the competition of newer manures, such as sulphate of ammonia and basic slag. The wholesale prices have been about as follows :

	Unit of N in nitrate of soda	Unit of water-soluble P_2O_5 in superphosphate
	s	*s* *d*
1870	25	9 6
1890	15	6 6
1912	14	3 5

Potash salts and limes show no distinct change over the last decade but a slight rise has very recently set in. Kainit was at 18*s* a ton in 188 and down to 15*s* in 1900, while 40 per cent. potash salts have been sold a about £3 4*s* per ton since 1890. Since the Potash Law came into force (beginning of July 1910) the crude salts with 12 to 15 per cent. of K_2O have been sold at 1*s* per unit (carnallit with 9 to 11 per cent. only 10*d*), while the prepared salts with 40 to 42 per cent. K_2O have made 1*s* 6 ½*d* per unit

The Dairy Industry of Great Britain

by

C. W. WALKER-TISDALE, F.C.S., N.D.D.,

Member of the Council of the British Dairy-Farmers' Association.

For the last twenty years the Dairy Industry in Great Britain has been steadily growing in importance, and dairy farming has to a large extent taken the place of other kinds of farming.

This may be accounted for by the increased consumption of milk by the populace, which has been and still is being educated to realise the high feeding value of milk, which has become more and more part of the national everyday diet of adults as well as children.

An estimate made some time ago put it that the annual increase in the consumption of milk amounted to some 5 000 000 gallons, but it is doubtful if such will continue the annual figure if the retail price of milk is unduly increased. But whilst people are learning more concerning the value of milk in their daily dietary, it is as yet difficult for the majority to realise that in proportion to its cost it is the cheapest food obtainable. Thus, whilst the price of most foods has gone up recently, that of milk also has been slightly increased. An increase in the price of milk, however, is generally resented by the public, which resentment is apt to show itself in the form of a decreased consumption. People would not, however, endeavour to effect economies in their living expenses by cutting down the quantity of milk purchased if they possessed a proper knowledge of the feeding value of this food in proportion to its cost. Undoubtedly no other food can be obtained in Great Britain at as cheap a rate, taking into consideration its food value.

Now of what value is the Dairy Industry of Great Britain at the present time? The answer is supplied in some figures recently published by the Statistical Department of the Board of Agriculture, by which it is shown that the estimated quantity of milk produced, after allowing for the amount used for calf-rearing, is 1 208 000 000 gallons per annum.

As to the manner in which this milk is dealt with, it is calculated that 70 per cent., or 850 000 000 gallons, is sold as milk, whilst the value of the dairy products respectively as sold by the farmers is :

£24 963 000	for	milk
£ 590 000	»	cream
£ 2 940 000	»	butter
and £ 1 400 000	»	cheese.

These figures show very clearly the great value to the farming industry of the milk sold for consumption in the towns, whilst the total sum realised for the milk and its products is about the same as that realised for the wheat, barley and oats grown. Furthermore it nearly reaches the sum obtained for cattle sold as meat.

It would be interesting and instructive to compare these figures with similar estimates for say two decades back, but unfortunately this cannot be done, such returns not being available. What has happened, however, in recent years is that dairy farming has steadily been taking the place of corn growing, and arable land has been turned into pasture to suit the altered class of farming, thus resulting in an ever decreasing area of cultivated arable land.

Where corn growing has not been found to pay, dairy farming has generally been substituted, and it has also largely taken the place of fattening cattle—a class of farming which has not been very remunerative of recent years, owing to the large importation of foreign and colonial meat that has come into operation.

Now whilst the importation of butter and cheese from abroad largely influences the value of these commodities as produced in Great Britain, there is practically no importation of milk to affect the value of the new milk trade. The populace of Great Britain, whilst existing and being dependent chiefly on foods imported from abroad, is fortunately able to obtain a supply of home-produced milk to meet its requirements fully. Small quantities of fresh milk are imported from countries within easy reach of the British Isles, but the quantity is negligible and the trade at present shows no prospect of developing.

Milk selling has been described recently as the sheet anchor of the English farmer, and certainly it has assisted him to an extraordinary extent when other systems of farming have failed. He realises that he is free from the competition created by imports from abroad that exists in the case of most other commodities, and thus is able to develop his trade without the fear of having to compete with others who can produce milk at cheaper cost. The retail price in towns varies from 1*s* 2*d* to 1*s* 4*d* per gallon. In many large towns up to within about four years ago milk was sold at 1*s* per gallon all the year round, but it is now generally sold at 1*s* in summer and 1*s* 4*d* in winter, making an average price of 1*s* 2*d*, though in many of the large towns it does not vary from all 1*s* 4*d* the year round and 1*s* 8*d* per gallon is charged for the best class trade in London.

Generally speaking the wholesale price of milk throughout the country may be taken as about 7½*d* per gallon net to the farmer throughout the year after the freight charges have been deducted. About 8 ½*d* net is obtained in the winter and about 6 ½*d* net in the six summer months. The cost of transport in the country generally may be taken as 1*d* per gallon which conveys the milk up to 100 miles. Comparatively little milk travels short distances so as to secure the ½*d* per gallon rate which conveys it for 20 miles.

It is not the same with the butter and cheese trade, however, for these have to compete with imports from very many parts of the globe. The imports of butter into Great Britain are valued at £24 000 000, and those of cheese at £7 000 000, which totals more than the whole amount realised for milk, cream, butter and cheese produced in the country. The cost of production in most countries from which butter and cheese

are received is much less, owing to cheaper land, cattle, feeding, etc ; hence the development of the milk trade in Great Britain at the expense of the manufacture of cheese and butter, as shown in the figures previously quoted.

The question arises as to what is being done to cope with the increased demand for milk and the possibility of the demand being greater than the supply. As previously mentioned, more and more arable land is being converted into pasture, which is the main requirement for dairy farming ; but apart from this must be considered the number of stock capable of being carried by the total amount of land available. Farming in Great Britain is still regarded as one of the less important industries, though there are many movements on foot at the present time to make it more productive and to increase the area of land available for agricultural purposes, by bringing under cultivation soil which at present is more or less unproductive. If, however, these points are left out of consideration and it is assumed that the present available land is carrying practically all the stock it is capable of doing, which we think is by no means the case, there is still a means of increasing milk production. This is by means of increasing the yielding capacity of the dairy cows, or, in other words, devoting special attention to breeding and selecting animals for high yields of milk. A great deal of work is now being done in this direction both by individual dairy farmers and public bodies—work that ten years ago merited but little attention. If the average yield per cow, as is estimated for Great Britain, is only some 350 to 400 gallons, then it follows that much improvement is possible. Milk records are being carried out by various County Councils and Dairy Associations (1) the results of which show the quantity and quality of the milk yielded annually by each individual cow in the herd, and this information enables the farmer to retain only the cows which give satisfactory results.

In Scotland a number of Dairy Societies have been started and have been in operation some five or six years, with the result that Milk Record Schemes of great value have been obtained and much growth in this is being continued. It is found that in most herds the variation in the annual yield per cow is great, for whilst the poorest animal may give 350 gallons or less the best may be yielding 1 000 or perhaps more. Now the cost of keeping and tending an animal yielding a large quantity of milk does not much exceed that of a poor cow ; hence if only good cows of tested capacity are kept, as much as 50 per cent. more milk may be obtained from a similar number of cows.

Most dairy farmers, even men who have been engaged in the work for many years, seldom know the milk yield of each cow in their herds, and milk records have shown as wide a difference between two herds on adjoining farms as 200 gallons per cow. Thus the farmer whose herd averages 600 gallons per cow per annum, may look forward by exercising care in selecting his cattle to increasing the yield to 800 in the course of a few years.

(1) See No. 1439, *B*, Oct. 1912. (*Ed.*).

Numerous dairy farmers, however, do not breed their own stock, but instead buy cows which they retain for one, two or three years and then sell them off fat to the butcher. The calves of such animals are usually also sold to the butcher, and this system of dairy farming tends to reduce the quantity of milking stock in the country and many of the best dairy cows are thus lost. Such may be considered a very extravagant method of dairy farming, and to the farmer in this case milk records do not appeal, as he does not keep his cows a sufficient length of time and does not retain any of the progeny, even of the best ones.

The favourite breed of Dairy cattle throughout the country is the Dairy Shorthorn — an animal of Shorthorn type but not of pedigree strain. A good animal of this class may be valued at from £18 to £25.

The factory system of dairying is not extensively carried on in Great Britain, but in Ireland there are a very large number of Creameries, and butter-making on Danish methods is practised. In England the large centres of population require the milk for consumption, but in Ireland there are but few large towns and their requirements of new milk are limited, allowing for an extensive manufacture of butter. Where factories exist in Great Britain they usually engage in all branches of the dairy industry, selling milk to the towns whenever possible and making cheese and butter. The former generally gives better returns than converting the milk into dairy products, hence the manufacturing periods are chiefly when milk is plentiful and the markets overloaded. Of course in many cases there are factories where cheese or butter is manufactured and milk selling not undertaken, but these are becoming fewer and exist chiefly in the more isolated districts. The greater part of the butter and cheese produced is still made on the farms, but even this is rapidly changing and where farmers formerly manufactured the milk at home they are commencing the sale of the milk.

A number of factories on co-operative lines are being established. Such factories, started and run by the farmers themselves, are proving a very satisfactory means of regulating the milk trade, as when there is a surplus of milk it need not be placed on the market and so lower prices, but can be converted into cheese and butter. Further, where the milk is manufactured at a factory it is possible to produce an article of more uniform quality than is the case at individual farms, and the smaller dairy farmers are thus enabled to obtain a better return for the milk produced on their holdings.

Whilst it is still a fact that the finest quality butter and cheese is produced at the best farms, it is nevertheless true that the bulk compares very unfavourably in quality with that turned out from the factory where skilled labour and scientific methods are in vogue. Much expenditure has been made in teaching butter and cheese-making for many years past, and doubtless some general improvement in farm-made dairy products has resulted, but on the whole the return has been small in proportion to the expenditure involved. It has indeed become generally recognised that it is better for a group of farmers to start a dairy together, properly equip it and employ the best skilled labour rather than continue the manu-

facture of dairy products at home. Better means of marketing are possible and generally better financial returns are the result.

For the protection of the public, various laws affecting the production and sale of milk have been put into operation recently and further restrictions on the sale of milk will come into force when what is known as Mr. Burns' Milk Bill at present before Parliament becomes law. Parliament, after many years of apathy, has become alive to the needs that the nation has of supplies of pure wholesome milk. It doubtless realises that the health of the nation depends greatly upon supplies of pure milk, especially as milk has now become so commonly used in the daily dietary of the great majority, and moreover it is the chief food of children who need most protection.

Following upon the reports of the Royal Commission on Tuberculosis, whose investigations and findings during the last twenty years have shown that tuberculosis or consumption in human beings is largely caused by tuberculous milk and meat, an order came into force on May 1st by which all tuberculous cattle must be notified. Such cattle are to be examined by Veterinary Inspectors appointed by the County Councils, and on their recommendation all obviously tuberculous animals and cows suffering from tuberculous udders will be slaughtered, compensation to the extent of one quarter of the estimated value of the animal being paid to the farmer where advanced tuberculosis is discovered. Where tuberculosis is manifest but not advanced three quarters of the value will be paid — in each case half the cost of the valuation and examination to be deducted.

This is an important move in protecting the public, especially children, from tuberculous milk and meat, as unfortunately a fairly large percentage of tuberculous milk is now marketed ; indeed some recent figures of extensive analyses made of London's milk supply showed no less than 10 per cent. of the supply as containing the tubercle bacilli. Municipal authorities can exercise powers to prevent the entrance of milk in towns from any source when it is proven to be tuberculous, but such powers are seldom used. Whilst the Tuberculosis Order will doubtless in a few years result in the killing off of most badly tuberculous cattle, there will still remain the animals that are apparently healthy but are really tuberculous as shown by the tuberculin test. In several instances private enterprise has embarked upon the supply of milk solely from cows which have passed the tuberculin test and are kept periodically tested, which is the only sure way of obtaining a milk supply guaranted free from tubercle germs.

This alone is not the only part of the scheme, as if milk is obtained pure from healthy cows it must not be allowed to get contaminated from human infection afterwards and before it reaches the consumer, and to prevent this it must be handled and distributed under proper hygienic conditions. There is a minimum Government standard of quality which specifies that if milk contains less than 3 per cent. of fat and 8.5 per cent. of solids-not-fat it is presumed, until the contrary is proved, that the milk is adulterated.

The law also prohibits the use of any chemical preservative whatever in milk, though harmless colouring matter is not debarred. Recently too the use of preservatives in cream has been restricted and it is now illegal to add any preservative whatever to cream containing less than 40 per cent.of fat. If cream containing over 40 per cent. fat is preserved, only borax, boric acid, and hydrogen peroxide are permitted to be used, and all receptacles in which such preserved cream is sold must have affixed to them a label printed in letters of a specified size varying with the size of the vessel, stating the preservative used, and if borax or boric acid or both be present, the percentage expressed in terms of boric acid must be stated on the labels. Restaurants and Refreshment Rooms serving preserved cream are required to display notices to this effect.

Appendix.

TABLE I. — *Number of churns of milk delivered daily at London railway stations by the various railway companies in* 1907.

	No.
Great Western Railway	3 999
London and South-Western Railway	2 477
London and North-Western Railway	1 670
Great Northern Railway	1 153
Midland Railway	1 094
Great Eastern Railway	952
London, Brighton & South Coast Railway	941
South-Eastern & Chatham Railway	377
Great Central Railway	175
North London Railway	122
Metropolitan Railway	50
West London Extension	16
Total	13 026 churns

or 13 026 × 17
= 221 442 gallons

Approximately therefore the amount of milk reaching London daily by rails is 221 442 gallons and the quantity brought to London by road or produced in London is small.

The North-Eastern Railway Company has kindly supplied the following figures for the imports of milk into Newcastle during 1911: estimated number of gallons 1 952 502. As this City has a population of 266 603 this means roughly 7.3 gallons per head, but it should be taken into consideration that the milk arriving by rail is by no means all the milk received in Newcastle, as a large number of farmers in the district convey to and retail milk in the City.

SECOND PART.

ABSTRACTS

AGRICULTURAL INTELLIGENCE

GENERAL INFORMATION.

698 – **Legislation for the Protection of Moors in Germany.** — *Landwirtschaftliches Wochenblatt für Schleswig-Holstein, amtliches Organ der Landwirtschaftskammer*, Year 64, No. 18, pp. 405-406. Kiel, May 1, 1914.

LEGISLAT
AND ADM
STRATIV
MEASURE

The law of March 4, 1913, for the protection of moors in the province of Hanover has been extended (April 1, 1914) to the provinces of Pomerania and Schleswig-Holstein.

The object of the law is to prevent the uneconomical exploitation of the moors. It prescribes that plots of land which alone or with others form a compact area of moor more than 25 ha. (62 acres) in extent, so far as public interest requires it, can only be worked for peat in such a way as to ensure their further profitable use for agriculture or forestry.

The use of such plots for cutting out of peat requires the authorization of the district committee, for which an application has to be made. Before granting the authorization a competent office to be nominated by the Minister of Agriculture, Domains and Forests has to be consulted, as well as the Improvements' officials. If requested, an expert named by the applicant has also to be heard. Against the decision of the district committee the applicant may appeal within two weeks to the Minister of Agriculture. Undertakings which had already begun cutting out peat before the law had come into force may continue to work for six months longer without being subject to the limitations of the new law.

The authorization to cut out peat is not required when the peat is used in the household or farm of the owner, farmer, or person entitled to excavate peat or of an agricultural labourer under permanent engagement to the owner of the peat bed, when his agreement authorises him to cut peat for his own household or farm. Further the authorization is not required when the peat is cut for sale, provided such cutting be conducted by not

more than six persons and without machinery. The district police, however, may issue regulations with regard to peat cutting in order to safeguard the interests of agriculture or forestry.

699 – **Experiments with Plots of Different Sizes** (1). — SCHNEIDEWIND, in *Mitteilungen der Deutschen Landwirtschafts-Gesellschaft*, Year 29, Part 21, pp. 298-300. Berlin, May 23, 1914.

Experiments have been undertaken at the experimental farm at Lauchstädt, with the object of comparing the yield from different sized and differently arranged plots, and the influence of manuring on the respective yields. The plots have been laid out on a very uniform piece of land, and the experiments, which are to be continued for a considerable time, are arranged as follows.

I. 30 plots of 9 sq. metres (10 $^3/_4$ sq. yds.) each, adjoining one another without intervals.

II. 20 plots of 9 sq. metres each, in the form of a square with an unplanted margin 80 cm. (31 in.) wide all round.

III. 18 plots of 100 sq. m. (120 sq. yds.) each adjoining one another, without intervals, and without any unplanted borders.

IV. 6 plots of 200 sq. m. (240 sq. yds.) each, but otherwise resembling Group III.

In 1913 sugar-beets were sown on the plots. One row of plots in each of the four groups received 1.6 cwt. and one row 3.2 cwt. of nitrate of soda per acre, while the third received no nitrogenous manure.

The returns are only complete for Groups I, II and IV. The yield of the plots with borders round them (Group II) was, in the "unmanured" cases, superior to that of Groups I and IV (without borders) by about 4 tons an acre of fresh roots.

The nitrogenous manure had less effect on the plots with borders, where more nitrogen and moisture were available for the plants on account of the free space, than on the other areas : while 3.2 cwt. of nitrate of soda per acre produced on the Group I plots an increase of about 2 tons of roots an acre, and on those of Group IV an increase of about 37 cwt., a similar dressing only gave an increase of 23 cwt. on the plots with borders. The results obtained from the 1.6 cwt. per acre dressing of nitrate of soda do not agree satisfactorily with the above.

700 – **The Work of the Buitenzorg Botanic Gardens for 1913.** — DE JONG, A. W. K. in *Mededeelingen van het agricultuurchemisch laboratorium*, No. VII, pp. 1-49. Batavia, 1914.

The experiments carried out at the Botanic Gardens in Buitenzorg during 1913 led to the following conclusions.

1. Earthnuts ploughed in green not only increase the following rice crop but also the next earthnut crop taken after the rice.

2. The largest increase with manioc was obtained when complete manures were used, but nitrogenous manures alone were almost as efficient.

(1) See No. 795, *B.* July 1913. (*Ed.*).

3. No increase was obtained in crops of sweet potato, lemon-grass and earthnut when dung was added to potassic fertilizers.

4. Earthnuts grown continuously on the same field appear to become more resistant; the number of dead plants gradually diminishes.

701 – **Formation of an Agricultural Office for Tripoli.** — *Bollettino di Informazioni dell'Ufficio Economico del Ministero delle Colonie*, Year II, No. 4, pp. 271-273. Rome, April 1914.

The Royal Decree of March, 1914, instituted an Agricultural Office in Tripoli for the purpose of carrying out experiments of a technical and economic nature in that country and to study the means of encouraging the native agriculture and colonisation. The office comprises:

a) an experimental section, technical and economic;

b) an administrative section;

c) a section including the meteorological, engineering, statistical and other departments necessary for the development of the Office.

The staff of the Office may be chosen from amongst Civil Servants or from private individuals possessing the required qualifications and will be made up as follows:

	No.
Director	1
Heads of the administrative and technical departments	2
Technical experts	4
Secretary	1
Laboratory assistants	4
Field men	4
Labourer	1
Porter	1

In accordance with the suggestion made by the Commission appointed to investigate the agricultural conditions of Tripoli, the Minister of the Colonies has decided to let experimentation precede demonstration and the giving of advice, with regard to both technical and economic questions. The first director to be appointed to the office is Prof. De Cillis, from the Royal Agricultural College at Portici, Naples, and he will also form part of the Government Commission for investigating the agricultural conditions of Tripoli.

CROPS AND CULTIVATION.

SOIL PHYSICS, CHEMISTRY AND MICROBIOLOGY

704 – **Separation of Soil Particles according to their Specific Gravity, and the Relations between Plants and Soils.** — KÖNIG, J. (Report from the Agricultural Experiment Station at Münster-in-Westphalia), in *Landwirtschaftlicher Jahrbücher*, Vol. XLVI, Part 2, pp. 165-251. Berlin, 1914.

I. *Separation of Soil Particles according to their Specific Gravity.*

The writers have separated out the constituents of seven soils by means of liquids of different specific gravities; the liquid used was a mixture of bromoform and benzol, which may be considered as without action on soils. The separation was carried out at first by shaking followed by settling till the liquid was clear, the floating particles remaining at the surface and the remainder at the bottom; subsequently an improvement was made by centrifuging the liquid for 10 minutes instead of allowing it to stand. Altogether four of the mixed liquids were used, with S. G. 2.36, 2.49, 2.55 and 2.64, giving five soil fractions. Two of the soils (one clay and the other schistose) could not be separated by shaking and settling, in the case of the schistose soil owing to the constituents being practically uniform; it was also found that organic material adhered to the heavier particles and could not be separated even by continued shaking. With the help of the centrifuge the separation was better, and even the clay and schistose soils could be dealt with.

Physical and chemical examination of the five fractions led to the following general conclusions:

1. The facility or otherwise of the separation is an indication of the heterogeneity or homogeneity of the soil. The clay gave none of the two heaviest fractions (I and II) even on centrifuging, while the lightest (fraction V) amounted to only 1.08 per cent. Of other soils, those containing plenty of humus and colloids give considerable amounts of the lighter fractions, whilst preponderance of the heavier fractions indicates a soil lacking in humus and therefore of low fertility.

2. Fraction I (S. G. more than 2.64) is almost lacking in clays; in the sand, the loamy sand, the loam and the calcareous soil it does not exceed 1 per cent., while in the schistose soil it reaches 7.3 per cent. It consists largely of silicate fragments.

3. Fraction V (S. G. less than 2.36) contains large quantities of organic matter, as well as the bulk of the colloids and nutritive substances of use to plants.

4. It should be noted that fraction V (or in general the fractions containing most nutritive material) also contains the largest amount of silicic acid, iron oxide and alumina, *i.e.* colloids; the humus is so intimately connected with these minerals that it cannot be separated from them mechanically. This tends to support the view arrived at in previous work that the humus in the soil is present, at any rate in part, in the form of complex humate-silicates.

5. Comparison of the five fractions shows that in all four soils examined in detail (sandy garden soil, calcareous soil, loam and sand) there is an almost regular rise in the relative amount of nutritive material from I to V or at any rate from II to V.

8. The distribution of clay (*i.e.* the portion of the soil freed by sulphuric acid) in the different fractions varies with the type of soil.

II. *The Relations between Plants and Soils.*

Culture experiments have been in progress since 1904 in connection with the work on the investigation of the soil (1), especially with a view to determining the relation between the amount of dry matter produced and such properties of the soil as catalytic energy, nutritive material freed by oxidation, or by steaming under pressure, osmotic pressure, colloid content and oxidizing power. Six types of soil (sand, schistose soil, clay, loam, calcareous soil, and sandy loam) were used, and the experiments were made both in the open and in pots under glass.

During these investigations the following points were elucidated:

1. The plants grown in pots under glass generally gave higher yields for a given area than those growing in the open, but the difference in the experiments was not so great as in many conducted elsewhere.

2. In hot dry summers, the absorption of minerals, particularly phosphoric acid, may be much greater than in cool rainy ones, but this is not necessarily associated with increased production of dry matter. The increased absorption of phosphoric acid in hot dry weather is no doubt due to increased oxidation, and consequently increased solubilisation, of the phosphoric acid in organic combination, owing to increased penetration of air into the soil.

3. The relations between the principal nutritive elements absorbed and the dry matter produced are shown in the accompanying table:

Conditions of experiments		Parts of dry matter produced for 1 part of:					
		Nitrogen		Phosphoric acid		Potash	
		Limits	Average	Limits	Average	Limits	Average
10-year average for six soils	under glass	59–65	62	—	177	38–86	69
	in the open	57–62	59	137–176	161	36–57	48
In the very good garden soil		31–67	49	79–153	109	30–83	47
Previous experiments under various conditions		30–82	57	92–272	169	29–94	61

For lime, the ten-year averages gave figures ranging from 61 to 100, average 83. It appears that the following values may be used for determin-

(1) Published in *Landw. Versuchs-Stationen*, 1907 to 1913.

ing the necessity of manuring for any particular soil (using averages of the various crops) :

	Relative dry-matter value: Minimum below which manure is not required	Maximum above which manure is required
Nitrogen	50	62
Phosphoric acid	100	170
Potash	47	60

Individual crops show marked deviations, as shown by the following values for potash :

Cereals	73
Potatoes	38
Red clover	37
Mangels	29

For lime, red clover gives a value of 31, while the average of the other field crops is 126.

4. The general relations of the four nutritive materials to one another in the dry matter of plants are :

N	P_2O_5	K_2O	CaO
100 :	35 — 40 :	130 — 140 :	75 — 80

Here again there are deviations for individual crops, in particular Leguminosae ; thus the P_2O_5 per 100N is only 19 for red clover against 44 for the other crops and 56 for mangels.

5. The sum of potash + lime is fairly constant, being 3.0 to 3.5 per cent. of the total dry matter.

6. Unbalanced manuring with potash and phosphates, in soil not requiring these elements, and especially in time of drought, may reduce the amount of dry matter produced.

7. In all the soils except the sandy loam, very good correlation has been established between the amount of dry matter produced by the plants and the following chemical or physical properties of the soil :

a) amount of ammonia absorbed (Knop) ;

b) amount of potash and phosphates absorbed (M. Fesca) ;

c) hygroscopicity (A. Mitscherlich) ;

d) absorption figure for methyl-violet ;

e) osmotic absorption of water ;

f) electrolytic conductivity (the last three in the Münster investigations).

8. The best method for determining the amount of potash available for plants is steaming the soil for 5 hours under a pressure of 5 atmospheres. In the individual experiments as well as in the 10-year average the amount of soluble potash down to a depth of 6 to 8 in. determined in this way was very near the amount taken up by the plants.

It may be concluded that soils giving only 5 mgms. of potash soluble in this way per 100 gms. of soil require potash manuring, while soils

containing more than 8 mgms. do not require it. Here again, of course, individual crops vary, beets and clover taking more than the amount considered " available ".

9. The " available " phosphoric acid determined by various methods does not show any close agreement with the amount taken up by plants : it appears that the higher the content of the soil in lime, magnesia, iron oxide and alumina, the more difficult is the absorption of phosphoric acid. Weather and plant-species are also of importance. At the same time it may be said that soils giving less than 4 mgms. of phosphoric acid per 100 gms. of soil by the steaming method, require phosphatic dressings.

10. For nitrogen and lime no definite relation between the absolute quantity in the soil and the quantity absorbed by plants has been determined.

11. Application of either the electrolytic conductivity or the steaming under pressure method before and after the culture period is useful for determining the amount of nutritive material removed from the soil by the plant. In these experiments, the amount of phosphoric acid taken up ranged from 23 to 34 per cent. (average 29 per cent.) of that in a soluble condition after steaming.

705 – **Rocks and Soils in their Relation to the Nutrition of Plants.** — BLANCK, E. in *Die landwirtschaftlichen Versuchs-Stationen*, Vol. LXXXIV, Part V and VI, pp. 399-425. Berlin, 1914.

The writer has carried out vegetation experiments with eruptive rocks and crystalline schists having the following percentage composition:

	Quartzite schist	Porphyry	Granite		
			1	2	3

The material used in the experiments consisted of unweathered rubble as it comes from the quarry. It was then crushed so that it resembled more or less fine-grained groats and in this form it was placed in the culture pots. As experiment plants, oats and peas were used. No manure was

given, except 0.1 gm. of ammonium sulphate for the oats. The peas received a solution of soil in which peas had grown, so as to inoculate the nodule bacteria. Thus the action of any artificial manure on the components of the rocks may be said to be practically non-existent.

The results of the experiments are summarized as follows by the writer :

1. The four igneous rocks examined, namely three granites and a porphyry, proved superior to the quartzite schist in the crop of oats and peas, but the plant food contained in the quartzite schist was much better utilized than that contained in the igneous rocks.

2. These experiments have demonstrated that mica-potash, especially biotite-potash, is much more accessible to plants than the potash of felspar.

3. Sandstones, according to previous experiments made by the writer, are much more suitable for the growth of plants, both for the amount of yield and for the utilization of the plant food, than quartzite schist, granite or porphyry.

706 – **A Further Case of Soil Sterility in the Dutch East Indies.** — Ledeboer, F. and Berkhout, A. E. in *Mededeelingen van het Proefstation voor de Java-Suikerindustrie*, Year XXII, No. 18, pp. 653-672. Surabaya, May 1914

Soil sterility due to the presence of excessive quantities of chlorides and sulphates is a well-known phenomenon in the Dutch East Indies ; such salts are probably derived from flooded craters ; but a case of sterility has recently been investigated from the Pemalang district which revealed the presence of large quantities of soda mostly in the form of carbonate ; the percentage being much higher than that given by O. Maior (1) for sodic soils at Sipote (Jassy). This large quantity of soda accounts for the curious character of the Java soil : when it rains the soda forms adsorption compounds with the soil colloids, thus producing hydrogels, then dries out very slowly, undergoing such a large decrease in volume that cracks appear at the surface.

Manurial experiments have already proved that the addition of 1.2 per cent. of quicklime produces a wonderful improvement, while the addition of 3.6 per cent. injures the vegetation but completely changes the structure of the soil, as the lime displaces the soda in the colloidal compounds and causes flocculation. Gypsum employed in similar cases in America and India gave even better results, as the sulphuric acid formed neutralizes the alkali which is injurious to plant roots.

Analyses of subsoil water revealed a content of 492 mgm. of sodium carbonate per litre, showing that the soda comes from the subsoil.

707 – **Relations of Certain Higher Plants to the Formation of Nitrates in Soils.** — Lyon, T. Lyttleton and Bizzell, James A. in *Cornell University Agricultural Experiment Station, Memoir* No. 1, pp. 9-109. Ithaca, N. Y., 1913.

The relation of timothy grass to the nitrogen content of the soil has been studied for six years at the Experiment Station at Cornell University.

(1) Die Salzböden Rumäniens, *Kühn Archiv*, Vol. I, p. 426.

During 1907, 1908 and 1909 nitrate determinations were made of samples of soil taken from field plats under timothy, maize and oats in rotation. The results obtained were no doubt considerably influenced by the heavy clay soil, which made the movements of nitrates very slow and hence emphasized the relationship between the plant at any particular stage of growth and the nitrate content of the soil.

Each plat was divided into sections, of which one was always kept bare but received the same soil treatment as the planted sections of the plat, thus permitting a constant comparison of the nitrates in the planted and the unplanted sections.

It was found that : 1) The nitrate content of soil under timothy, maize, potatoes, oats, millet and soy beans was different for each crop when on the same soil and there was a characteristic relationship between the crop and the nitrate content of the soil at different stages of growth.

2) During the most active growing period of the maize crop, nitrates were frequently higher under maize than in cultivated soil bearing no crop, and under a mixture of maize and millet, nitrates at this period were higher than under millet alone, although the crop yields were about the same on both plats.

3) Under both maize and oats the nitrate content was higher during the period when the crop was making its greatest draft on the soil nitrogen than in the later stages of growth, but under these crops and under millet there was no increase in nitrates late in the season when nitrogen absorption had practically ceased, although uncropped soil showed a very large increase in nitrates at that time.

4) Changes in the moisture content or in the temperature of the soil after early summer had no important effect on the nitrate content of the soil under crops.

These phenomena may be accounted for on the assumption that nitrate formation is stimulated by some processes connected with the active growth and absorbing functions of some higher plants, particularly of maize. This, together with the fact that the maize plant probably obtains a large part of its nitrogen in some form other than as nitrates, would account for the very high nitrate content of the soil under maize. The differences in the production of nitrates below different crops would be accounted for by supposing differences in the stimulating or inhibiting influences on nitrification, as well as in the relative rates, amounts and forms of nitrogen absorption.

The nitrifying power of the soil under different conditions of cultivation was determined by incubation with dried blood.

It was found that : 1) The rate of nitrification of alfalfa soil was greater than that of timothy soil ; this effect was maintained for two years after removal of the crop.

2) There is a distinct relation between the nitrifying power of a soil and the nature of the crop previously grown.

3) Nitrates were most abundant after a maize crop, the next highest being after a potato crop and the least after oats.

4) Freezing and thawing renders the soil more favourable to nitrate formation, but it is not known if this effect is due to the cold readjusting the equilibrium of the bacterial flora, or overcoming the depressing influence of some previous crop.

5) Timothy grass maintains a lower nitrate content in the soil than any other crop, and mixed grasses gave much less nitrogen in the crop and drainage water combined than was found in the drainage water from unplanted soil. This would suggest a possible explanation of the injurious effect of grass sod in orchards in which the supply of nitrogen is deficient. The influence of a crop on nitrification may be an important factor in crop rotation also.

708 – **Chemical Composition of Moor Hay provoking Excessive Licking in Cattle.** — *Communication from* HJALMAR VON FEILITZEN, *Director of the Experiment Station of the Swedish Moor Cultivation Union.*

A former field agent of the Swedish Moor Cultivation Union reported that hay from a meadow sown down on fen land had proved injurious as winter fodder for cows : they lost their appetite and fell off in condition, some even having to be slaughtered.

An investigation of the fen in question was made by the Station. The first cut had given 2 tons of hay per acre, although the farmer had given it only a light dressing of manure: 1 ¼ cwt. per acre each of super and 38 per cent. potash salts. Samples were taken from the injurious part of the 1912 hay, as well as from a fen hay and a mineral-soil hay of the 1913 crop; unfortunately no 1912 hay from a mineral soil could be had.

A botanical examination showed no marked differences : all three samples consisted of nearly pure timothy (97.6t o 97.8 per cent.), with a little smooth-stalked meadow grass, red fescue, fiorin (*Agrostis*) and foxtail ; the hay from the mineral soil contained some red and alsike clover (2 per cent.). The fen hay contained one or two pieces of *Potentilla erecta*, *Rubus saxatilis* and *Spiræa Ulmaria*. The only marked feature of the fen hay was the presence of a few brown tips to the leaves.

A thorough chemical analysis was made, comprising determination of fat, crude fibre, crude, pure and digestible protein, lecithin, ash constituents (iron oxide, alumina, lime, magnesia, potash, sodium, phosphoric acid, sulphuric acid — also sulphur in organic combination — and chlorine) ; but no defect was found in the fen hay. Naturally the total ash was higher in the hay from mineral soil ; the fat content was also somewhat higher ; fibre was rather more in the fen hay, no doubt owing to later cutting. Protein was highest in the 1912 fen hay, rather lower in the 1913 sample; digestible protein was also highest in the 1912 sample provoking " Lecksucht " (excessive desire to lick) ; indeed the feeding value shown by analysis was better in this than in the hay from mineral soil.

Of the individual ash constituents, potash was lower in the fen hay than in the mineral-soil hay ; a heavier dressing of potash would have been advisable, but that insufficient manuring cannot have caused the toxicity is shown by the fact that the normal 1913 fen hay contained even less potash than the 1912 sample. The " Lecksucht " hay contained considerably

more sodium than either of the other samples, but this cannot be considered a disadvantage since it is usual to add salt to the rations. The phosphoric acid was very low in all three samples (in hay with 15 per cent. moisture, 0.295, 0.177 and 0.293 per cent., as compared with 0.35 to 0.40 per cent. in normal Swedish hay samples), so that this cannot have been the cause; the phosphorus in organic combination as lecithin and other phosphatides is also very low (0.014 and 0.012 per cent. P in the fen hays, and 0.020 in the mineral-soil hay), but here again the slight differences are of no significance on such small quantities. Of the other constituents, only chlorine is rather high in the "Lecksucht" hay (1.05 per cent. against 0.42 and 0.50), but this of course goes with the high sodium content.

Comparative chemical analysis therefore shows no reason for the injurious properties shown by this particular fen hay.

TILLAGE AND METHODS OF CULTIVATION

709 – **Tillage Experiments in Algeria** (1). — *Bulletin de l'Office du Gouvernement Général de l'Algérie*, Year XX, No. 11, pp. 178-179. Paris, June 1, 1914.

Tillage experiments were carried out at the Agricultural School of Maison Carrée in 1913, and it would appear from the results that no advantage was gained by subsoiling the land the previous autumn; in fact, in many cases the crops of hard wheat obtained on the subsoiled plots were inferior to those on the control plots.

710 – **Trials of the Zehetmayr Method of Drilling Cereals carried out in Sweden** (2). — RHODIN, SIGURD in *K. Landtbruksakademiens Handlingar och Tidskrift*, Year LIII, No. 2, pp. 94-105. Stockholm, 1914.

The Zehetmayr method of drilling consists in planting the seed at the bottom of small furrows which serve as a protection during the winter and are flattened out in the spring by means of a special harrow. Trials of this method at the Central Agricultural Institute in Sweden did not give the good results expected; in fact in many cases the yield was lowered where this method was adopted. The failure is probably due to the mechanical condition of the rather heavy soil, a fine tilth and free working soil being necessary in order that the drill should work satisfactorily.

MANURES AND MANURING

711 – **The Influence of Lime as Quicklime and Carbonate on the Physical Condition of Various Soils.** — ENGELS, O. (Speyer Agric. Exp. Station) in *Die landwirtschaftlichen Versuchs-Stationen*, Vol. LXXXIII, Part 5 and 6, pp. 409-466. Berlin, 1914.

Experiments have been carried out as to the effect of lime in a number of types of soils: in each case soil treated with 1 per cent. of quicklime was compared with that receiving 1 per cent. of calcium carbonate and with untreated soil.

Measurements were made of the various physical properties. In general quicklime had a more marked action than the carbonate; the increase in water capacity, permeability, hygroscopicity and friability and the decrease in contraction on drying were greater in soils containing more clay, whereas the decrease in capillarity due to liming was greater in the sandy soils.

(1) See also No. 1707, *B.* June 1911; No. 2098, *B.* July 1911. (*Ed.*)
(2) See No. 1272, *B.* April 1911; No. 403, *B.* April 1913. (*Ed.*).

712 – **Influence of Straw on the Utilization of the Organic Nitrogen of Manures.** — Von May, F. in *Mitteilungen der landwirtschaftlichen Lehrkanzeln der k. k. Hochschule für Bodenkultur in Wien*, Vol. II, Part 3, pp. 433-454. Vienna, May 15, 1914.

On the effect of straw as a manure there are a great number of papers in agricultural literature. In most cases experiments on the subject have shown that manuring with straw is followed by a diminution of the crop, after which some increase may be observed in the succeeding year. Most of these experiments have been carried out in pots or on very small plots in the open. The writer has sought as far as possible to carry out his experiments under field conditions.

The two experiments here reported upon dealt with the behaviour of the plants immediately after being manured; their results are summarized by the writer as follows: The utilization of a given quantity of organic nitrogen by plants grown immediately after an application of manure suffers a depression when a substance lacking nitrogen (in this case straw) is added. The magnitude of this depression depends principally upon the ratio between the available nitrogen and the nitrogen-free organic matter, which in its turn depends upon the ratio between the composition of the manure and the quantity of nitrogen in the soil. The more this ratio varies in favour of the nitrogen-free matter the greater the depression, and under the same circumstances those plants which require their nitrogen in the shortest time suffer most. The cause of this fact is attributed to the withdrawal of soluble nitrogen by the micro-organisms of the soil, which avail themselves of the nitrogen-free organic matter as a source of energy.

713 – **On the Action of Sulphate of Ammonia and Superphosphate of Ammonia in Calcareous Soils.** — Wlodeck, J. (Institute of Agriculture of the Jagielli University, Cracow) in *Odbitka z czasopisnia Kosmos zeszyt* 10-12 *z. r.* (Article in German). Lemberg, 1913.

Two field experiments were made on calcareous and sandy soils at the Experiment Farm of the Jagielli University, of Cracow, to determine the losses of nitrogen in manuring with sulphate of ammonia and to test the effect of superphosphate of ammonia in calcareous soils. The plants used in the experiments were cereals.

When the crops obtained in these experiments on calcareous and sandy soils are compared with those obtained by the use of nitrate of soda taken as 100, the following ratios are obtained:

	Calcareous soil	Sandy soil
Nitrate of soda	100.00	100.00
Superphosphate of ammonia	91.33	91.33
Sulphate of ammonia	76.49	99.85
Without nitrogen	70.50	78.85

The action of superphosphate of ammonia was thus the same in the two kinds of soil, while that of sulphate of ammonia was lower in the calcareous soil than in the sandy one. The writer comes to the conclusion that when conditions are very favourable to the volatilization of ammonia losses up to 20 per cent. occur, and that these losses can be avoided or considerably reduced by using superphosphate of ammonia.

714 - **The Utilization of Peat in Italy.** — Summary of a Lecture by Prof. UGO ROSSI given at a meeting of the Association of Italian Agriculturists, April 20, 1914. — *Società degli Agricoltori Italiani, Bollettino quindicinale*, Year XIX, No. 10, pp. 356-361. Rome, May 31, 1914.

Several of the more important peat beds in Italy have been worked chiefly with a view of utilizing the peat as fuel. Most of the peat is however too poor to compete with imported coal, hence the lack of success of all such undertakings even where they were connected with land reclamation schemes. Attempts have also been made to use peat for other purposes, such as litter, packing and isolating material, etc., but the quantities thus used are too insignificant to be of any economic importance. Of late, however. the nitrogen contained in peat has attracted considerable attention ; this nitrogen is practically in an inert condition in the raw material and in order to utilize peat successfully as a manure, the nitrogen must be transformed into a more active compound such as a salt of ammonia.

The idea of subjecting peat to the water-gas process was suggested by Dr. L. MOND and the first plant erected for the purpose was that at Orentano in the province of Lucca, Italy ; it has since been much improved by the addition of plant for preparing and drying the peat. The next important works of the kind were those at Osnabruck (Hanover) under the direction of Drs. FRANK and CARO, but owing to the difficulties connected with the preparation and drying of the peat, these works may be considered as being still in the experimental stage, as are other works started in England. The last works to be erected were those at Codigoro, Italy, where all difficulties have been successfully overcome. In fact the only two important undertakings for the utilization of peat are those of Orentano and Codigoro belonging to the " Società per l'utilizzazione dei combustibili italiani ".

The process adopted for treating peat is the following : The peat, properly dried and broken up, is thrown into a turret-shaped oven 26 to 33 feet high, called the gas oven, which is fed at intervals from the top. The peat burns only in the lower part of the turret, the combustion being regulated by a jet of hot air and steam. The water vapour decomposes on the incandescent mass, producing, together with the other combustion gases, the so-called water gas, or in this case Mond gas, which collects in the top of the oven. It is produced at the lowest possible temperature and the nitrogen evolved from the peat combines with the nascent hydrogen and forms ammonia. The gas thus produced is then washed to free it from the tarry products it contains and led into a leaden chamber where it is met by a spray of sulphuric acid which converts the ammonia into sulphate, while the remaining gas is purified,

cooled and burned under the steam boilers, in the drying ovens or in gas motors. In this way about three-quarters of the quantity of nitrogen contained in the peat is converted into sulphate of ammonia. A peat containing 2.5 per cent. of nitrogen yields about 175 lbs. of sulphate of ammonia to the ton.

The first factory was erected at Orentano in 1907, but only began to work in 1910. At first the peat was dried in the open, but as this system proved quite unsatisfactory artificial drying was resorted to. Peat taken from the pit contains 50 per cent. by weight of water, and this quantity is now most successfully reduced to 25 per cent.

At present 1800 cu. ft of peat can be treated daily, yielding 50 tons of sulphate of ammonia per month, and before long the output will be doubled. The gas is used in the works and at a central station developing about 800 H P.

The results obtained at Orentano encouraged the company to erect large works at Codigoro (Ferrara, Italy) in 1912 ; these are now capable of dealing with 150 tons of dried peat daily and of turning out from 10 to 12 tons of sulphate of ammonia per day. The peat beds at Codigoro are upwards of 2500 acres in extent. The Company has already spent £240 000 on the two factories, but it can now produce sulphate of ammonia at 4*s* 10*d* to 5*s* 7*d* per cwt. while the market price is above 12*s* per cwt.

715 – **Talbot Slag**. — DAFERT, O. in *Zeitschrift für das Landwirtschaftliche Versuchswesen in Oesterreich*, Year XVII, Part 5, pp. 301-302. Vienna, May 1914.

The " Talbot slag " obtained in the manufacture of steel by Talbot's process differs very little in outward appearance from ordinary basic slag.

According to the results of four analyses its composition varies as follows :

	Talbot slag		Basic slag. Average according to F. W. Dafert	
	Range per cent.	Average per cent.	I (*) per cent.	II (**) per cent.
Mg O	3.75 – 4.60	4.25	2.97	—
Ca O	45.70 – 50.42	48.10	47.33	45.26
Mn O	3.50 – 6.46	4.91	4.51	6.44
$Al_2 O_3$	3.58 – 7.48	5.28	1.87	—
Fe O	5.45 – 9.23	7.34	10.85	—
$F_2 O_3$	2.75 – 7.35	5.25	5.38	—
$Si O_2$	8.86 – 10.04	9.48	8.34	8.83
$P_2 O_5$	14.01 – 17.90	15.99	17.38	18.49
S	0.22 – 0.88	0.51	0.42	—
$S O_3$	traces – 0.16	0.08	0.28	—

(*) According to an older analysis. — (**) According to recent analysis.

The citric-acid-soluble phosphoric acid ranges from 74.2 to 90.1 or an average of 81.3 per cent. of the total phosphoric acid ; it is thus within the usual limits of basic slag, from which it does not appear to differ much as a fertilizer. Manurial experiments now being carried out at the Vienna Experiment Station for Agricultural Chemistry will soon settle this point.

716 - **The Effect of one Crop upon Another.** — The Duke of Bedford and Pickering, S. U. in *Journal of Agriculture Science*, Vol. VI, Part 2, pp. 136-151, + 1 plate. Cambridge, May 1914.

The writers review the results of the investigations on the effect of growing grass over the roots of fruit and other trees carried out at Woburn since 1895, and give an account of recent work on the effect of grasses and clover on various crops and on each other. In addition to field experiments, trees were grown in pots fitted with annular trays. Both metal and earthenware trays were used. The ratio of the weight of soil in the pot to that in the tray was 31.9 and the relative surface of the grass-grown soil in the tray to the surface of the pots was 1:2. All the water required to keep the pots up to a given weight was put into the trays. The dry weight of the matured crops was used to determined the effect of the different conditions.

Out of 23 instances only four showed a favourable effect and in 12 instances the effect of grass in the trays was to reduce the crop in the pots to an average of about one-half. The reduction varies with the crop, tobacco being more sensitive than tomatoes and mustard, and these more sensitive than barley. In the case of tobacco the amount of the reduction was proportional to the growth of grass, and, in a former experiment where the effect of 18 different grasses on apple trees was examined, the magnitude of the effect was found to vary with the vigour of the grasses.

Since the smaller crops (*i.e.* those in the pots below the grass-grown trays) remove less nitrogen from the soil, the soil in these pots should be richer in nitrogen than those without grass. Analysis of the soils showed this to be the case. Therefore the reduction in the growth of the crops under grass must be due to some toxic substance which reduces the power of the crop to utilise the available plant food.

Removal of the trays containing grass before maturity resulted in a great increase in the growth of the crop, so that the plants not only made up for lost lee-way, but actually outstriped those without grass. This effect was undoubtedly due to the destruction of the toxic substance by oxidation with the formation of beneficial products. Leachings from growing grass, if oxidised, were found to be beneficial instead of toxic, and it has been found that soil removed from grassed ground is more favourable to the growth of trees than that from similar tilled ground. Further, it is possible that partial grassing might have a beneficial effect, when the grass is at such a distance from the tree roots that the toxin becomes oxidised before reaching these roots. This was found to be the case at Woburn : apple trees with grass at a distance of 3 ft. from the stems grew more rapidly for a time than trees with grass 6 ft. away or with grass up to the stems.

Recovery from the toxic effect may not always occur, for this effect may produce permanent injury, especially in the case of hard-wooded plants.

The toxic effect between the same plants is greater than that between different plants. Also, the toxic effect of heating a soil is much greater than that produced by the growth of a crop in both cases the toxin, after oxidation, increases the fertility of the soil. There is therefore no reason for assuming that the toxin is an excretion from the plant, the debris from the growing roots being probably sufficient to account for its formation.

717 – **The Action of Certain Nutrient and Non-nutrient Bases on Plant Growth** (1). — McCool, M. M. in *Cornell University Agricultural Experiment Station, Memoir* No. 2, pp. 121-216, figs. 1-15. Ithaca, N. Y., August 1913.

I. *The antitoxic action of certain nutrient and non-nutrient bases with respect to plants.*

An extensive series of experiments has been made on the toxic and antidotal action of various ions on plant growth, particularly with respect to the elongation of the roots of seedlings. The chief conclusions of these experiments are as follows:

1) Each of the following radicles (in the order given) is poisonous to seedlings: Ba, Sr, NH_3, Mg, Na, K.

2) Mutual antagonism exists between the following pairs of cations when present together in solution:

Mg and Sr	Na and K
K and Sr	Na and NH_3
Na and Sr	K and Ba
Mg and Ba.	

3) Calcium is the most effective of any of the substances studied in preventing toxic action.

4) Protective action is not confined to the so-called essential nutrients; Na, Sr and Ba (the non-essential ions) also possess this property.

The injurious action resulting when unbalanced conditions prevail, and the importance of calcium in correcting this action, make it probable that in many cases the beneficial effects obtained from calcium compounds are due to antagonistic relations. In any event the general trend of results indicates that where any single fertiliser has proved injurious it would be useful to apply a calcium compound, at least in limited quantity. Various theories have been advanced regarding the causes of antagonistic action between different ions, and the writer has made experiments which show that the permeability of the cell is altered, details of which will be published later.

II. *The toxicity of manganese and the antidotal relations between this and other cations with respect to green plants* (2).

Pure solutions of manganese salts are extremely poisonous to pea and wheat seedlings. The degree of toxicity is greatly reduced in full

(1) See also No. 13, *B.* Jan. 1914.
(2) See also No. 613, *B* July 1914. (*Ed.*).

nutrient solutions and in soil cultures. The injurious action appears chiefly in the upper portions of the plant, chlorosis being the first indication of an overdose. Protection from light diminishes the injurious effects. Calcium, potassium, sodium and magnesium ions are each effective in counteracting the poisonous action of manganese.

III. *The toxicity of various cations.*

Comparative studies of the poisonous action of the chlorides of calcium, potassium, sodium, magnesium, ammonium, barium, strontium and manganese in distilled water, in full nutrient solution and in soil cultures have been made. The concentrations in which no further elongation of seedlings takes place, those in which slight growth occurs and those that result in no injury to seedlings have been determined. Field pea seedlings were employed as indicators and in some cases wheat seedlings were also used. It was found that :

1) Calcium ions are the least toxic and require concentrations only a little lower than those causing plasmolysis to inhibit growth.

2) No appreciable root growth appears in solutions stronger than

$\frac{N}{50}$ KCl, $\frac{N}{75}$ NaCl, $\frac{N}{500}$ $MgCl_2$, $\frac{N}{1000}$ NH_4Cl, $\frac{N}{4000}$ $BaCl_2$ and $\frac{N}{5}$ $SrCl_2$.

3) In full nutrient and soil cultures, the lethal concentrations of the various bases with the exception of strontium and barium, are practically identical, namely $\frac{N}{3}$ to $\frac{N}{5}$.

4) Under experimental conditions, much stronger solutions are required to prevent top growth than to kill the roots of seedlings.

5) Seedlings that have grown for 10 days in either distilled water, tap water, or full nutrient solutions, are far more resistant to any toxicant studied than are those that are placed immediately in the toxic solutions.

6) The chlorides of ammonium, magnesium, potassium, and calcium, in the order given, are injurious to germination in pure solutions and in soil cultures. These results suggest that fertilisers should be judiciously applied to soils.

An extensive bibliography and a review of previous work on this subject is also given.

718 – **Edible and Poisonous Fungi from the Nancy District.** — BERTRAND and SARTORY, A. in *Bulletin des séances de la Société des Sciences de Nancy*, Series III, Vol. XIV, No. 2, pp. 82-214. Nancy, April-July 1913.

An account of the edible, poisonous, and innocuous fungi, together with a key for identifying the Agaricineae, Polyporeae, Hydneae, Clavarieae, Lycoperdeae, Morchelleae, Helvelleae and Pezizeae. Vernacular and scientific names are given ; the distribution of the species according to the various soils is discussed ; toxicity, poisons and antidotes are also discussed.

PLANT BREEDING

719 – **Inheritance of the Capacity for Production.** (1) — Roemer, Th. in *Fühlings Landwirtschaftliche Zeitung*, Year 63, Part 8, pp. 257-268. Stuttgart, April 15, 1914.

Opinions are still divided as to the importance of Mendelian laws for breeding practice. The chief reason for this is the prominence given in agricultural breeding work to "performance", that is to the combined action of a more or less complex series of characters of a biological nature, which are much more difficult to observe and test than morphological ones. At the same time, the inheritance of such biological characters has been tested in a considerable number of cases, including: fertility in *Stizolobium*, self-sterility in *Cardamine pratensis* and *Reseda*, pollen sterility in potatoes, size of grain in maize, flintiness and flouriness in wheat and maize, chemical composition of the seed in maize, hardiness in wheat, resistance to cold in *Mirabilis*, flowering-time in peas, production and quality of leaves in tobacco, standing power in wheat, rust-resistance in wheat, time of ripening in wheat, oats, barley and maize, discontinuity in the ear in barley, annual and biennial condition in *Hyoscyamus*, power of growth in ducks, fertility in hens, temperament in dogs, defects of vision (non-traumatic) in horses.

These investigations have shown that there is no essential difference in mode of inheritance between morphological and biological characters. In the splitting up in the second generation, however, biological characters show a preponderance of the ratio 1 : 2 : 1 over the ratio 3 : 1. These biological characters appear to be the expression of a number of units; this makes the investigation of the Mendelian inheritance of the capacity for production very difficult, as numerous slight variations which cannot be successfully grouped arise in the second generation.

From the above, the importance of Mendelism in breeding for productivity is already evident. As a complete analysis of the hybrids according to their capacity for production appears not to be possible, agricultural breeding work cannot make use of Mendelian laws to the same extent as some branches of horticultural work, in which the results of certain crosses can be predicted. At the same time we have to thank the new studies of heredity for the knowledge that in the crossing of two races all the possible combinations of the unit characters borne by each will turn up; further, that an abundant second generation will already show just what can be reached as the result of any particular cross, and that the progeny of an individual is the only sure test of its hereditary disposition and therefore of its breeding value, outward appearance being quite unreliable. These points hold for all types of breeding, while in breeding for productivity the knowledge that we can obtain forms surpassing the more productive of the two parents, and at the same time combining the valuable characters of both parents in a new and favourable manner, is highly important; in practice it allows an improvement in productivity to be obtained by crossing forms of equal productive power, that is to say without having to resort to parents which

(1) See also No. 1547, *B.* Nov. 1912; Nos. 490 and 495, *B.* May 1913; No. 959, *B.* Aug. 1913; and No. 1045, *B.* Sept. 1913. (*Ed*).

may combine extremes of the desired character with insufficient development of other characters of production. As this departure from the average invariably appears in the second generation and can be determined in the offspring of these individuals, that is in the third generation families, the breeder may already reach a definite result by this third generation, without any fear of valuable material being unwittingly discarded.

720 – **International Factors connected with the Physiology of Germination in Wheat Grains.** — NILSSON-EHLE, H. (Svalöf, Sweden) in *Zeitschrift für Pflanzenzüchtung*, Vol. II, Part 2, pp. 153-187 + 1 plate. Berlin, April 1914.

The following results have been reached after many years' study of the germination and anatomy of wheat.

1. The rapidity or slowness of germination immediately after ripening is a hereditary character distinctive for different varieties, and in the offspring of crosses shows decided segregation on the usual lines.

2. This physiological character is shown, both by comparison of different varieties and strains and by segregation after crossing, to be in the main independent of hardiness (Winterfestigkeit) and early ripening, which characters depend on other internal factors. It is possible to combine high or low resistance to germination with high or low hardiness and early-ripening properties.

3. These differences in germination characters between different varieties of wheat are connected with a series of internal hereditary factors.

4. Among these factors, that of « redness », which produces the red colour of the grain, is of special importance in hindering germination immediately after ripening. The white wheats, which generally lack red factors, germinate most readily; next come those with a single red factor, while those with several red factors germinate most slowly.

5. The germination characteristics of the different varieties are only partially dependent on the red factor; other internal factors act as co-determinants. In particular readiness to germinate and the specific course of this condition in individual varieties are probably independent of the red factors and dependent on other internal factors; at the same time the red factors act in preventing germination in the same direction as insufficient ripeness.

6. The observed facts throw fresh light on the important part played by the pericarp in the physiology of germination; the principal action is no doubt exerted by the corky layer, to which Schröder attributes regulation of the permeability and in which the red factor is localised.

7. The white and one-factor red wheats examined show somewhat more rapid absorption of water than those with more than one red factor.

8. The action of the red factors in hindering germination is at any rate partly exerted through their influence on the structure of the pericarp. In the absence of red factors the inner integument is thinner and more delicate than otherwise.

9. The pericarp consists of two quite separate integuments, insoluble in concentrated sulphuric acid; in red varieties each consists of two layers

of cells, while in white varieties the inner one is quite structureless in the ripe grain.

The writer considers this demonstration of a physiological characteristic composed of a number of internal factors as of considerable theoretical importance ; the proof of this has been facilitated by the circumstance that the simultaneous morphological action of the factors is readily observable.

These observations are also in support of the theory that adaptation takes place by accumulation or some other type of combination of various hereditary factors.

It certainly seems that cultivated plants are more adapted for the study of general biological questions than wild ones, owing to the great variety of forms protected under cultivation ; wild species, on the other hand, may often contain only adapted forms in which all the factors for a particular character are present together, preventing the possibility of any genetic analysis.

721 – **Xenia in *Phaseolus* Crosses.** — DANIEL, JEAN, in *Revue horticole*, Year 86, No. 11, pp. 253-257. Paris, June 1, 1914.

The Spanish bean (*Phaseolus multiflorus*) was crossed with the black Belgian bean (*P. vulgaris nanus*) and the resulting progeny were investigated more especially with regard to xenia (*i. e.* the reaction of the hybrid embryo on the surrounding tissues in the seed) exhibited by the seed coat.

The Spanish bean is large and spotted black and violet, while the Belgian bean is small and has a shiny black surface. Pedigree seed was used in the experiments. The pods obtained as a result of the cross in 1910 contained seeds in size and shape like those of the Spanish bean, but in colour shimy black like those of the male. The same cross in 1912 gave three kinds of pods : some which contained shiny black seeds, some which contained seeds of a chocolate brown colour and others whose seeds were light dun, showing that xenia may vary in intensity according to circumstances.

In all cases, sections showed that the pigment in the cells of the testa was the only character affected.

Two of the 1910 progeny mentioned above were sown in 1911. The resulting plants were exactly like the female parent (*i. e.* Spanish bean with red flowers); they were selfed, producing spotted seeds which were sown in 1912. In this next generation all cotyledons were hypogeous as in the maternal parent, which they also resembled in having the climbing habit. The flowers however were of three types : some plants had red flowers like the maternal parent ; others had red standards whith wings and keel white or white with red spots ; others again had flowers of a dirty white colour. The all-red flowers yielded nothing but purple spotted seeds of various shades ; the red-and-white flowers yielded brown spotted seeds and the white flowers yielded white seeds more or less reticulated (1).

(1) See No. 115, *B.* Feb. 1914. (*Ed.*).

A plant belonging to each type was again selfed, and the resulting seeds again showed segregation, but without the recurrence of violet flowers or black testa.

722 – **The Inheritance of Germination Energy, Germination Capacity and Sensitiveness to Light in Seeds of *Poa pratensis*.** — PIEPER, H. in *Fühlings Landwirtschaftliche Zeitung*, Year 63, No. 10, pp. 362-368. Stuttgart, May 15, 1914.

As the result of a series of tests with seeds of *Poa pratensis*, the variations of germination energy, of germination capacity and of sensitiveness to light appeared to be hereditary characters in the different strains. The possibility of using this fact in breeding work will depend on the correlation of the above characters with other desirable ones, the existence of which did not become apparent in the trials. Neither was it possible to decide from the trials whether the differences observed in the germination capacity were due to the structure of the seed or to that of the fruit.

723 – **Researches on the Germination Capacity and on the Capacity of the Plumule to Emerge from the Soil.** — GISEVIUS and CLAUS in *Fühlings Landwirtschaftliche Zeitung*, Year 63, Part 9, pp. 297-318. Stuttgart, May 1, 1914. AGRICULTURAL SEEDS

The writers compare the germination capacity with the capacity of the plumule to emerge from the earth or from the layer of sand covering the seeds. They experimented upon 9 samples of winter rye, 42 of winter wheat and 24 of spring barley. The determination of the germination capacity was carried out at different times, according to the regulations of the Union of Agricultural Experiment Stations, in a germination box provided with ventilation and a thermostat, and always with four samples. The determination of the capacity of emerging was made in Hiltner boxes; these were partially filled with quartz sand the grains of which did not exceed 1 mm. in diameter; the seeds were pressed into this and covered with a layer 3 or 5 cm. deep of coarse sand (1 to 2.5 mm. diameter) which would not form a crust over the sprouting seeds. In this case also four tests were made for each sample. These boxes were placed in a room kept at the most uniform temperature possible of about 18° C.

The result of the investigation into the capacity of emergence of the plumule in rye, which was tested 100 and 160 days after harvest, was the following: if the determination of the energy and capacity of emergence of the plumule are to be determined by the same method as the energy and capacity of germination, the figures obtained on the 7th and 12th day using a covering of 3 cm. of sand are considered suitable. It is not yet known whether this would be the case also in spring (these experiments were made in November and January). The 5 cm. covering of sand did not offer any advantage over the 3 cm. covering.

Wheat was tested 33 and 153 days after harvest, barley 70 and 160 days after, but for oats the tests were not complete; for all three the same conditions as for rye may be taken.

It appears that the capacity of germination is generally greater than the capacity of emerging. As it was not possible to carry out both determinations immediately after reaping, a complete judgment on the significance

Report on seed examined in April 1914.

of the capacity of emerging is not yet possible. These experiments have, however, shown that there is a practical method for determining the capacity of emergence and that the greater amount of time required by the test is not so considerable as to prevent its being used instead of that for germination capacity ; the emergence test is in itself more precise and, as these still incomplete experiments seem to point out, allows the concurrence of factors influencing the sprouting of seed, such as the effect of saline solutions or of an attack of *Fusarium*, to be distinctly recognised.

724 – **Impurities in Seeds in Victoria, Australia.** — *Communicated by* S. S. CAMERON *Director of Agriculture.*

(See table on opposite page).

725 – **Researches on the Ears of Wheat and of Spelt for the Precise Characterisation of Varieties.** — KONDO, M. in *Landwirtschaftliche Jahrbücher*, Vol. XLV, Part 5, pp. 713-817 + 3 figs. Berlin, 1913.

CEREAL AND PULSE CROPS

These investigations extended to 62 winter wheats and 20 spring wheats (of which 80 were *Triticum vulgare* Vill.) and 16 spelts (*T. Spelta* L.). They were all of them of the 1911 crops and either bred at Hohenheim or the second crop from the original seed. Of each variety about thirty ears were selected and from these five typical ones were again picked out (large, medium and small) ; of each the awns, colour of the glumes, the presence of hairs, density of spikelets, weight and size of the ear, and colour of seed, were observed. Further investigations were made for each variety on groups of three ears (heavy, medium and light) as to the distribution of weight of the grains and spikelets in the ear and as to the constitution of the grains.

The results are the following : In common wheats the ears possessing medium density always show the highest weight of ear, the highest grain weight of ear and the greatest weight per thousand grains. In the dense-eared wheats the decline in the grain weight towards the tip is greater than in the medium or loose-eared ones. In the upper end of the ears the grains are much smaller than in the lower end. In medium and loose ears the weight of the grains is relatively the same. The best form of ear of common wheat is not the dense club form, but the medium parallel-sided form.

In spring wheat in general, the weight of the ears, of the total grain and of the thousand grains, as well as the number of ears and grains, are much lower than in winter wheats. The weight of the ears and of the grain of spelt are almost the same as in spring wheat. The number of grains in spelt is much inferior to that in winter and spring wheat. On the other hand the thousand-grain weight is higher. The belt of the heaviest grains in the ear varies according to the several varieties ; in some it is in the central third of the ear, in others on the border between the central and lower third, or in the middle and lower third and often in the upper third. In the dense ears the belt is mostly on the limit between the lower and middle third. In the medium dense and loose ears it is in the middle third. In winter wheats the belt of the heaviest grains is scarcely ever in the upper

third, while in spring wheat it is most frequently in the middle or in the upper half of the ear. In spelt it is mostly in the middle of the ear and very rarely in the upper third.

In general it can be stated that in winter and spring wheat and in spelt the number of grains in a spikelet and the average grain weight are at their highest in the middle third of the ear. The ratio between the bottom and the top third is not constant, and varies according to the variety and species. In winter wheat in general, the lowest third is superior to the highest in every respect ; in spring wheat the number of grains in the upper third and the individual grain weight in the lower third are at their lowest. In spelt the number of grains is smallest in the lower third and the individual grain weight is least in the upper third.

The distribution of grains in the ears is characteristic of the several varieties. In general the length of the rachis, the number of grains, the total grain weight and the thousand-grain weight vary with weight of the ear, but inversely with the density of the spikelet and the number of sterile spikelets in the lower part of the ear. The ratio between weight of ear and the number of spikelets and the density of the grain is not constant. It is therefore not advantageous to endeavour to breed wheat for greater density of spikelets, but it is very important to improve the lower part of the ear.

As for the colour of the grain, which depends upon various conditions, white and red may be assumed to be the fundamental colours which form the characters of the different varieties. The colour depends chiefly upon the pigment in the pericarp and only secondarily upon the mealiness or flintiness. In each ear the colour of the grain is quite uniform.

The form of the full grain and the presence or absence of the depression in the longitudinal furrow on the flat side of the grain are to be considered as characters of the variety. The hairs at the tip of winter and spring wheat grains are thick-walled, with narrow lumen, and straight ; they vary in length according to the variety. The hairs of spelt possess relatively thin walls, and large lumina ; they are often twisted and are longer than in common wheat. The length of these hairs is a character of the variety.

The writer considers size and weight of the wheat grains as to a certain degree characters of variety and species ; mealiness and flintiness are also characters of variety in spite of the fact that they are not invariable.

An important character for the determination of variety and species is the middle layer of the four which make up the pericarp in the species of *Triticum*.

726 - **Six Years' Trials of Winter Wheats in Denmark (1907-1912).** — From Report of the Danish Crop Experiment Organisation (1). — *Communicated by the Committee on Plant Breeding.*

These trials were carried out at the Experiment Stations at Abed (Lolland) and Tystofte (West Zealand) ; the experiment ground is in each case on a good loam.

(1) A full report is given in *Tidsskrift for Landbrugets Planteavl*, price 6 kr. (6s 7d) the vol. of 800 pp.

At Tystofte two series of trials were made each year, one after bare fallow and the other after a fallow cropped with turnips; at Abed the wheat was always sown on bare fallow land. In each trial there were 6 to 8 adjacent plots of $^1/_{200}$ tondeland (33 sq. yds.) in area ; on every third plot Tystofte Standwell was grown for comparison. Altogether 23 varieties were grown, 8 of them in all the trials; the yields of the others were calculated in comparison with the average of these eight.

The winters were on the whole favourable ; in one of the six trials at Abed some damage was done, but at Tystofte none. For this reason the less hardy varieties gave relatively high yields.

Heaviest croppers. — A yield of 43 to 44 ctn. per tondeland (58 to 59 bushels per acre) was given by : 1) Queen Wilhelmina II, 2) Tystofte Small II, and 3) Tystofte Standwell II. All three are improvements on the originals of the same name obtained at Tystofte ; they none of them differ from their originals except in giving 8 to 10 bushels more grain.

Queen Wilhelmina II gives a very heavy yield under favourable conditions ; it is not very tall and tillers relatively little, but stands very straight ; it is, however, not very hardy, about equalling the ordinary Squarehead.

Tystofte Small II can be relied upon to give a heavy yield ; it tillers rather more than the preceding, but is somewhat liable to lodge.

Tystofte Standwell II has a rather shorter and stiffer straw than the Small; it is very hardy and tillers well, but for this reason may grow too thick and become liable to lodging or to imperfect development of the grain ; it stands late sowing better than the other two. At Tystofte it gave a lower yield than the Small after bare follow, but beat the latter after a cropped fallow.

Second group. — The following gave a yield of 39 to 41 ctn. per tondeland (52 ½ to 55 bushels per acre) : 4) Abed Large-eared, 5) Svalöf Extra Squarehead II, 6) Svalöf Grenadier II, 7) Carter's Standup, 8) Webb's New Standup, and 9) Svälof Sun.

Abed Large-eared tillers fairly well, is only moderately hardy, but stands very straight ; with favourable weather it gives a plentiful crop of grain ; the bushel-weight is below the average.

Of the Svalöf varieties, Extra Squarehead II is very hardy, Grenadier II only moderately so ; these give some 2 to 4 bushels more than the older varieties of the same names. The Sun wheat is very hardy ; at Abed it did better than the other two, but at Tystofte less well.

Webb's and Carter's Standup wheats are very much alike ; they tiller little, are not very hardy and have short and stiff straw ; under favourable conditions they are heavy croppers and at the same time stand up well.

Light croppers. — Yields of 33-37 ctn. per tondeland (44 ½ to 48 ½ bu. per acre) were given by : 10) Tystofte Bearded, 11) Strube's Bearded No. 56, 12) Scotch Squarehead from Lidsö, 13) Strube's Squarehead, 14) Erh. Frederiksen's Squarehead, 15) Bencard's Red, 16) Svalöf Auger, and 17) Abed Lancet.

Minnesota No. 529 gives only 24 ctn. (31.3 bu. per acre) of grain.

727 – **Field Trials with Spring Wheat** (1) **and Oats in Germany in 1909-10.** — 1. ZADE, A. Haferanbauversuche auf leichteren Böden 1909-10. — *Arbeiten der Deutschen Landwirts-Gesellschaft*, No. 252, 99 pp. — 2. ROSE, H. Sommerweizenanbauversuche 1909-10. — *Ibid.*, 59 pp. Berlin, 1913.

I. *Trials of oats on light soils.*

The number of experiments was 50 in 1909 and 56 in 1910 ; they were distributed over the whole of Germany. The three varieties taken in the main trials were : Leutewitz Yellow, F. von Lochow's Yellow and Svalöf Golden Rain.

The reports are drawn up like those of the other variety trials made by the German Agricultural Society. The positions of the three varieties as regards the various qualities are shown in the following table :

	Yield of grain		Yield of straw		Resistance to lodging		Bushel weight		Percentage of chaff (1)	
	1909	1910	1909	1910	1909	1910	1909	1910	1909	1910
F. von Lochow's Yellow. . .	I	I	III	III	II (2)	III	II	II	I	I
Svalöf Golden Rain.	II	III	I	I	I	I	I	I	II	II
Leutewitz Yellow.	III	II	II	II	II (2)	II	III	III	III	III

(1) I = lowest. — (2) Equal 2nd.

It is seen that the results for the two years are fairly concordant.

II. *Trials of spring wheats.*

The trials of wheats were made at 37 places in 1909 and 38 in 1910. The varieties taken for comparison were Rimpau's Red Schlanstedt for early sowing, good soils and favourable weather conditions, and Strube's Bearded for later sowing, light soils and unfavourable weather conditions ; the other trial varieties were Heine's Japhet and Wohltmann's Blue Dame.

The average yields of grain of the four varieties are shown in the accompanying table (in lbs. per acre).

	Comparison of all four varieties		Comparison of three varieties	
	1909 (13 trials)	1910 (10 trials)	1909 (12 trials)	1910 (19 trials)
Rimpau's Red Schlanstedt	2 865	2 040	2 700	2 358
Strube's Bearded	2 579	2 158	—	—
Heine's Japhet.	2 869	2 032	2 740	2 410
Wohltmann's Blue Dame	2 654	1 828	2 643	2 200

(1) For loose-eared varieties of winter wheat, see No. 227, *B.* March 1914 (Abstract of *Arbeiten der D. L. G.*, No. 248). (*Ed.*).

Rimpau's Red and Heine's Japhet are seen to be very nearly equal, while Blue Dame comes decidedly behind them. Strube's Bearded was the best in 1910 under certain circumstances, such as soils hardly to be classed as wheat land, unfavourable places, or East German continental conditions with low rainfall. For straw yield Rimpau's Red and Strube's Bearded came off best ; Blue Dame was lowest in this respect, but at the same time the most resistant to lodging. Strube's Bearded showed the shortest period of growth in each year ; it also gave the flintiest grain.

Results of preliminary trials of other varieties are also given.

728 – **The Early Fruwirth Goldthorpe Barley.** — WACKER, H, in *Zeitschrift für Pflanzenzüchtung*, Vol. II, Part 2, pp. 233-248. Berlin, April 1914.

The writer describes the origin of the Early Fruwirth Goldthorpe barley, which is a pure line in Johannsen's sense ; it is descended from a plant observed by Fruwirth in 1899 in a field of Goldthorpe barley on the experimental ground of Hohenheim Agricultural College. The variety, which the hairs on the rachilla shew to belong to *Hordeum distichum erectum*, is described as follows: It exhibits a close-set ear of medium length, with fairly wide spreading awns. The grain is of medium length and stout, of a yellowish-white colour, with rather narrower glumes than ordinary Goldthorpe barley, and has a high starch content. The stem is of medium length, rather thin, but wiry and strong, and therefore does not easily lodge. The yielding capacity is excellent, and ripening takes place 8 or 10 days earlier than with ordinary Goldthorpe barley. Smut occurs very rarely, as the spikelet remains closed after flowering. This fact also precludes any chance of cross-fertilization. Nevertheless, in 1908 some plants appeared among the descendants of plants selected in 1899-1902 for early maturity and grain yield and simply allowed to multiply from 1902 to 1907, which produced descendants differing from others in the colour of the grain and in the strength of the stem. According to the writer, spontaneous variations within the pure line must therefore have occurred.

Cultivation is now being carried on with a view to further improving the variety, which has been included in the Register of the German Agricultural Society.

729 – **Formation of Aerial Tubers in Potatoes.** — FOITIK, TH. in *Monatshefte für Landwirtschaft*, Year III, Part 5-6, pp. 111-120 + 3 figs. Vienna and Leipzig, 1914.

The writer has observed the occurrence of aerial tubers in the potato varieties Topas (since 1910) and Marius, and occasionally in a selection from Prof. Wohltmann. These tubers occur on the main stem and branches, singly or in clusters, and may be as big as pigeon's eggs ; they are grass-green with purple spots. They often bear nodosities, from which, or from the tubers themselves, rosettes of soft leaves may arise. The formation of aerial tubers takes place especially on haulms which have got bent down to the ground, but in this case the tubers may be of normal size. The writer believes the occurrence to be favoured by heavy manuring combined with cool damp weather.

On planting some of the 1910 aerial tubers of Topas, yields were obtained in 1912 and 1913 heavier than the average of the variety.

730 – ***Dalembertia populifolia*: an Edible Plant in Mexico.** — Bois, D., and Diguet, L., in *L'Agriculture pratique des pays chauds*, Year XIV, No. 134, pp. 257-265. Paris, May 1914.

Dalembertia populifolia Baillon, known as " Jicama de baryta " or " Jicama del cerro ", is a shrub; at certain times of the year its roots produce tuberous swellings which are edible and are sold in large quantities in Central Mexico. The plant only exists in the wild state and to collect the tubers, which are usually close under the surface of the ground, a hole is first dug close to the stem, and the roots are followed horizontally, care being taken not to injure the base of the stems, as the plant is perennial. The writers cultivated the plant experimentally and found that it could be propagated by seeds and cuttings, but that the tubers could not be used for this purpose. Though containing little nutritive matter, *Dalembertia* is popular as an article of diet, either cooked or raw, and is eaten either alone or with other foods; it is of special value for quenching thirst on a long march in the burning sun.

FORAGE CROPS. MEADOWS AND PASTURES

731 – **Observations on the Laying-down and Care of Permanent Pastures.** — Elofson, A., in *Svaenska Mosskultur-Föreningens Tidskrift*, Year 27, No. 2, pp. 77-95. Jönköping, March 1914. (From the writers summary).

The writer begins by calling to mind the great importance of cattle-breeding in relation to the national food supply, as well as to agriculture, especially in districts unsuited to arable farming. With the aid of control societies, a gross return had been reached in cattle breeding such as could scarcely have been dreamt of before, but those stock-farms which were carried on on highly intensive lines were now merely marking time, or even declining, both as regards their milk-production, and also in return per 100 food units. The zenith, as regards the capacity of the animals, had therefore been reached, and the net returns now no longer corresponded to the high gross figures.

The writer sees the reason for this in the fact that too much stress has been placed on the results of chemico-biological research in scientific cattle feeding, without reference to the great demands of biology, an omission which is bound to bring retribution, since the attainments of the animals must always in the long run depend on their constitutions. The fruits of intensive, unnatural stall-feeding are decreased power of resistance, lessened reproductive power, etc.: hence great expense in rearing fresh stock, and less complete utilization of raw foodstuffs.

The main food should consist of hay and roots in winter and pasture in summer. Special attention should be paid to the improvement of hay-production, so that a heavy, and also cheap, crop may be forthcoming. When hay can be produced, as it is on several farms in Sweden, at 25 to 32s per ton, it forms a cheap feed, even when used in large quantities.

Pasturage is the cheapest food, in relation to production, that there is, as modern Swedish pasture farming also demonstrates. Since pasture farming on a large scale considerably diminishes the farmer's labour-bill, and provides him with the greatest possible quantity of foodstuff per unit of area (1), the writer recommends Swedish farmers to make use of the advantages of modern pasture farming. The first step in this direction is the improvement of great areas of natural pasture. It is to be noted that only such areas as are not very well suited for growing cereals should be used for this purpose, or at least only so much of the better land as circumstances may demand : for example, if young stock is to be raised and there is no other land available, or where pasture for dairy cattle is required close to the homestead. Pasture farming on a large scale should not be allowed to interfere with the output of cereals.

The preliminary conditions necessary to make permanent pastures pay are present in Sweden. For land is cheap and the distribution of the rainfall is favorable ; most rain falls in late summer, when the pastures are most sensitive to drought. Our light nights, and the fact that the energy of growth increases as the northern frontier is approached, make the production decidedly large in proportion to the length of the growing period.

In laying down permanent pastures, especial attention must be paid to manuring. For sowing in a bleak climate, the seed must be of varieties which stand the winter well. These are not usually in stock on the seed markets, but they grow wild everywhere in northern countries, and include, for example, meadow fescue, red fescue, smooth-stalked meadow-grass, rough-stalked meadow-grass, foxtail, etc. A firm seed-bed and a heavy seeding are essential conditions for the success of the pasture.

The dressing of manure should be :

8 to 16 cwt. lime
2 ½ to 3 ¼ cwt. superphosphate or 5 to 7 cwt. basic slag
5 to 6 ½ cwt. kainit
} every three years.

Heavy and dry soils should get as much manure supplying humus as possible ; nitrogen should be given according to requirements : the quantity used in these parts is about ½ cwt. of nitrate of soda and sulphate of ammonia an acre a year.

The results so far obtained in Sweden are satisfactory. At Vallinge, in Södermanland, Hr. Kleen obtained 1200 food-units (2) an acre at a cost of production of £3 5*s*, including all expenses. This works out at two thirds of a penny per food-unit. If foodstuffs have to be purchased, the cost of production rises to at least twice as much.

(1) Experiments in Denmark show that grass mown 6 times (e. g. Cocksfoot) gives a lighter crop of hay, but a larger amount of digestible foodstuff, than when mown only twice. ("Om Vaeksten af Hundegräs och Draphavre", etc., by E. LINHARD, in *Tidskrift för Landbrugets Pianteavl*).

(2) A food-unit is equal to about 1.33 lb. of starch value.

The daily increase in live-weight of young stock amounts to 600 to 700 gms. (20 to 25 oz.) per head. At Latorp, where the mean rainfall is 13.7 in. for the six months April to September the increase per head per day exceeded 900 gms. (2 lbs.).

On the experimental farm of the Swedish Moor Cultivation Society at Flahult, near Jönköping, excellent results have also been obtained from peat soils, with a net profit of over £2 4s per acre.

In Central Sweden the pasturage period lasts about 150 days, that is about the same as in Germany.

732 – ***Beckmannia erucaeformis* Host., a New Grass for Moor Meadows.** — WITTMACK, L. (Berlin) in *Mitteilungen der Deutschen Landwirtschafts-Gesellschaft*, Year XXIX, Nos. 22 and 24, pp. 309-312 and 356, + 3 plates. Berlin, May 30 and June 13, 1914.

The writers gives a description of *Beckmannia erucaeformis* Host.; this grass has also been referred to *Phalaris* (Linnaeus) and *Cynosurus* (Aiton and Willdenow), but is now made the only representative of the genus *Beckmannia*.

This species is found in Italy, Hungary, S. E. and E. Europe, N. and C. Asia, and in America from Alaska to Minnesota ; several varieties have been described. It occurs along rivers and in swamps, in Russia also in saline marshes. In Germany it has been introduced here and there.

There is little information as to its feeding value. In Russia, where it has already been grown on a large scale in some places, it is considered useful, though giving a rather coarse hay. It appears to resist frosts and fungi, and grows very tall. The abundance of salts characteristic of most of its stations in Russia does not seem to be essential. The production of seed is abundant, in spite of its perennial character ; the trade " seed " consists of the whole spikelets.

733 – **A Fodder for the Dry Season: *Tripsacum fasciculatum* Trinius.** — PEDROSO, A. in *Journal d'Agriculture Tropicale*, Year 14, No. 155, pp. 137-138. Paris, May 31, 1914.

Trials have been carried out in Costa Rica with *Tripsacum fasciculatum* Trinius, a perennial grass somewhat similar to sugarcane in appearance. It may reach a height of more than 16 ft., produces adventitious roots and continues to vegetate almost indefinitely. Cattle eat it readily, horses rather less willingly and then only the leaves or the young stems cut up. The special advantage of *Tripsacum* is that it remains green during the dry season and yields good crops even on poor soil.

Propagation takes place by means of slips which are set about 3 ½ in. deep and 20 in. apart. For the first six months after planting the land must be kept hoed and free from weeds. Four cuts per annum are obtained, the last of which should take place at least one month before the end of the rainy season in order that the plant should be sufficiently recovered to stand the subsequent drought.

734 – **African *Bombax*.** — VUILLET, J. in *L'Agronomie coloniale*, Year I, No. 10, pp. 97-105. Paris, April 30, 1914. FIBRE CROPS

The existence of numerous natural hybrids makes it frequently very difficult to identify the various species and varieties of *Bombax ;* moreover complete specimens of the trees are not easy to obtain, as they only flower after the leaves have fallen, and the new shoots do not appear till after the fruits have dropped. The writer distinguishes four *Bombax* in the Nigerian Soudan :

1. *B. with ribbed fruits.* — The ovary has five well marked furrows on its upper half, which alternate with the lines corresponding to the valvular sutures in the fruit and form a five-toothed crown at the top ; the capsule has five deep inter-sutural furrows clearly defined in the upper half ; the seeds are sub-spherical instead of pyriform.

2. *B. with papillose fruits* — Calyx not very villous and only half the length of the flower instead of two-thirds ; capsules slightly papillose.

3. *B. with long fruits* — Calyx always longer than half its diameter and showing a very irregular edge when burst by the opening flower; ovary longer than in other species (6 to 7 mm. in diameter at the base by 10 mm. long) and not concave at the top ; fruits sub-cylindrical and drawn out in the shape of a sausage.

4. *B. with yellow flowers.* — Leaves usually made up of five leaflets, thicker and forming a more obtuse angle at the base than other Soudan species ; flowers yellow or yellowish-green on the outer surface of the petals, brighter yellow on the inside; fruits slightly furrowed at the base and having small ridges in the upper half.

735 – **The Oil Palm *(Elaeis guineensis).*** — BECCARI, ODOARDO in *L'Agricultura coloniale*, Year VIII, Nos. 1-4, pp. 5, 108, 201, 255. Florence, January-April 1914. CROPS YIELDING OILS DYES AND TANNINS

The writer discusses the work of ADAM and of CHEVALIER on *Elaeis* and draws up the following classification of the oil palms to serve as a basis in selecting and breeding new varieties for cultivation. He also describes a new variety, *E. guineensis macrocarya* Becc., with remarkably large fruits, the nut of which varies in weight from 23 gm. to 54 gm. (1 to 2 oz.) and may measure up to 50 × 43 mm. ; the shell of the nut is very thick and the kernel is small and irregular in shape ; the albumen has a rather large central cavity and the albumen tissue is made up of larger cells than that of any other variety and contains a larger number of crystalloids.

Classification of Elaeis.

RUBBER, GUM AND RESIN PLANTS

736 – **Manuring Experiments with Hevea.** — DE JONG, W. K. in *Teysmannia*. Year XXIII, No. 3, pp. 133-144. Batavia, 1914.

An account of manurial experiments carried out on 80 trees aged 7 to 7 ½ years.

737 – **Tapping Trials with *Funtumia elastica* in the Belgian Congo.** — GISSELAIRE, A. in *Bulletin agricole du Congo belge*, Vol. V, No. 1, pp. 95-104. Brussels, March 1914.

Tapping experiments were carried out in the Bangala district on trees 7 to 9 years old. The tapping was done in the early morning, being finished at half-past eight or nine at the latest; herring-bone incisions were employed, single or double according to the size of the trunk, all trees of over 20 in. circumference at 3 ft. from the soil receiving the double incision ; lateral incisions were 10 in. from the central incisions and large trees were tapped to a height of 16 ft. Coagulation was brought about by boiling water.

The following results were obtained at Musa : 1696 trees yielded 75 gallons of latex from which 375 lbs. of raw rubber were coagulated, or 3.6 oz. per tree including scrap. As the trees can probably be tapped twice a year this quantity should be doubled to estimate the annual production.

At Katu, 1368 *Funtumia* yielded 67 gallons of latex from which 345 lbs. of raw rubber were obtained, or 4.3 oz. per tree including scrap. The rubber lost 23 per cent. on drying so that 3.3 oz. of dry rubber were obtained per tree or 6.6 oz. per tree per annum, and one acre planted 10 ft. apart would yield 200 lbs. of dry rubber per annum.

Samples from both localities were submitted to experts, who reported favourably on their quality and estimated their value as equal to that of plantation hevea.

738 – **The Nipa Palm (1) as a Commercial Source of Sugar.** — PRATT, D. S., THURLOW, L. W., WILLIAMS, R. R., and GIBBS, H. D., in *The Philippine Journal of Science*, Vol. VIII, Section A, No. 6, pp. 377-398. Manila, December 1913.

SUGAR CROPS

The nipa palm (*Nipa fruticans* Wurmb.) covers large tracts of land in the Philippines which amount to 18 000 hectares (45 000 acres) in the provinces of Bulacan and Pampanga alone. Up to the present the sap exuded by the flower stalk has only been utilized on a large scale as a commercial source of alcohol; it was examined by the writers with regard to the possibility of extracting the sugar contained.

The yield amounts to about 40 litres (9 ½ gallons) of sap per season of 150 days per annum, or, with 750 trees per hectare, to 30 000 litres per hectare (2650 galls. per acre) per annum, the maximum flow occurring during the second month. As it flows from the palm the sap contains about 15 per cent. of saccharose and has an apparent purity of not less than 85, only traces of invert sugar being present; the addition of about 0.5 per cent. of sodium chloride slightly reduces the purity without lowering the extraction of sugar as it is classed among the non-melassigenic salts; waxes, acids, pectins and other foreign materials are practically absent ; the sap contains active enzymes of the invertase and peroxidase types, the latter being present only during the final period of secretion and being capable of oxidizing sucrose and invert sugar in either neutral or alkaline solution.

(1) See No. 2884, *B.* Aug.-Sep.-Oct. 1911 and No. 604, *B.* May 1913. (*Ed.*).

The sap is usually collected in bamboo tubes known as "tuquils", containing a little milk of lime and sulphite, which destroy the enzymes and avoid the necessity of subsequent bleaching ; the use of small funnels to convey the juice to the bottom of the tuquils avoids stratification and results in more perfect conservation with but small additional expense. The total cost of collecting the sap and delivering it to the mill amounts to $1.50 per 1000 litres (2*s* 9*d* per 100 galls.).

A thousand litres of sap yield on an average 115 kg. of commercial white sugar polarising at from 99° to 99.5°. No important modification of methods now used in sugar practise is necessary in dealing with nipa juice ; furthermore, no expense corresponding to the grinding of cane or the extraction of beets need be incurred, while the fuel supplied by the bagasse may be easily substituted by the cheap and plentiful wood of mangrove swamps.

As about 9 000 litres of sap are required to produce 1 ton of 96° sugar, 90 000 litres daily would be required to run a 10 ton mill at full capacity, that is the produce of 450 hectares. A mill designed to manufacture sugar from nipa juice would be available for refining Philippine sugar during that portion of the year when no sap is flowing, a process in which there is a reasonable profit. All estimates are conservative and there is every indication of the establishment of a successful industry.

The Bureau of Science (Manila) will gladly furnish samples of nipa sugar to any one interested.

739 – **Analysis of Sugar-Beets.** — PELLET, H. in *Sucrerie Indigène et Coloniale*, Vol. LXXXIII, Nos. 19 and 20, pp. 441-446 and 466-471. Paris, May 13 and 20, 1914.

As the result of a long series of analyses, the writer concludes that there is no relation between the size of sugar-beets and their sugar content.

STIMULANT, AROMATIC, NARCOTIC AND MEDICINAL CROPS

740 – **The Cultivation of Cacao in Trinidad and the Gold Coast.** — FREEMAN, W. G. in *Bulletin of the Department of Agriculture, Trinidad and Tobago*, Vol. XIII, No. 79, pp. 75-83. Trinidad, March-April 1914.

A reply to an article in the *Philippine Agricultural Review* attributing the recent decline in the exports of Cacao from Trinidad to bad cultural practices, overshading of trees and severe fungus disease.

The writer points out that this decline corresponds to seasons of abnormally low rainfall and gives figures showing a considerable improvement in the production of cacao during 1913 corresponding to an improvement in the climatic conditions. Reference is also made to reports of the Gold Coast Department of Agriculture showing that the remarkable increase in the exports of cacao from West Africa is due to the natural advantages of suitable areas and cheap labour, rather than to the application of scientific horticultural methods.

741 – **Manurial Experiments with Tobacco.** — VRIES, O. in *Proefstation voor Vorstenlandsche Tabak, Mededeeling* No. IX, pp. 42. Amsterdam.

Manurial trials with tobacco were carried out on poor soils in Java during the years 1912 and 1913, with the object of determining the effect of the fertilizers on the quality of the tobacco.

The following results were obtained : on the " brown " soils potash had little effect on the quality of tobacco, while superphosphate injured its combustibility without spoiling the colour of the ash ; on the blue clay and sandy soils potash was again without action, while superphosphate sometimes proved beneficial and sometimes harmful both to the combustibility and to the colour of the ash. Sulphate of ammonia had no harmful effects and occasionally affected the quality beneficially ; its use is therefore advocated, as it always increases the yield.

742 – **Experiments in Harvesting Tobacco Leaves.** — De Vries, O. in *Proefstation voor Vorstenlandsche Tabak, Mededeeling* No. VIII, pp. 43. Amsterdam.

Experiments on methods of harvesting tobacco leaves were carried out during 1912 and 1913 in Java. It is recommended that all picking should be done in the early part of the day and that leaves from the lower parts of the plants should be picked singly, except in wet years, when it would probably be better to pick the whole plant at once, for in that case the over-maturity of the lower leaves would be an advantage during the curing process.

MARKET GARDENING

743 – **The Market-Gardening Districts of Northern Germany.** — Weirup, in *Arbeiten der Deutschen Landwirtschafts-Gesellschaft*, No. 250, pp. 1-40. Berlin, 1913.

The above publication is a report of the horticultural conditions in the Luneburg district, in the Hamburg district and in West Holstein presented to the " Deutsche Landwirtschafts-Gesellschaft ". These districts are partly under fruit trees and partly under early potatoes, strawberries, rhubard and vegetables. The chief markets are Hamburg and Altona, but at the present time these outlets are not sufficient to deal with all the cabbages produced, and the marketing conditions generally should be improved. The large market at Hamburg with its store rooms is specially described, also the premises of the " Fruchthandel-Gesellschaft " of Bremen, which organises the supplies of fresh market-garden produce not only from the local districts but also from more distant ones.

FRUIT GROWING

744 – **Fruit Growing in Australia.** — Hattrick, J. M. in *Deutsche Obstbauzeitung*, No. 11, pp. 231-244. Stuttgart, June 1, 1914.

The rural population of Australia is small as compared with the urban population — the total population only amounting to five millions — and of

Table I. — *Distribution of surface (acres).*

	Total area	Total area cultivated	Under cereals	Vineyards	Fruit plantations
Western Australia	624 588 800	855 023	648 801	2 795	16 737

the rural population only a small part grow fruit. Yet the area under fruit is already considerable in spite of the industry being still in its infancy. Table I gives the distribution of the area in 1911 in Australia and New Zealand.

In every State except South Australia the area under vineyards is smaller than that under fruit trees ; the latter has increased at the rate of about 4500 acres per annum for the last ten years in Australia and New Zealand.

Kinds of fruit. — The climate being well adapted to fruit growing, especially in the coastal regions (S. Queensland), most kinds flourish ; the distribution of the various kinds is given in Table II.

There are no available data for New Zealand and it is pointed out that as different methods of collecting the returns are employed in the various States, the figures are only approximate.

The most important Australian fruit is the apple, followed at a distance by orange, peach, pear, plum, and small fruit. Queensland produces the tropical fruits (oranges, bananas and pineapples), New South Wales grows citrus fruit more especially, but peaches, apples and pears also flourish there ; in Victoria, the so-called " Orchard State ", the fruits of temperate climates (apples, pears, etc.) predominate, though citrus fruits do well in the northern part ; Tasmania is above all the apple orchard of Australia ; South Australia grows more especially apples and almonds ; and lastly Western Australia grows apples.

Average yields. — Average yields for each kind of fruit are obtained by dividing the official returns of production for each State by the number of trees in that State. The resulting figures are sometimes very low ; in certain parts, especially in Western Australia, the area under fruit trees

has been more than doubled during the last seven years, with the result that many of the orchards are very young and yielding small crops ; besides this, many orchards are planted in unsuitable places by inexpert townspeople and the poor returns from such orchards reduce the average yield for the State. In Table III are set out the average yields of various fruits in each State.

The average yield for apples varies from 22 lbs. to 46 lbs., being lowest in Queensland and highest in Victoria and New South Wales ; the yield in Tasmania is depressed by the fact that the trees are planted too close together in some of the old orchards ; Western Australia only averages 26 lbs. in spite of her eminently suitable climate.

Varieties grown. — Owing to the variable climatic conditions met with in the various States, the varieties grown are very numerous.

Apples (classed in order of importance).

Planting Fruit Trees. — Land may always be obtained from the Government on very favourable terms for the purpose of planting fruit, provided that the holder builds a house and lives on the land. Usually payment is made in twenty small annual instalments. Such land always consists of unbroken bush or forest, so that the formation of an orchard is a laborious matter ; felled timber is unsaleable and has to be burned on the spot. Young trees are provided by the large Australian nurseries ; they usually consist of pure varieties and are planted on the square or the quincunx method at the rate of 90 to 100 trees per acre. Trees come into bearing very early owing to the warm climate : apples, for instance, yield fair crops at five or six years old.

Cultivations. — The hot climate and the summer droughts, occurring just at fruiting time and lasting three, four, or even six months, necessitate repeated cultivations, which on the other hand are limited by the scarcity of labour. Immediately after the fruit has been gathered, the soil is ploughed deeply in order to absorb as much water as possible during the winter. A second ploughing is usually given at the end of July or beginning of August to destroy weeds, and during the summer the surface is kept stirred to prevent evaporation.

Manuring. — Most of the land under fruit is sufficiently fertile not to require manuring, but fruit has also been planted on some poorer soils where it soon became evident that the trees were being starved and consequently manuring had to be resorted to. Farmyard manure is rarely available, as the farmers only possess the bare number of horses required to work the holding and these are not often in the stable. In the neighbourhood of towns where it may be bought cheaply , dung is frequently employed ; in other parts it is replaced by green manuring to make good the loss of humus, which decomposes rapidly owing to the hot climate. Green crops are only grown during the winter, as their drying effect would be bad during the summer ; they consist almost entirely of leguminous crops, which do well in the cool winter months. Peas and vetches are chiefly employed ; the orchard is cultivated in autumn (February-March) as soon as the fruit crop has been harvested, and seed is sown in April ; in August the green crop flowers and is ploughed in. A few growers use forest leaf mould instead of a green crop where shallow cultivations are employed in order not to injure the roots of the fruit trees. Artificial manures are also in common use, especially bone flour or other phosphatic manures, because the soils while very rich in potash are exceptionally poor in phosphoric acid ; a more complete manuring is becoming usual.

Irrigation. — Good returns are obtained by irrigating fruit orchards in Australia, and a fair proportion of the land under fruit is irrigated in spite of the undeveloped state of the country :

New South Waies	1 000 acres
Victoria	17 550 »
South Australia	3 600 »
Total	22 150 »

Victoria is justly called the Australian Irrigation State, though New South Wales completed in July 1913 a colossal dam which is to hold up almost as much water as the Assuan dam in Egypt, and to help to bring 40 000 acres under irrigation by means of a canal 240 miles long. At the present moment the Mildura district, Victoria (6 500 inhabitants), is the most important irrigation area. It is situated on the Murray and extends over 9 700 acres, having been founded in 1887 by the Chaffey Bros., who received large grants of land in Victoria and undertook to construct an irrigation system. At present the land is occupied by small holders ; the holdings vary in size from 10 to 40 acres and the right to water goes with the land. Four pumps with a total capacity of 22 million gallons per minute raise the water 50 to 90 ft. above the level of the river ; the irrigation works are administered by a committee elected from amongst the holders, which levies the water rate and regulates the distribution of the water ; rates vary from 10s to £2 per acre. The pumps usually work for about 120 days per annum, providing one watering in winter, two following close on one another in the summer, and one in the autumn. The chief crops at Mildura are raisins, lemons and peaches.

Another important irrigation scheme, in this case belonging to the State of Victoria, is situated in the valley of the Goulburn, where reservoirs have already been constructed to hold 60 000 million gallons ; others are planned to raise the total storage capacity to 360 000 million gallons, which will be sufficient to irrigate 750 000 acres. Small irrigation plants in the Doncaster district should also be noted ; almost every holder has a tank at the top of his orchard into which water is pumped by means of a windmill or a petrol engine and from which the water is led in channels to all parts of the holding. The chief irrigation scheme in South Australia is at Renmarck, also on the Murray and on the same principle as Mildura, but of about one-third the size of the latter.

Management of trees. — Usually half-standards are planted; four to five or even nine main branches are trained in a cup shape, the centre of the tree being kept as open as possible; all secondary branches are kept short so that the fruit is formed close to the main branches which is said to facilitate the feeding of the fruit. Pruning varies with the different varieties, but the writer is inclined to think that it is always somewhat excessive, except in the case of lemon trees, where only the dead wood is cut out.

Enemies and their control. — Codling moth (*Carpocapsa pomonella*) causes serious damage to apples; lead arsenate washes are used against it as well as grease bands. American blight (*Schizoneura lanigera*) is also very prevalent ; it is checked by means of paraffin emulsion washes. A desease known as " bitter pit " causes serious harm and is being investigated at the present time. Other parasites frequently met with are: red spider (*Tetranychus telarius*), San Jose scale (*Aspidiotus perniciosus*), peach leaf curl (*Exoascus deformans*), *Clasterosporium carpophilum*. Certain preventive measures are prescribed by law.

Fruit Trade. — All small fruit, as well as a large part of the citrus fruit, finds a market in the Australian towns. Apples, lemons and dried fruits

find an Australian market at certain times of the year but are also important export products, more especially in the case of apples ; the development and extent of the apple trade is given in Table IV.

TABLE IV. — *Exports of apples in tons.*

State	1910	1911	1912
Western Australia.	198	281	1 163
South Australia	2 335	1 258	3 369
Victoria	2 935	5 303	5 447
Tasmania	10 320	12 824	14 669
New South Wales.	250	136	306
Total . . .	16 038	19 801	24 954

Apples are mostly sent to Great Britain, but also to Germany (about 180 000 barrels in 1912), the Far East, South Africa and South America. In the modern orchards only those varieties are grown which are suitable for export. The production is continually increasing so that it is constantly sought to improve the existing markets and to find new ones, a matter which should not prove difficult as the apples are of excellent quality and arrive in Europe from March to May, at a season when the home crop is already consumed ; they consequently fetch good prices.

While the organisation of the export trade is excellent, that of the home trade is poor, especially with regard to marketing, so that the producers are sometimes completely in the hands of the town retail dealers and it frequently occurs that producers receive very little for their crops when the consumers are paying a high price.

Cost of planting and production. — Conditions are so variable that the data can only be given approximately. The cost of buying the land, clearing, cultivating, fencing, planting and management up to the time the trees are in full bearing is estimated at from £75 to £100 per acre. A twelve-year-old apple orchard should bring in £20 per acre per annum.

745 – **South American Fruit.** — *Boletin de la Union Panamericana*, Vol. XXXVIII, No. 3, pp. 318-335. Washington, March 1914.

The writer describes the general conditions of fruit growing in South America and the possible developments of the industry in view of the variations of climate met with in the different parts of the continent and of the new transport facilities afforded by the opening of the Panama Canal. He points out the difference between fruit growing in North America, where deciduous trees prevail, and in South America, where the tropical and subtropical fruits are more general and native apples, pears, peaches and plums do not exist. Native fruits of South America are as follows :

Guava (*Psidium Guaiava*).
Custard apple (*Anona Cherimolia*).
Passion fruit (*Passiflora edulis*).
Spondias dulcis.
Prickly pear (*Opuntia* sp.)
Gomortega nitida Queule.
Murta murtella (*Myrtus Ugni* Molina), with berries very like the blueberry (*Vaccinium*).
Miqui (*Aristotelia Macqui*), sometimes mixed with grapes in the manufacture of wine.
Grapes, an unimportant variety found in the extreme north.
Capuili or Capoilles (*Prunus salicifolia*), rather like the American wild cherry.
A few other kinds which are little known.

Very few of these fruits are given in the American Pomology and many are of little commercial importance, but there is every reason to believe that the usual commercial kinds can also be produced as many have already been successfully introduced: for example sapotas, mangoes, bread fruits, tamarinds, pomegranates, avocados (*Persea gratissima*), olives, figs, citrus fruits, are grown in sub-tropical regions, while the ordinary fruits of the United States are grown in the temperate regions.

In the Argentine the vine is the only fruit cultivated on a large scale, the vast plains of the region being little adapted to fruit growing; nevertheless, in the pampas, and especially in the neighbourhood of Buenos Ayres, some attention is now being paid to the matter. The so-called Tigre Islands at the mouth of the Paraña are famous for their peaches. Around Tucuman citrus fruits, especially oranges, are cultivated and the industry might well be developed with improved means of transport and better methods of packing. Regions in the province of Salta are well adapted to sub-tropical fruits, such as the custard apple and avocado, which are as yet only produced for local consumption. In the provinces of Neuquen and Rio Negro some wild apples occur, which, according to tradition, are descended from trees imported by the Jesuits and which still yield fruit of good quality. But the vine is the only fruit possessing any real commercial importance in Argentine at the present day; of late years its cultivation has greatly increased and proved very remunerative in the province of Mendoza; a well equipped school of viticulture has even been founded in Mendoza itself and is to be extended next year. The prosperity of the industry dates from the arrival in the district of some Italian vine growers. High quality table grapes are produced and the erection of a small refrigerating plant makes it seem likely that the Buenos Ayres market will soon be within reach. Other fruits cultivated on a small scale in the Mendoza and San Juan districts are peaches, nectarines, apricots and pears.

In Chili the general conditions are very similar to those prevailing in California and similar kinds and quality of fruit are produced, though the industry is much less developed in Chili; fruit of excellent quality and appearance is found on the markets of Valparaiso, Santiago and Concepcion. Between the Andes and Valparaiso, sub-tropical fruits such as avocado, custard-apple and papaya are found, though they are inferior in size and

quality to similar fruits produced in their native tropical habitat ; citrus fruits are cultivated in fairly large quantities in districts south of Santiago which are not subject to frosts, but are not abundant on the markets between January and April. As in the Argentine, grapes are the most important kind of fruit in Chili ; they are mostly employed for the manufacture of wines which are very popular in South America and are exported to Argentina in large quantities; the wine-growing region extends from Santiago to Concepcion. In the south very good pears and apples are cultivated; in fact the apples of Valdivia are renowned throughout Chili and important orchards are found near Angel, south of Concepcion. Further south is a wooded region rather similar to parts of the States of Oregon and Washington ; this southern region is frequently considered the most fertile in Chili, though very little has yet been done in the direction of bringing the land under cultivation except round Rio Buenos, where a German colony has completely transformed the neighbourhood.

Peru and Bolivia are quite in the tropical zone, though the altitude of certain regions modifies their climate. Those tropical fruits which are capable of resisting the somewhat primitive methods of transport are found on the Peruvian markets and are of excellent quality ; the grapes are good, but after transport are only fit for wine making ; from April to June, apples and peaches abound but these are not of first quality. Other fruits cultivated are oranges, bananas, avocados, custard-apples, sapota (to a height of 6500 ft.), guavas, "ciruela agria", "gravadilla" (*Passiflora ligularis*), "tumbo" (*Passiflora quadrangularis*), prickly pear (*Opuntia Tuna*) which is very abundant, and a kind of wild cherry with fruit about the size of Richmond cherries which is picked from wild trees in the Urubamba Valley (north of Cuzco) and marketed in May. The fertile soil and excellent climate in parts of both Peru and Bolivia should make it possible to increase the production of fruit very considerably ; it is at present much lower than it was several centuries ago before the Spanish occupation and the region only requires the restoration of the irrigation system in order to become once more productive. The period of ripening of the various fruits is as follows :

Apples. — March, or in rares cases January — February, to November.
Cherries. — November to February.
Peaches. — December to March.
Pears. — February to May.
Plums. — January to March.
Apricots. — December to February.
Grapes. — January to June.
Oranges. — September to December.
Lemons. — All the year round.

The fruits all mature at a time when the European and North American markets are without home supplies and would consequently fetch good prices; land is cheaper in South than in North America, irrigation water is abundant, labour is not costly, soils and climate are eminently suitable for fruit

growing; consequently it is likely that transport difficulties will soon be met and that the four countries discussed above are destined to become important producers of fruit.

746 – **Influence of Different American Vine Stocks upon the Quantity and Quality of the Wines.** — FAES, H. and PORCHET, F. *Etude de l'influence de divers Porte-greffes sur la Qualité et la Quantité de la récolte.* Station viticole de Lausanne, 46 pp. Lausanne, 1914.

The Lausanne Vine-growing Station possesses in several parts of the Canton of Vaud, nine experiment vineyards, each about two-thirds of an acre in extent ; they represent the most various conditions of soil and aspect; except for two which serve other purposes, each is divided into three portions. The first is planted with Chasselas Fendant grafted on various stocks ; the second with direct-bearers (white and red) about which the results obtained have not yet been published ; the third (which is kept as a check plot) is planted with European vines, especially Chasselas, on their own roots. The vines in these three portions are all of the same age, so that the influence of the stocks upon the wine can be freely studied in comparison with that produced by European vines upon their own roots. Each graft-bearing stock is represented by 80 or 100 specimens. The following have been tried : *Pure Americans* — Riparia Gloire de Montpellier and Rupestris du Lot ; *Americo-Americans* — Rip. × Rup. II F., Duforer, 101-14, 3309 and 3306, Sol. × Rip. 1616, Berl. × Rip. 420 A., 157-11, 34 E., Rip. × Cord. - Rup. 106-8 ; *Franco-Americans* — Aramon × Rup. 1, Mourvèdre × Rup. 1202 and Chasselas × Berl. 41 B.

The yield of each stock of grafted vines is carefully recorded and the must is examined chemically. The experiments were continued from 1911 to 1913. The most important results are summarized as follows :

Among the pure American vines, Rupestris du Lot in general appears inferior to Riparia Gloire. The vines grafted on Rup. du Lot yielded a higher crop, marked by a lower sugar content, while the amount of acidity was frequently rather high ; the quality and quantity were more satisfactory when the grafted vine was trained as a cordon (in one vineyard all the vines were thus treated). Rip. Gloire does not thrive equally well on all soils.

The group of Rip. × Rup. hybrids gave very uniform and good results and their yield was in general the highest of all stocks, the maximum being given by 3309 ; the next best was Rip. × Rup. 11 F., the third 101-14. In this group a normal connection between quality and quantity was observed, while Rup. du Lot, for instance, even with diminished quantity, yielded grapes of inferior quality.

Sol. × Rip. 1616 behaved very well during all three years. In two of the experimental vineyards it yielded the highest crops. The grapes in general are sweet and have a low acid content.

The vines grafted on Rip. × Berl. give, as is well known, a limited production during the first years ; this was very clearly shown in 1911 in comparison with the hybrids Rip. × Rup. Of the former, No. 157-11 was, during the three years, the most productive ; nevertheless the percentage of

sugar in the must was sufficient. In 1912 the difference in yield between the Berl. hybrids and those of Rip. × Rup. was already less marked and in 1913 the yield of the former approached still more that of the other stocks. Excepting in one experimental vineyard 34 E gave lower yields ; it was also less rich in sugar than 157-11. The writers do not yet pronounce definitively on the Teleki Rip. × Berl. hybrids, which were only recently planted.

Rip. × Cord. - Rup. 106-8 gave a satisfactory yield ; in 1911 it bore more than the Rip. × Berl. hybrids on the Franco-Americans.

In general the Franco-Americans during the three years, notwithstanding their vigorous development, yielded a crop lighter than and inferior in quality to that obtained by using as graft-bearers the less vigorous Rip. × Rup. hybrids. Aramon × Rupestris 1 and 1202 made no exception saving in two and one vineyards respectively, in which the compact and heavy soil seemed admirably suited to the Franco-Americans. But here also their yield did not come up to that of 3309. The sugar content in the grapes of these two common Franco-Americans did not show improvement in connection with the diminished quantity of yield. In comparing the two, it appears that 1202 often produced grapes with a higher acidity than Aramon × Rupestris 1. Stock 41 B behaved very differently in the various vineyards, as regards both quality and quantity; nevertheless in some it was fairly successful. Cabernet × Berlandieri (only recently planted in two vineyards) was not very productive and gave a must with too low a sugar content. The must of vines grafted on Vinifera × Rupestris 84-3, which were also only recently planted , showed in 1912 and 1913 a minimum of sugar and a maximum of acidity.

From the observations made it appears that in general (there are some exceptions) the content in sugar diminishes or increases inversely to the bulk of crop, while with acidity the reserve is the case.

747 – **Experiments in Growing Vine Hybrids in Styria.** — MATIASIC, FR. in *Zeitschrift für Weinbau und Weinbehandlung*, Year I, Part 5, pp. 209-218. Berlin, May 1914.

In Styria a great portion of the vineyards have been reconstituted (32 000 acres up to 1912) on American stocks ; in many localities, especially in the south, these suffer from chlorosis, so that some of the plantations gradually perish.

In order to ascertain which are the most suitable stocks for these difficult conditions, the soil often containing large quantities of lime, the Government established a nursery at Dvor in 1903 ; here the hybrid stocks recommended for calcareous soil are tested. This nursery consists of a plantation of stocks for multiplication, a nursery proper in which the cuttings, some of them grafted and some not, are set to root, and another nursery of stocks under observation in which the hybrids are tested as grafted stocks.

The soil of the nursery for multiplication purposes is partly on marl and partly stony and it contains from 63 to 72 per cent. of lime. The nursery is about 2 acres in extent and has 3301 mother plants belonging

to 45 varieties of hybrids. The writer divides these hybrids into three groups.

The first includes those which have always been free from chlorosis : Riparia-Cordifolia-Rupestris de Grasset 106-8, Berlandieri-Riparia 420 A, Aramon Ganzin 1 (it has to be defended against mildew), Chasselas-Berlandieri 41· B (it also has to be protected against mildew), Riparia-Monticola 1 R and Riparia-Rupestris. Their growth is very satisfactory (41 B is somewhat weaker) and the same may be said of the maturing of their canes ; they are not susceptible to drought.

The second group contains the hybrids that are not immune from chlorosis but which from other points of view are still fairly satisfactory : Solonis-Riparia 1616, Mourvèdre-Rupestris 1202, Solonis-Rupestris, Berlandieri-Riparia 420 B and C, 33 and 34 E. M., Riparia-Berlandieri Teleki 4, 5, 6, 7, 8 and 9, Riparia-Berlandieri 157-11, Rupestris-Solonis 215-1 and 217-1, Riparia-Berlandieri 150-15, Pinot-Rupestris 1305, Rupestris-Berlandieri 301 A, Malbec Berlandieri 1a, Taylor-Narbonne, Gamay-Couderc and Aramon-Riparia 143 B. The canes of all of them mature satisfactorily. Solonis-Rupestris and 1616 on their own roots at Dvor are not very resistant to phylloxera and consequently they are not to be considered as graft bearers. No. 1202, Gamay-Couderc, 1305, 143 B and 1 A suffer from mildew.

The third group embraces those hybrids which do not resist chlorosis, do not grow satisfactorily, or are somewhat susceptible to drought, and which consequently have been partly eliminated and replaced by better hybrids : Rupestris-Berlandieri 219 A, 220 A, 301 B and C, 301-37-152, Cabernet-Berlandieri 333, Cabernet-Rupestris 33 A (liable to mildew), Rupestris-Berlandieri Teleki 10 a, Riparia-Rupestris 3306-3309, 101 and 101-14, Colombeau-Riparia 2502 and Rupestris-Solonis Pecs. No. 101-14 was also eliminated as subject to phylloxera and suffering from frost. Nos. 219 A, 301 C., 301-37-152, 3309 and 333 developed to a very limited extent and produced only thin useless canes.

On the subject of the use of Riparia-Berlandieri-Teleki hybrids (4, 5, 6,7, 8 and 9) no opinion can be formed until the new plants selected at Dvor have been tried. They are hybrids which represent a mixture of forms.

In the nursery, where the soil is a heavy loam, difficult to work, the cuttings, some of them grafted and others ungrafted, are set to root. Nos. 219 A, 301-37-152, 301 A, B and C, 3309 and 333 strike root in insufficient numbers, as in fact do all the hybrids of the third group. The others strike roots in the proportion of 50 per cent. and some even above 70 per cent.

In grafting, the successes attain as much as 63 per cent. In a grafting experiment carried out in 1910 with Hengel St. Severinus' grafting machine the same percentage of successes was scored as by hand grafting, but it was observed that in machine grafting the stock does not keep the scion so well as with hand grafting. In the percentage of successful grafts no difference was observed between those stocks which had been previously forced

in a greenhouse and those which had not been so treated. The lowest percentages of successes were those with Riparia-Monticola 1 R (20.2) Aramon-Ganzin (29.8), Riparia-Berlandieri (33) and Aramon-Rupestris 143 B (33.5).

The experimental nursery for grafted vines (1.04 acres) is situated on a highly calcareous soil (68 to 72 per cent. of carbonate of lime). It has been planted gradually since 1906. In this nursery the behaviour of each hybrid when grafted is different from that which it shows when ungrafted ; for this reason the test of the various grafted hybrids is very important.

From 1906 to 1912 inclusive, 1270 vines, grafted on all the above-mentioned hybrids, were planted. Their development, notwithstanding all the care bestowed on them, cannot be said to be satisfactory. Chlorosis attacks more or less all the grafted stocks, so that it has already been necessary to uproot 521 of them on account of their excessive weakness (partly also on account of phylloxera in the case of Sol.-Rup 1616, 101-14 and 106-8). The vine " Grüner Sylvaner " suffers severely from chlorosis, especially on 1616, Aram.-Ganz. 106-8 and on the Teleki hybrids 6, 7, 8, 9 and 10a. This vine adapts itself badly to 1616, for during the six years that it has been grafted it has been sickly and has never yielded any crop. Grüner Sylvaner has hitherto succeeded only on Rip.-Mont. 1 R ; Welsch Riesling succeeds well, that is without suffering too badly from chlorosis, on Aramon-Ganzin 1202, 420 A, 33 and 34 E. M. Solon.-Rup. and 1 R. Gutedel (Chasselas) planted in 1906 and 1907 is relatively healthy only on 1616 and on Aram.-Rup. ; on 106-8 it has already become sickly. Weisser Burgunder (Pinot Blanc) planted in 1908 is of all scions employed the one which has been most successful on the hybrid stocks ; on 1 R and 41 B it succeeds very well and on Aram.-Ganz. and on 1202 satisfactorily.

The productiveness of all these grafted stocks is very low.

Of the 45 hybrids which have been experimented upon, only those of the first group (and in this excluding 106-8 which does not resist the attacks of phylloxera) can be taken into consideration for soils as calcareous as those of Dvor. Nevertheless the experience gained at Dvor during ten years already allows the conclusion to be drawn that in such soils viticulture has not much chance of success even adopting these hybrids.

748 – **Self and Cross-Fertilization Experiments with Vines.** — GARD, M. in *Revue de Viticulture*, Year XXI, No. 1069, pp. 649-656. Paris, June 11, 1914.

Referring to previous work (1) an attempt is made to determine the relative importance of different methods of pollination in vines and the variation which occurs according to the nature of the vine and the general external conditions. Three methods of pollination are distinguished : 1) self-pollination ; 2) pollination by another flower on the same plant and frequently on the same bunch ; 3) cross-pollination. Flowers are of four kinds: *a*) those which do not open at all ; *b*) those which open like ordinary phanerogamic flowers, the petals remaining attached to the floral receptacle; *c*) those which raise the corollary hood but do not push it right off (met with in certain natural and artificial hybrids, such as Croton, 117-4 Couderc,

(1) See No. 1430, *B.* Oct. 1912. (*Ed.*).

Secretary, 150 Seibel, Concord, Jacquez, Black Hawk) ; and *d*) those which open in the normal way. In wild species numerous male plants exist and cross-pollination is the rule, the hermaphrodite plants having short, curved stamens and being self-sterile, while in the European cultivated vine there is a distinct tendency towards self-pollination.

Certain cultivated species also have short, curved stamens, which, at flowering time, rapidly grow out of reach of the stigma ; a number of such plants were selected and a bunch of grapes on each was freed from unopened flowers with the exception of a single bud left at the extremity of the bunch; this was enclosed in a bag and when about to open, the cap was lifted and pollen from two of the anthers was shaken over the stigma ; negative results were obtained in all the following cases : *Vitis cordifolia* (6 flowers), Black Eagle (4 flowers,) Jaquez d'Aurelles (7 flowers), Blue Favourite (9 flowers), Massassoït (5 flowers), Catawba (1 flower). Some of the flowers fell off at once while others dried up gradually.

Whole bunches of the varieties Jacquez d'Aurelles and Blue Favourite were put into paper bags and showed that the flowers of a particular bunch were not inter-sterile. Castrated flowers of Jacquez d'Aurelles and Massassoït were also successfully fertilized by pollen from another bunch on the same plant. Fifteen castrated Massassoït flowers gave positive results with Black Eagle pollen.

749 – **The Cultivation of Olives in Tunis.** — GUILLOCHON, VERRY, TOURNIÉROUX and ROBINET, in *Bulletin de la Direction Générale de l'Agriculture, du Commerce et de la Colonisation*, Year XVIII, No. 77, pp. 268-296. Tunis, May 1914.

After a few historical notes on the cultivation of olives in Tunis, the writers discuss the various methods of propagation from seed, suckers, cuttings of different kinds and grafts. The number of cuttings to be obtained from a tree was determined ; two trees were chosen, both about a hundred years old ; one, with a solid trunk, produced 400 cuttings weighing about 1 lb. each, and the other, with a hollow trunk, produced 280 cuttings.

In Northern Tunis the olive groves are nearly all under the control of the Ghaba, which is an organisation founded to encourage the production of olives. The distribution of the groves in the various districts is as follows :

District	No. of olive trees
Grombalia	1 843 066
Tunis	1 026 704
Bizerte	476 631
Kef (including Tembourouk)	91 440
Beja (including Medjdez-el-Bab)	74 986
Maktar	72 303
Souk-el-Arba	83 798
Total	3 668 928

In Central Tunis the olive groves are found in a coastal belt about 56 miles long and from 2 ½ to 12 miles wide. The land is undulating

and those portions which are unsuitable for planting serve as catchment areas, being provided with trenches 2 to 6 ft. wide to lead the water into reservoirs. Groves may contain from 30 to 60 trees per acre. Their distribution in the various districts in 1913 was as follows:

District	No. of olive trees
Sousse	4 578 495
Kairouan	186 062
Tala	11 106
	4 775 663

In Southern Tunis the rainfall is very irregular so that plantations yield a less uncertain crop than annual plants and amongst trees the olive predominates. The following numbers existed in 1913 :

District	No. of olive trees
Sfax	2 803 642
Gafsa	196 743
Gabes	65 588
Military circle	259 633
Total	3 325 606

Numerous varieties are grown, both for the production of oil and for pickling, the most prevalent of the former kind being the Chitoui and the Chemlali of Tunis and Sfax.

The cost of harvesting, which is done either by hand picking or by knocking the fruit off with a pole, varies from 10 to 12 fr. per "caffis" (5*d* to 7*d* per bushel) in a good year to 40 fr. (2*s* per bushel) in a bad year. In those groves under the control of the Ghaba, the olives are sold by auction ; the owner then pays 20 per cent. and the buyer 3 per cent. of the sale price to the Ghaba for managing the grove ; usually a net return of 4*d* to 10*d* is obtained per tree, but the crop is very uncertain and varied from 48 000 tons in 1911 to 5000 in 1910. In Central Tunis the yield is also vary variable ; from data obtained during five consecutive years it is estimated that a return of 5 or 6 per cent. should be obtained. In the south, olive trees under good management are estimated to produce :

at 8 years	¼ to ½	bushel	per tree
» 10 »	½ to 1	»	» »
» 15 »	1 to 3	»	» »
» 25 »	3 to 5 and 7	»	» »

The trees may be expected to maintain their yield for a considerable time under good management.

Oil extraction is carefully done in Tunis, and the oil is chiefly sold in France and Italy. The relative production of oil in the northern, central and southern regions respectively is about 1 :1 : 4, the total production being as follows :

	Production in hectolitres (1 hl. = 22 galls.)	Value per kg. in frs.
1900	339 800	0.70
1901	265 200	0.70
1902	161 770	0.62
1903	392 500	0.62
1904	255 650	0.62
1905	244 800	0.62
1906	243 000	0.62
1907	392 900	0.60
1908	68 000	1.00
1909	420 000	1.00
1910	550 000	1.00
1911	420 000	1.00
1912	205 000	1.50
1913	345 000	1.50

Numerous parasites, both insect and fungoid, attack the olive trees in Tunis. The Government does a good deal to encourage the cultivation of olives ; over and above the institution of the Ghaba, pruning competitions are held, and it is compulsory that all fallen fruit should be collected in order to check the propagation of the olive fly (*Dacus oleae*); further, all grafted olive trees are exempt from land tax (canoun) for fifteen years.

750 – **Avocados: *Persea gratissima* Gaert. and *Machilus glaucescens* Wight.** — RIVIÈRE, C., in *Journal d'Agriculture tropicale*, Year XIV, No. 155, pp. 132-137. Paris, May 31, 1914.

Machilus glaucescens is still somewhat unknown as a fruit tree. The fruit is not as large as that of the avocado, sometimes more drawn out, always green with somewhat oval and pointed seeds. The flesh is greenish and similar to the avocado in consistency and flavour. The tree is prolific, especially every alternate year, and more resistant to violent fluctuations of climate than the avocado. Its hardiness should make it very suitable as a stock for the avocado ; methods of cultivation are identical for the two plants.

LIVE STOCK AND BREEDING.

751 – **Investigations on the Presence of Tubercle Bacilli in the Flesh, Blood, and Intermuscular Lymphatic Vessels of Tuberculous Calves.** — HAEUTLE, CHR. in *Centralblatt für Bakteriologie, Parasitenkunde u. Infektionskrankheiten*, Vol. 74, Part 1-2, pp. 91-130. Jena, May 27, 1914. HYGIENE

The writer made intraperitoneal injections into 161 guinea-pigs and 9 rabbits, with blood, muscular-serum, and serum obtained from the intermuscular lymphatic vessels of 36 more or less tuberculous calves, with a view to solving the question of the pathogenic power of bovine tuberculosis. The most important results may be summarized as follows :

1. In the case of fat calves suffering from severe tuberculous infection of the spleen, liver, kidneys, lungs and so-called lymphatic vessels of the flesh, no infection of the blood is as a rule discernible.

2. No tubercle bacilli can be discerned in the muscular tissue of tuberculous calves, even in those cases in which the lymphatic vessels immediately connected with it shew tuberculous lesions or swelling.

3. Tuberculous infection of the lymphatic vessels may be present, even if they exhibit no tuberculous lesions ; and in the case of such fresh infection of the lymphatic vessels, still imperceptible macroscopically, the muscular tissue proves free from tubercle bacilli.

4. The macroscopically latent infection of the lymphatic vessels in a calf does not presuppose the infection of the blood by tubercle bacilli. The infection of these vessels must, in the absence of infection of the blood, be considered as communicated through the lymph ducts from other already infected vessels.

5. The mere swelling of a lymphatic vessel of the flesh is not invariably to be regarded as a definite indication of the infection of that vessel or of the muscular region connected with it, and in the same way the fact that a vessel retains its normal shape and size is no guarantee that it is free from tubercle bacilli.

FEEDS AND FEEDING

752 – **The Importance of the Inorganic Constituents of Feeding Stuffs.** — ZAITSCHEK, A., in *Allatorvosi Lapok*, Year 37, No. 19, p. 225. Budapest, May 9, 1914.

In collaboration with St. Weiser, the writer instituted investigations into the influence of the inorganic ingredients of foodstuffs on the development of bone in young pigs. The experiments shewed in the first place that when the animals were fed exclusively on maize, they excreted, in in spite of putting on muscle, more calcium than they retained, and made up the deficit with magnesium. Later, when the quantity of dry food was raised somewhat (from 700 gms. to 918.9 gms. for example, in the case of a pig weighing 98 lbs.) and 5 gms. of calcium carbonate added to the maize food, the deficit in calcium was replaced by a heavy increase, the amount of magnesium retained falling at the same time from 0.5092 gm. to 0.1013 gm. Simultaneously the quantity of phosphoric acid retained rose from 13 per cent. to 30.1 per cent. When the pig, weighing 115 lbs. was fed on barley only, getting 900 gms. of barley and 160 of starch every day, a slight surplus of calcium resulted, which was not sufficient to ensure a corresponding development of bone. An addition of 3 gms. of calcium carbonate to the daily ration produced a high absorption of calcium and phosphoric acid.

As the minimum quantity of calcium required depends on a variety of circumstances, it cannot be definitely indicated in such a way as to admit of growing pigs bring kept accurately balanced as regards calcium. In the experiments, a high absorption of calcium and phosphoric acid resulted when 10 or 11 gms. of calcium carbonate were added to the food per 100 kg. of live-weight. When young pigs were fed exclusively on maize, or maize and barley, the bones did not develop properly but seeing that both maize and barley contain phosphorus in sufficient quantity, it appears unnecessary to use the more expensive calcium phosphate in place of calcium carbonate. Pigs reared in the open usually pick up lime along

with earth, etc. and therefore under such circumstances it is superfluous to give them lime ; but animals, and especially young fattening pigs, in the sty, cannot supply their requirements as regards lime, and the lack of it only too easily renders the fattening process unsuccessful.

753 – **Feeding Experiments with Lupin and Horse-Chestnut Flakes.** — HAUSEN, REISCH, EWALD and LILIENTAL in *Illustrierte Landwirtschaftliche Zeitung*, Year 34, Nos. 42 and 43, pp. 391-392 and 399-400. Berlin, May 27 and 30, 1914.

The writers conducted some feeding experiments with lupins and with horse chestnuts deprived of their bitter principles by a new German process (1) and rendered suitable for feeding purposes. They used only the flakes prepared from blue lupins and from horse chestnuts without any other admixture. The contents in nutritive matter which the writers compared with previous analyses by Bässler are the following:

	Lupin flakes		Horse-chestnut flakes per cent.
	Writers' analysis per cent.	Bässler's analysis per cent.	
Dry matter	82.0	91.4	85.0
Crude protein	25.7	27.7	6.7
Pure protein	22.9	—	5.1
Crude fats	4.0	2.1	3.9
Nitrogen free extract	36.3	42.6	67.8
Fibre	9.1	11.2	3.5
Ash	7.2	7.7	3.2

The lupin flakes still had, as Bässler had also observed, a fairly bitter taste ; their alkaloid content was 0.18 per cent.

If the coefficient of digestibility for disembittered lupins and for horse chestnuts given in the literature on the subject be taken for these new flakes, they would contain the following amounts of digestible food :

	Dry matter per cent.	Crude protein per cent.	Fat per cent.	Carbo-hydrates + crude fibre per cent.	Protein per cent.	Starch value per cent.
Lupin flakes	82.0	23.4	3.5	41.8	20.6	63.8
Chestnut flakes	86.0	4.9	3.3	63.0	2.4	72.4

(1) The process, invented by VON FEHRENTHEIL of Liegnitz, is described and illustrated by P. HOEPFNER in *Illustrierte Landw. Zeitung*, No. 6, 1912.

(2) See *Landwirtschafliche Wochenschrift für Pommern*, p. 12, 1911.

Lupin flakes are therefore a food rich in protein and chestnut flakes in starch.

The animals experimented upon were cows and sheep; it was intended to feed them with both kinds of flakes, but the cows refused the lupins on account of their bitter taste and so only chestnuts were given to them.

I. *Fattening lambs with lupin flakes.* — The animals experimented upon were 24 yearling lambs divided into two equal groups. The first group was fed a basal ration of meadow hay, mangolds and barley groats, and as food for purposes of comparison 0.4 lb. of bean groats and earthnut meal per 100 lbs. live-weight. The second group got the same basal ration plus 1.1 lb. of lupin flakes per 100 lbs. live-weight. The experiment proceeded without any noteworthy incident, the lupin flakes being eaten up readily. The result was as follows :

	Group I lbs.	Group II lbs.
Increase per animal in 73 days	28.82	28.38
» » per day	0.396	0.389
Carcase weight in percentage of live weight. . . .	47.9	47.9

The lupin flakes thus had the same nutritive effect as a corresponding quantity of nutriment given under the form of beans and earthnut cake.

II. *Fattening lambs with chestnut flakes.* — In this experiment 24 Hampshire lambs were employed ; they also were divided into two equal groups, the first of which was fed a basal ration consisting of meadow hay, dried beet slices and soy bean meal, and, for comparison with the chestnuts flakes, 1.1 lb. of wheat bran and 0.66 lb. of maize per 100 lbs. live-weight. The second group received the same basal ration and 2.64 lbs. of chestnut flakes per 100 lbs. live-weight. During the whole time the chestnut flakes were readily eaten, and notwithstanding the large amount fed, did not affect the health of the animals. The following are the results :

	Group I lbs.	Group II lbs.
Increase of weight per animal in 73 days.	24.42	15.84
» » » per day	0.33	0.22
Carcase weight in percentage of live weight	48.8	45.6

According to the opinion of the butcher the lambs of the first group were not perfectly fattened, but still fat enough and provided with sufficient tender meat, while the lambs fed on chestnut flakes were thin and their flesh was soft and watery. On the whole the chestnut flakes proved unsatisfactory.

III. *Experiments with chestnut flakes for milch-cattle.* — Four cows were fed a basal ration consisting of hay, dry beet slices and soy bean meal and, during three periods, 0.8 to 3 lbs. of maize groats and 2 lbs. of wheat bran per 1000 lbs. live-weight, in comparison with 2 lbs. of chestnut flakes, fed during one period and 4 lbs. of the same flakes fed

during another one, always per 1000 lbs. live-weight. The experiment proceeded without any hitch and after the first three days the cows ate their chestnut flakes readily enough. These flakes however had the drawback, that during the fortnight during which 4 lbs. of them were given all the cows suffered from scour. The same happened when at the end of the tests the flakes that remained were fed to all the cows in the experimental herd. On the milk yield the chestnut flakes did not seem to have any effect, favourable or unfavourable, from which it appears that in doses up to 2 lbs. per 1000 lbs. live-weight, they can be freely fed to cows.

From the above experiments the writers conclude that while the preparation of these flakes is certainly interesting, the difficulties attendant upon their use render it doubtful whether it will be profitable to go on producing them.

754 – **Breeding Ardenne Horses in Sweden.** — ABRAMSON, ERIK. Pp. 14, Köping, 1914. HORSES, ASSES AND MULES

Ardenne horses began to be bred in Sweden in 1873, when Count Wrangel imported into Värmland two Belgian Ardenne stallions. The results obtained were so satisfactory that after a few years Count Wrangel imported 18 pure bred stallions and 14 mares. By the early eighties the importations of Ardenne horses into Southern and Central Sweden had become almost general. The crosses between Ardenne stallions and the native mares were more satisfactory than the native horse improved by Norvegian and thoroughbred blood. It was especially in Västergötland that the breeding of Ardenne horses reached a high degree of perfection. About the middle and towards the end of the eighties other breeds, such as Clydesdales, Shires, Percherons and Pinzgauers were used for crossing, but about the middle of the nineties it was clearly recognized in Sweden that on the whole the most suitable horse for the country was the Ardenne.

Since then the breeding of Ardenne horses in Sweden, assisted also by the State, has continued to develop. Up to 1900 the distribution of prizes by the State was almost exclusively for outward conformation, but since then the value of pedigree has been recognized. From this reorganization of the standards for the distribution of prizes the consolidation of the breeding of Ardenne horses in Sweden may be said to date. A further encouragement was the foundation of the Studbook Society for Swedish Ardenne horses with the assistance of the State and of the agricultural associations. It published a studbook for the whole country, in which only the Ardenne horses recognized by the State Committee for prizes are admitted. Up to 1913 inclusive, 4631 horses, 680 of which are stallions, have been entered.

In Sweden, besides the Ardenne horses, which are the most important, another breed of heavy draught horses is raised in the most northern provinces. These breeds are kept separate and serve different purposes. The Ardenne horse is employed in farm work and the smaller draught horse of the north is in demand for work in the forests. To a small extent Clydesdales are also bred.

The State and the agricultural societies spend yearly about £17 600 under the form of prizes for the encouragement of the breeding of draught horses which is for the most part carried out by the peasants. The stallions belong exclusively to associations formed for the purpose or to private owners. In Sweden there are only very few stud farms for Ardenne horses, those of Blomberg in Västergötland and of Bjärka-Säby in Östergötland being the best known.

The importation of Ardenne horses from Belgium is limited at present to only the best breeding animals for which not infrequently from £550 to £825 are paid for stallions and £165 to £220 for mares. In general in Sweden it is not the largest and heaviest Ardenne horse that is bred, but a meium-sized one combining strength, resistance and agility.

CATTLE

755 – **Experiments on the Profitable Feeding of Milch-Cows.** — GOLDSCHMIDT, H. (Royal Veterinary and Agricultural College, Copenhagen) in *Dansk Land*, Year 1, December number, pp. 453-470. Copenhagen, 1913. (Summarised by the writer).

This experiment is a kind of continuation of previous feeding experiments. These latter aimed partly at a comparison between the effect, that is the economical result, of a ration composed according to the usual empirical rules and that of another composed, with due consideration to the amount of nitrogenous and nitrogen-free matter in the different foods, in a manner proportional to the yield of milk of the different cows ; the experiments were also carried out to demonstrate that the so-called equivalents (" Ersatzzahlen "), the use of which during the last decades has spread greatly in Scandinavia and other countries, cannot be used alone when it is a question of compounding profitable rations for milch-cows, though they may perhaps be useful in the calculation of the money value of the food. Besides, these experiments serve to detect some errors in the feeding of cattle, as for instance using straw *ad libitum*.

The present experiment, which takes, lucerne as basal ration, is to be considered as a preliminary one ; especially as lucerne is still of relatively recent introduction in Denmark.

In the experiment two groups of ten milch cows each were employed. At first, during the period of observation, the cows were fed exclusively on lucerne *ad libitum*. It appeared in this period, among other things, that the weight and performance of the individual cows did not stand in any approximatively constant relation to the quantity of lucerne consumed, and that the older and drier the lucerne, the less of it was eaten.

In the experimental period which followed the observation period the cows of both groups were given 77 lbs. of lucerne and 2.2 lbs. of straw ; but while Group I received also 1.02 lb. of oilcake (containing protein) for every 10 lbs. of milk, Group II received a quantity of oats corresponding to the equivalent figures (Ersatzzahlen), namely 1.33 lb. for every 10 lbs. of milk. These rations were fed for the first 25 days, after which, for the remaining 20 days of the experiment, Group I was fed oats and Group II oilcake.

In both groups oilcake produced the greatest yield of milk. If the equivalent numbers had been correct, under the above mentioned condi-

tions the two concentrated foods should have had the same effect upon the production of milk.

That the addition of oilcake to a forage so rich in protein as lucerne was able to cause a relatively greater increase in the milk yield than the oats is due not only to the fact that the content of digestible protein in the lucerne (77 lbs.) was not large enough without further addition to cover the want of this substance, but also to the fact that the relatively large amount of nitrogen-free matter contained in the oats was not capable of balancing the comparatively low content of protein in this food. or, in other words: the above result shows that it is comparatively easy to force the yield of milk by the use of protein at the expense of the fat contained in the body, when the cows are in good condition (which was the case in this experiment), while it is difficult to do so with carbohydrates at the expense of the protein-containing tissues of the body.

According to the calculations which have been made on the basis of the analyses of the foods employed in the experiment and according to the quantities of milk obtained and the weights observed (test milkings were made daily and the cows were weighed every 5 days,) the following conclusions were drawn :

1. Lucerne alone can only exceptionally and temporarily afford a profitable food for milch cows.

2. Lucerne combined with other food is one of the best fodders for milch cows. In proper proportions lucerne is admirably suited to increasing the profitableness of cattle keeping.

3. Under the given conditions, when it was a question of compounding an economical ration for cows in excellent condition, the addition of oilcake, to a limited quantity of lucerne (77 lbs.) was more favourable to the yield of milk than a corresponding quantity of oats (on the basis of equivalents).

The results of the experiment show further that the substitution of foods rich in protein by those rich in carbohydrates may produce exactly the same milk yield without justifying the conclusion that in any particular case one food can effectively replace a corresponding quantity of the other food. This observation has long since and repeatedly been made by the writer.

On the basis of these results and the considerations to which they give rise a series of general rules may be established for the use of lucerne during the various periods in summer.

1. As long as the lucerne is young, that is up to about the 15 th. of June, it is to be supplemented by mangolds (or if necessary cereals, etc.).

2. From the 15th. of June to about the 15th. of August lucerne, being older, is to be fed with oilcakes, or, if it is fed in smaller rations, with oilcake and cereals, etc.

3. From the 15th. of August to about the 10th. of September lucerne, should be supplemented by oilcake and mangolds.

The report contains a number of suggestions for mixtures of varying quantities of lucerne with several other foods.

PIGS

756 – **Investigations into the Metabolism and the Potential Energy of Foods in Growings Pigs.** — FINGERLING, KÖHLER, REINHARDT, BRETSCH, ARNDT and DIETRICH in *Die Landwirtschaftlichen Versuchsstationen*, Vol. 86, Parts 3 and 4, pp. 149-230. Berlin, May 25, 1914.

These experiments are a continuation of those of Kellner on the utilization of pure foodstuffs by ruminants. The method followed differed somewhat from Kellner's: the two animals under experiment were given, in a preparatory period, a basal ration consisting of a mixture of barley groats, meat meal, phosphate of lime (" Futterkalk ") and common salt. In the following period, pig. no. 1 was given successively, besides the basal ration, potato starch, earthnut oil, " strohstoff " (straw cellulose, obtained by boiling straw under pressure in an alkaline medium) and gluten; pig no. 2 was given meat meal (0.66 lb.) and sugar. Lastly both pigs were fed the basal ration again, the same in quantity and quality as at the beginning of the experiment. The different periods lasted 13 to 14 days (some only 12) and the observations made during this time dealt with the metabolism and consumption of energy, from which the utilization of the food given was calculated.

The result of these investigations demonstrated that pigs utilize the productive parts of food to a greater extent than is the case with ruminants. When the individual foods are given separately in an easily digestible form, as in gluten meal, starch meal, earthnut oil, " strohstoff " and sugar, their higher utilization by pigs as compared with the same by mature cattle is as follows:

Gluten protein	35.1	per cent.
Fat	31.8	» »
Carbohydrates	30.0	» »
Crude fibre	0.0	» »
Sugar	32.1	» »

With the exception of digestible crude fibre, which is not more utilized by pigs than by cattle, the better utilization of the different foods attains nearly the same value. It appears thus that Kellner's starch values, which are only relative figures, may be used also for calculating the rations of pigs, all the more as crude fibre has only a secondary importance in the rations usually given to pigs.

POULTRY

757 – **Rearing Ostriches in Madagascar.** — *Bulletin de l'Office colonial du Ministère des Colonies*, Year VII, No. 76, pp. 189-200. Melun, April 1914.

The ostrich farm at Tulear made satisfactory progress during 1912 and another is being established at Befamany. The diet of lucerne has proved very healthy for the birds whose plumage has considerably improved, the tail feathers of the male birds fetching as much as 36 *s* per lb. Anthrax has accounted for a good many deaths and it is suggested that the anthrax organism is able to live in the body of the ostrich as a saprophyte, becoming pathogenic when the general health of the bird is bad; the fact that large numbers of the organism are found in the body of ostriches who have died after excessive exercise, lends support to this hypothesis.

758 – **Mulberry Leaves Preserved in Cold Storage.** — BUFFA, P., 8 pp. Riccardo Bigontina, 1914. SILKWORMS

More than a ton of mulberry leaves were distributed in 39 boxes made of zinc or wood and in various sizes; the boxes were closed and kept in cold storage at a temperature of 2° C. (35.6° F.) from June to August, after which they were used to rear silkworms and compared with fresh leaves for that purpose. Atmospheric conditions were most unfavourable throughout the experiment.

From the results obtained the following conclusions were drawn:

1. Large quantities of mulberry leaves can be preserved by means of cold storage.

2. The temperature of the storage chamber should be constant between 1° and 2° C. (33.8 and 35.6° F.).

3. It is better to precool the leaves for a few hours before putting them into the storage chamber.

4. The containing boxes should not be of greater capacity than 3 cu. ft. (holding 56 lbs. of leaves) and should be packed in the chamber in such a way as to allow free ventilation in all parts.

5. Stored leaves were eaten with as much relish by the silkworms as fresh leaves and gave equally good results with regard to both the worms and the cocoons produced.

6. The cost of storing the leaves in a chamber of 4200 cu. ft. capacity amounted to 1*s* 9*d* per cwt.

759 – **Sericultural Products in Persia.** — LAFONT, F. in *Bulletin mensuel de l'Office des Renseignements agricoles*, Year XIII, No. 4, pp. 418-420. Paris, April 1914.

The trade in silkworm eggs in Persia is practically entirely in the hands of Greek merchants who obtain nearly all their graine from abroad. There are, however, a few isolated breeders in Persia and a certain amount of unselected graine is also produced and sold fraudulently as imported selected graine. Imports during the past 8 years are given in the following table.

Imports of graine in ounces of 25 gms. (= 0.88 *oz. avoir.*).

1905-1906	242 413
1906-1907	346 202
1907-1908	398 156
1908-1909	—
1909-1910	322 246
1910-1911	308 782
1911-1912	372 640
1912-1913	280 000

Four-fifths of the imports come from Turkey, and the rest from Russia, while insignificant amounts are obtained from France and Italy, the importation of graine from western countries being impeded by local prejudice. The eggs are usually sold on credit the cash price being about 4*s* per oz. of 25 gms.

There are no statistics as to the production of cocoons in Persia, but this is estimated at 5950 tons of raw material per annum. This low production is due to defective rearing methods and to the poor quality of the eggs which are frequently diseased. The cocoons are of poor quality and fetch 7*d* to 8 ½*d* per lb. in the raw state ; they are chiefly exported to France and Italy ; those not exported are worked up by the cultivators themselves, who only have very primitive apparatus at their disposal and turn out a rough, faulty, dull tissue which would be unsaleable in Europe ; the best qualities are worth 8*s* 6*d* to 9*s* 3*d* per lb. according to the state of the European market. Not more than about 120 tons of waste is produced per annum, best quality floss fetching about 1*s* 6*d* per lb. at Constantinople.

It would certainly be more profitable to export the silk in the form of good reeled silk than in the form of cocoons and there would seem to be an opening for European reeling mills in Guilan, Mazanderan, and Khorassan. The present production would require about 20 000 modern reeling units. The chief obstacle to the establishment of such mills is the mussulman customs which prevent men from entering the workshop where women are working, consequently preventing proper superintendence of the work.

FARM ENGINEERING.

AGRICULTURAL MACHINERY AND IMPLEMENTS

760 – **New Implements used at the Flahult Experiment Farm, Sweden, in the Year 1913.** — AKERBERG, H. in *Svenska Mosskulturföreningens Tidskrift*, Year XXVIII. No. 2, pp. 147-154 + 7 figs. Jönköping, March 1914.

At the Flahult Experiment Farm the following implements were tested last year : a dung spreader, a Swedish lime and artificial manure spreader, a combined field leveller (Ackerschleife) and spring tooth harrow, a rotary harrow and three different ploughs.

The *dung spreader* is built for one horse and consists of a cart with a moveable bottom, which, like an endless chain, carries the dung towards the back of the cart, where a distributor scatters it in a finely divided state behind on the same principle as that adopted by the large manure spreaders of the International Harvester Co. The width over which the manure is spread is 4 feet. One man and one horse working 10 hours can manure from 1 ¼ to 1 ½ acres a day at the rate of 8 tons to the acre. The machine is therefore suitable for small farms. The work done was excellent with both large and small quantities of peatmoss dung.

The *"Albion" artificial manure spreader*, which is built chiefly for spreading pulverized lime, was used for basic slag and potash salts. The work done was satisfactory, but attention had always to be paid to the speed at which the machine was driven, as this influences the quantity distributed. When the weather was damp the spreading was not so good. Further experiments with superphosphate showed that this fertilizer cannot be spread with the machine, as it is liable to choke it.

The *field leveller and spring-tooth harrow* "Svensk" was tried on a fen and on sandy soil, but with no great success, as the soil was too loose. On heavier and firmer soil it appears to work better.

The *rotary harrow* "Hankmo" from Finland resembles Wassis' spade harrow, but differs from it in that the axles are adjustable and the spades are replaced by narrow, pointed, slightly curved blades. This harrow was tried on moor and fen land, as well as on sandy soils; it was used on ploughed land, stubble and after beets, and every where worked satisfactorily. On old, stiff, unbroken meadows the soil was rendered fit for sowing by going over it twice with the Hankmo and once with a smoothing harrow. It requires considerable draught in consideration of the width of work done.

The *swing ploughs* Reval 1 and Reval 2, built by the Swedish Norrahammar works, for Russian moor soils, were used on moor and fen land. No. 1. proved very useful for cultivating and for breaking up old stiff tussocky meadows. No. 2, was not so good for moor soils.

The third *plough* tried, the "Victoria", was built on the American Albion type. The specimen tried had been specially modified for moor soils. On old compact moors the performance was satisfactory; for loose, imperfectly decomposed or wet moors it is not so suitable. On mineral soils it worked admirably.

761 – **Tile-Drain Trench-Digger.** — *Engineering*, Vol. XCVII, No. 2525, p. 708. London, May 22, 1914.

In countries where irrigation is recent, as in America, South Africa, etc., the tendency has been rather to neglect drainage, with the frequent result of waterlogged soil and a consequent falling off in the crops.

Where the tracts of land are large and labour scarce, drainage presents difficulties, which tend to the mechanical treatment of the problem. Thus the mechanical excavator has been adapted to this kind of work. The accompanying figure illustrates a successful form of tile drain ditcher built by the Austin Drainage Excavator Co., of Chicago, U. S.

It is constructed to travel over soft ground. Eighty-five per cent of the 5 ½ tons that the machine weighs is supported by an endless chain of flat feet on each side and at one end of the machine. The pressure per square foot on the ground is only 390 lbs. The other supporting wheels are of the usual broad-tyred pattern and they are not near the trenching operations.

The trench is cut by a series of scoops or buckets, with lips of forged steel, attached to an endless chain and carried by a ladder or boom which is hinged at one end to a vertical frame, on an extension of which pass the cables for adjusting the height of the ladder.

The buckets can easily be fixed or removed from the chain. They are made three sizes: 10, 12 and 15 inches, which, with side cutters, secure trench widths of 12, 15 and 17 in. respectively. The buckets are cleaned of their contents by a strong fixed scraper which clears clay as effectively as light soil. The material brought up is delivered by the belt of a conveyor to one side of the trench.

The ditcher can excavate to a depth of 6 ft. according to the position of the ladder.

For usual conditions, making a cut 10 to 15 in. in width, 6 ft. deep and advancing at the rate of 15 ft. per minute, a two-cylinder 14 to 16 HP petrol engine is mounted on the machine. Steam power can be applied if preferred. It is self-propelling and moves on roads at 1 ½ to 3 miles an hour. It can turn in its own length.

It is estimated that the cost of running under normal conditions in the United States, including repairs, is less than $10 per 10-hour day. Large sized ditchers cut trenches up to 40 in. wide and 12 ft. deep.

762 – **Spring-tooth Cultivator.** — From Report of Patents, in *Wiener Landwirtschaftliche Zeitung*, Year 64, No. 18-19, p. 164. Vienna, March 21, 1914.

The novelty in the cultivator recently patented in Germany in Class 45 a, under Number 60 999, consists in the flat spring teeth being laterally twisted in their lower extremity (see fig. 1). By this means the teeth can, according as they are raised or lowered and turned inwards or outwards, increase or diminish the heights of the ridges and adapt themselves to any form of ridge or bed and distance of rows. In the framework *a* are fixed two pivots *b* round which square axles *cc'* can turn. The spring teeth *dd* are fixed to the axles by clamps *ff*; a connecting rod *i* unites the levers, *hh'* attached to the axles *cc*. The lever *h'* is lengthened to an adjustable hand lever *h''*. The position of the wheels *n* can also be regulated as to height and width of gauge. Each of the spring teeth can be so shifted as to correspond to the shape of the ridge to be worked (see fig. 2), while the depth to which the teeth penetrate into the soil is regulated by turning the axles *cc*.

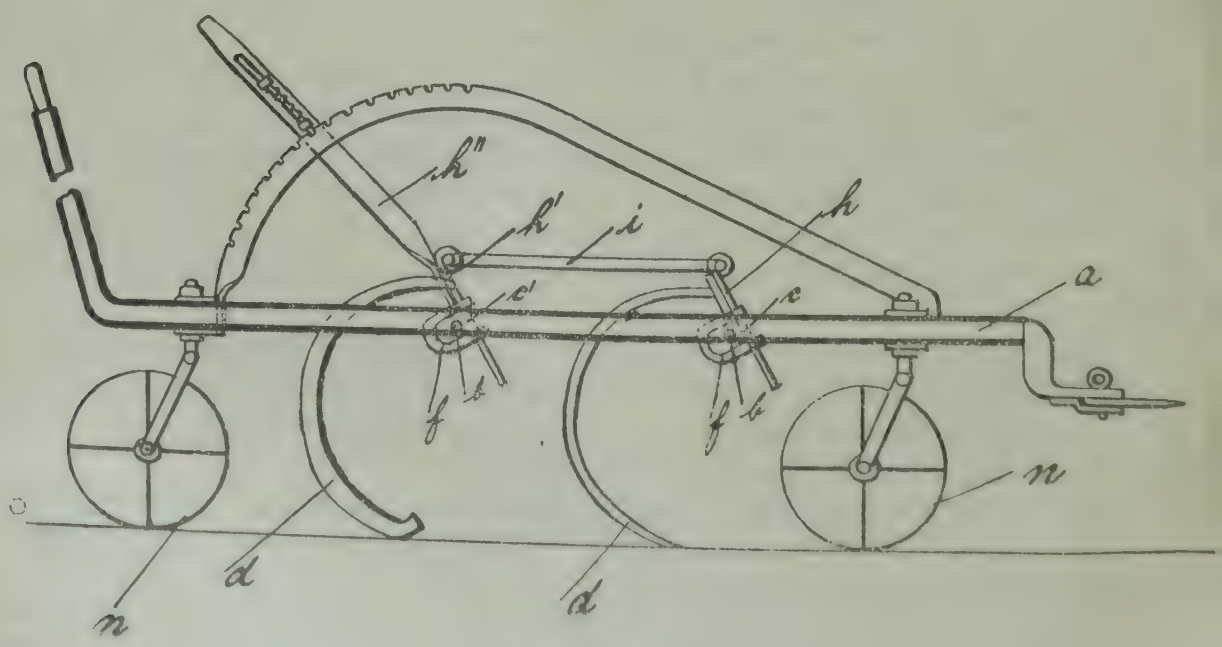

Fig. 1. — Spring-tooth cultivator (side elevation).

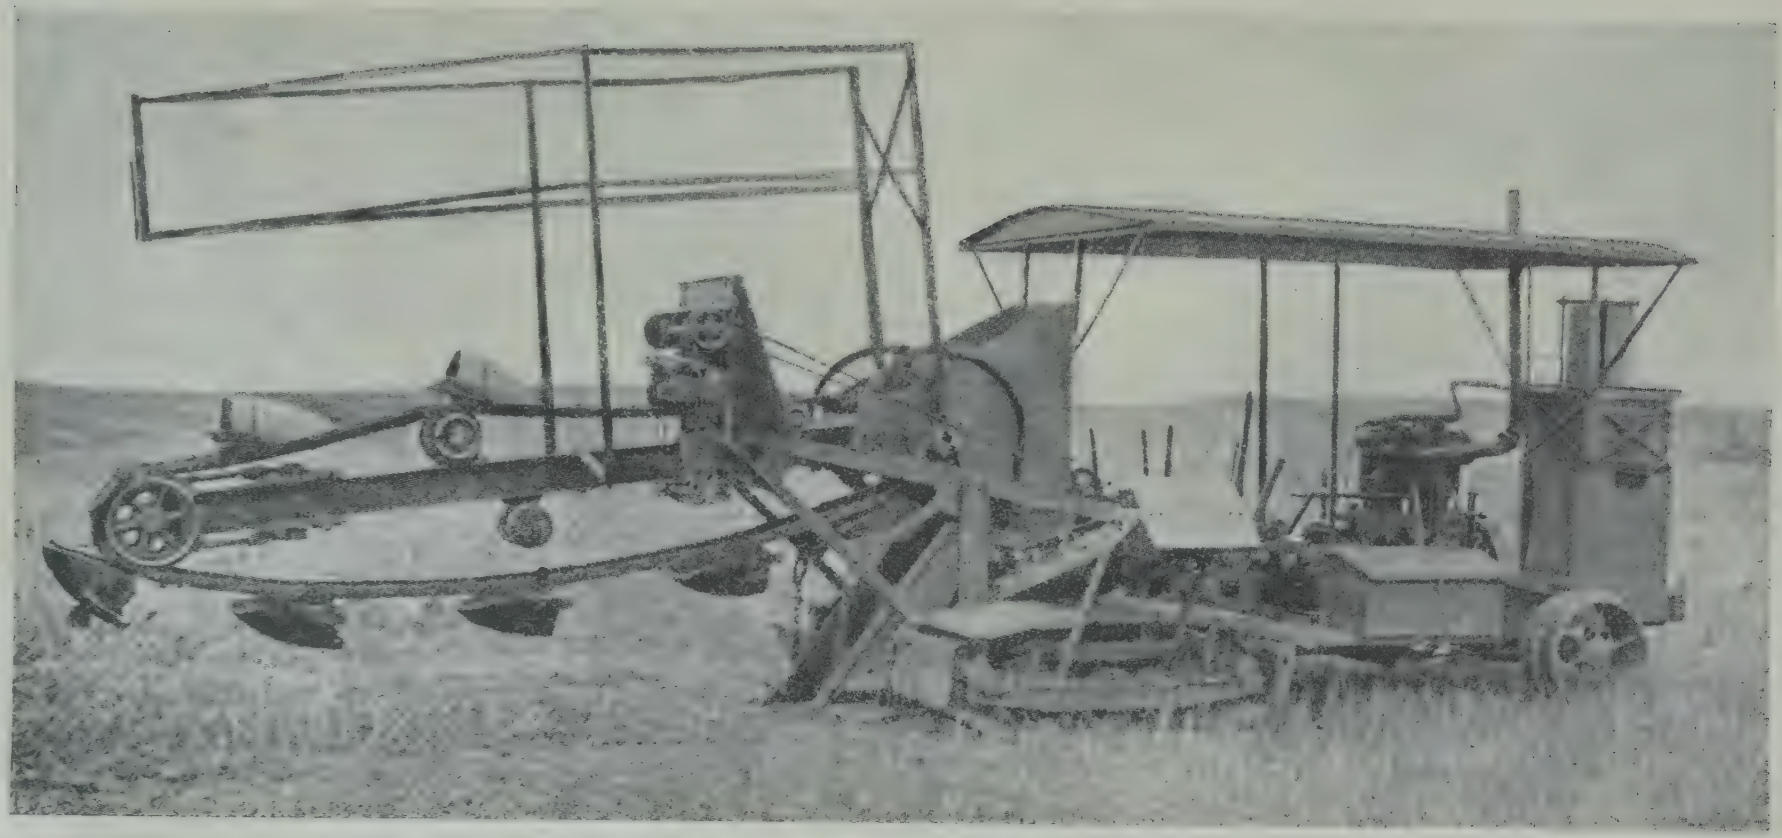

Tile-drain trench-digger made by the Austin Drainage Exavator Co., Chicago, U. S. A.

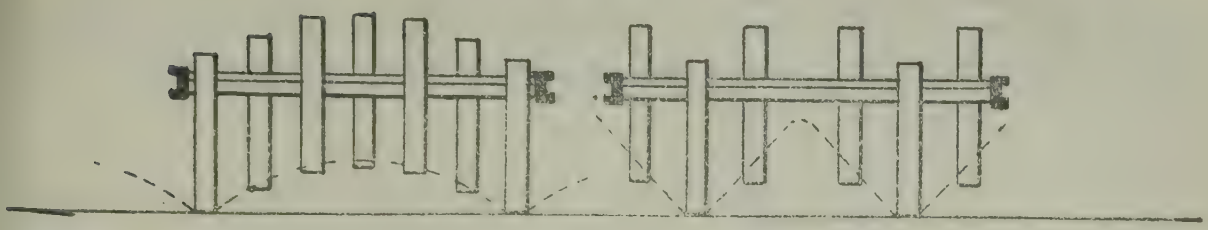

Fig. 2. — Spring-tooth cultivator, showing adaptation of teeth to ridges.

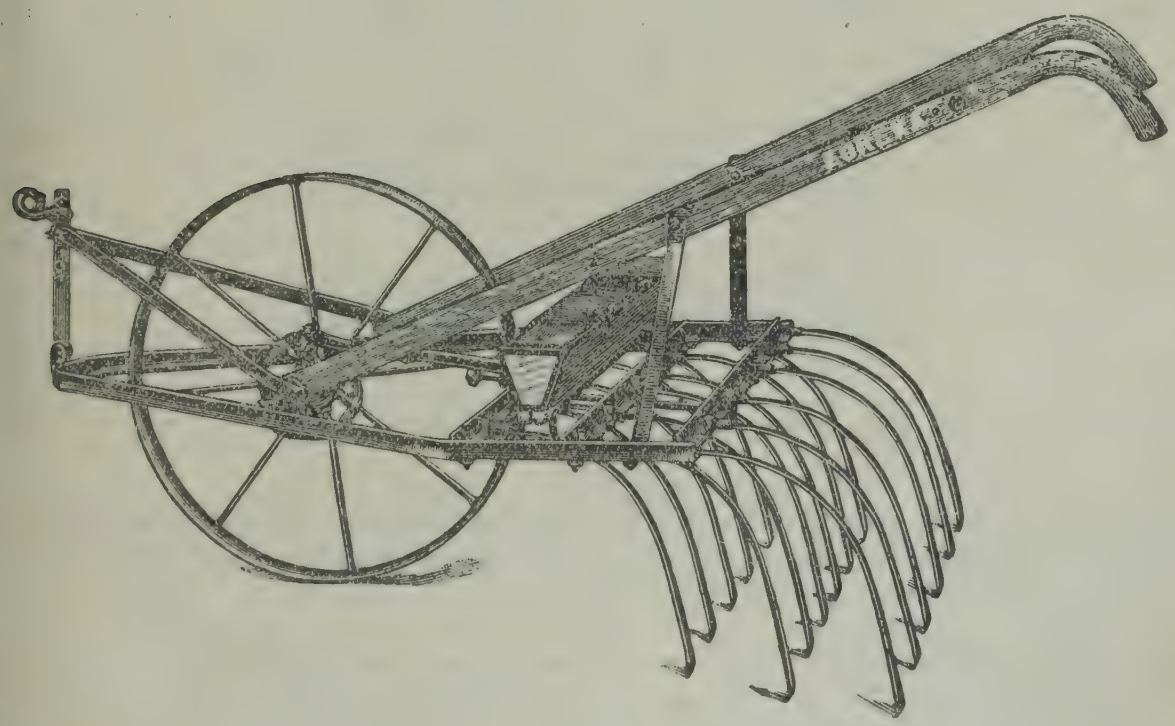
763 – **A New Mulcher and Seeder.** — *Farm Implement News*, Vol. XXXV, No. 16, p. 32. Chicago, Ill., April 16, 1914.

The new three-foot mulcher and seeder shown in the accompanying figure has lately been placed on the market. It is described as a mulcher, smoothing harrow, surface cultivator, seed sower and weeder, all in one. It enables farmers to sow grass seeds or grain between rows of other plants. The teeth cover the seed perfectly and level the ground . One horse only is needed.



A new mulcher and seeder.

764 – **Combined Horse-Hoe and Roll for Beets.** — *Blätter für Zuckerrübenbau*, Year XXI, No. 10, p. 161 + 3 figs. Berlin, May 31, 1914.

This device is patented in Germany under No. 267 840. It allows of several rows of beets being hoed and rolled at the same time.

The rollers and the hoes work independently of each other and can adjust themselves to inequalities of the field, being attached by separate arms, *b* and *d* (see fig. 1, side view, and fig. 2, plan), to the frame, *a*, of

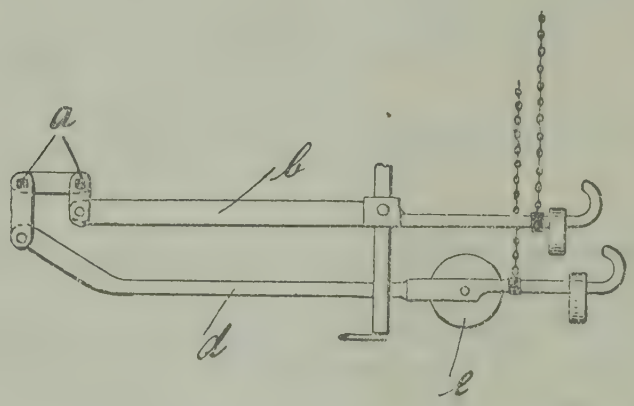


Fig. 1. — Combined horse-hoe and roll for beets (side elevation).

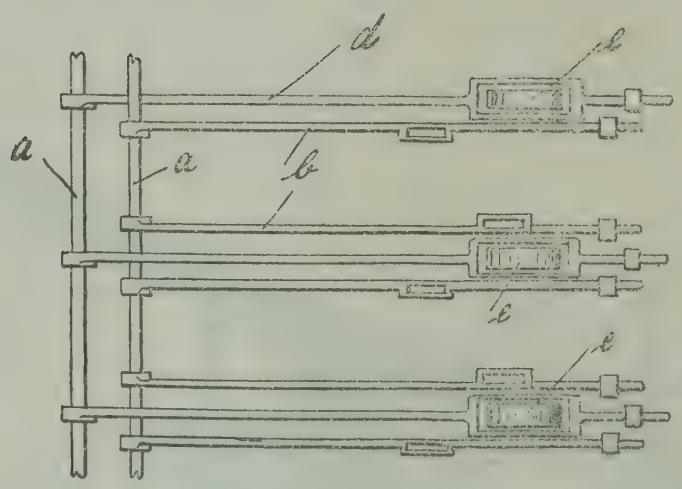

Fig. 2. — Combined horse-hoe and roll for beets (plan).

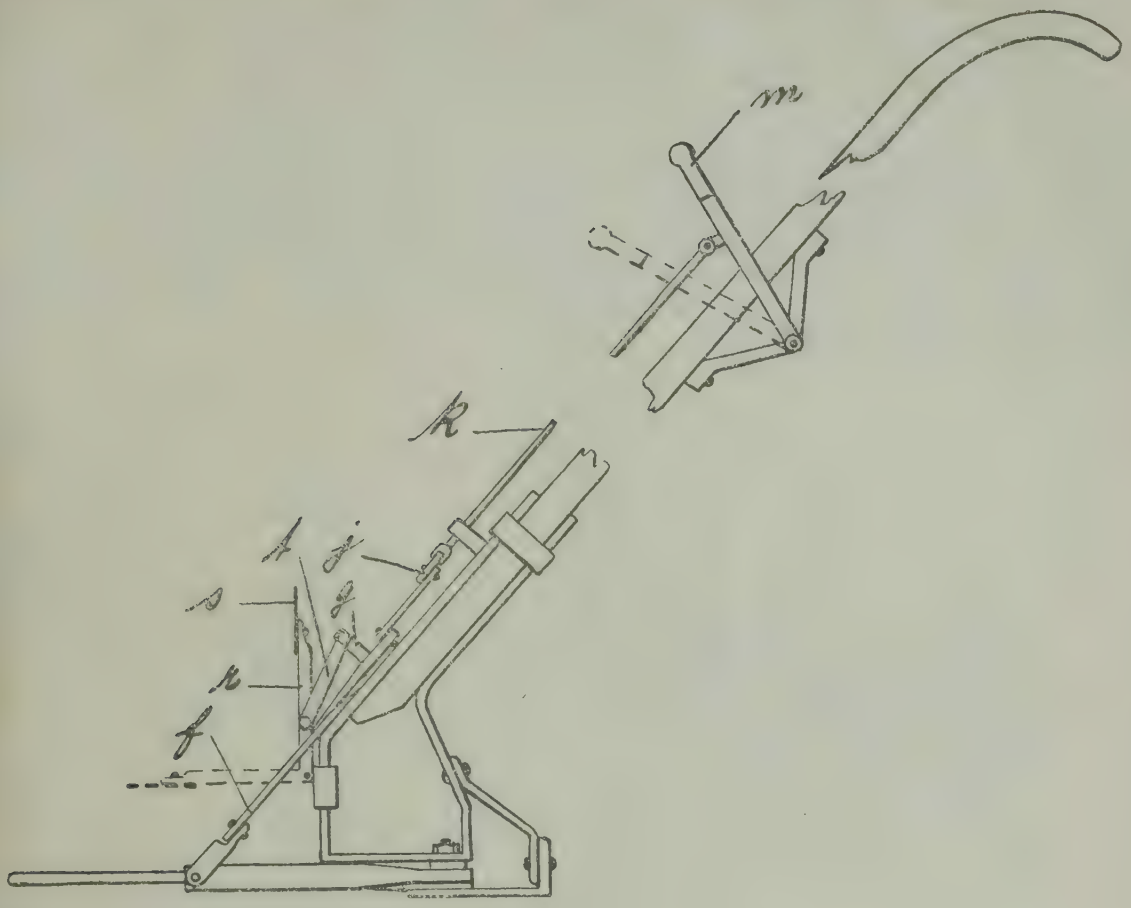
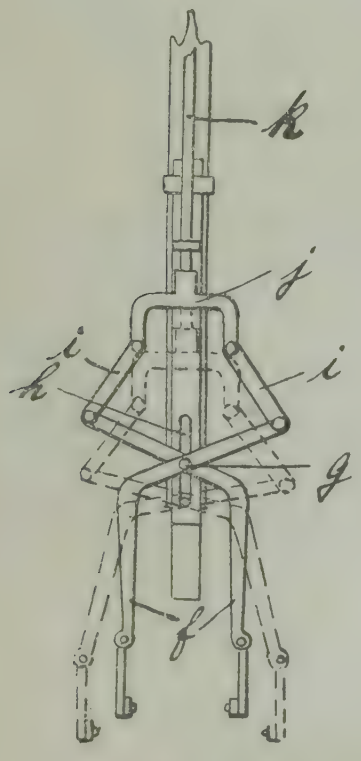
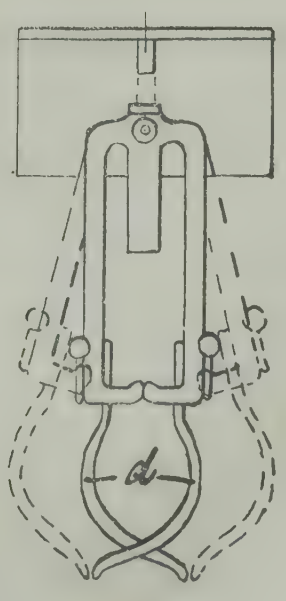
the machine. In heavy soils both hoes and rollers are provided with weights (*f*). The machine is fitted with steering gear fore and aft, so as to ensure the greatest precision of work.

765 – **Hand Beet-Lifter.** — *Blätter für Zuckerrübenbau*, Year XXI, No. 8, p. 129 + 3 figs. Berlin, April 30, 1914.

The hand beet-lifter shown in figs. 1, 2 and 3 is patented in Germany under No. 267230. It lifts and tops at the same time ; the cutting blade is fixed by an articulated joint to the rest of the implement in such a way that it assumes a position parallel to the jaws when these are open and turns up when they are closed. For opening and shutting the claws and lifting and lowering the blade *s*, the hand-lever, *m*, is used. It acts upon the connecting rod, *k*, a cross piece, *j*, the joint, *i*, and the claws, *f*, the bolt, *g*, of which works in a slot, *h*.



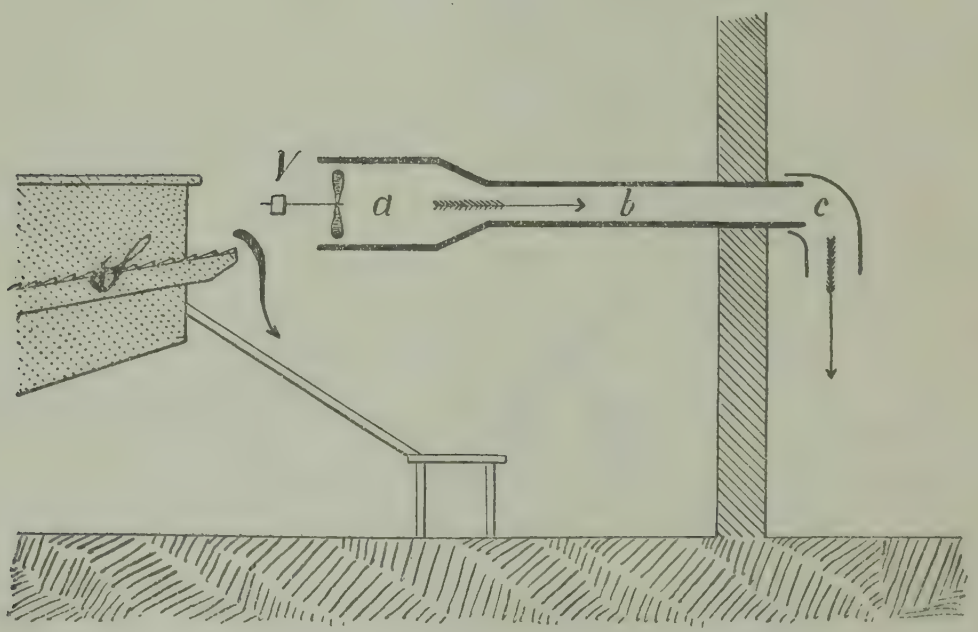




Hand beet-lifter.

766 – **Apparatus for Removing Dust while Threshing.** — DUVAL, CH. in *Journal d'Agriculture Pratique*, Year 78, Vol. I, No. 20, p. 624, Paris, May 14, 1914.

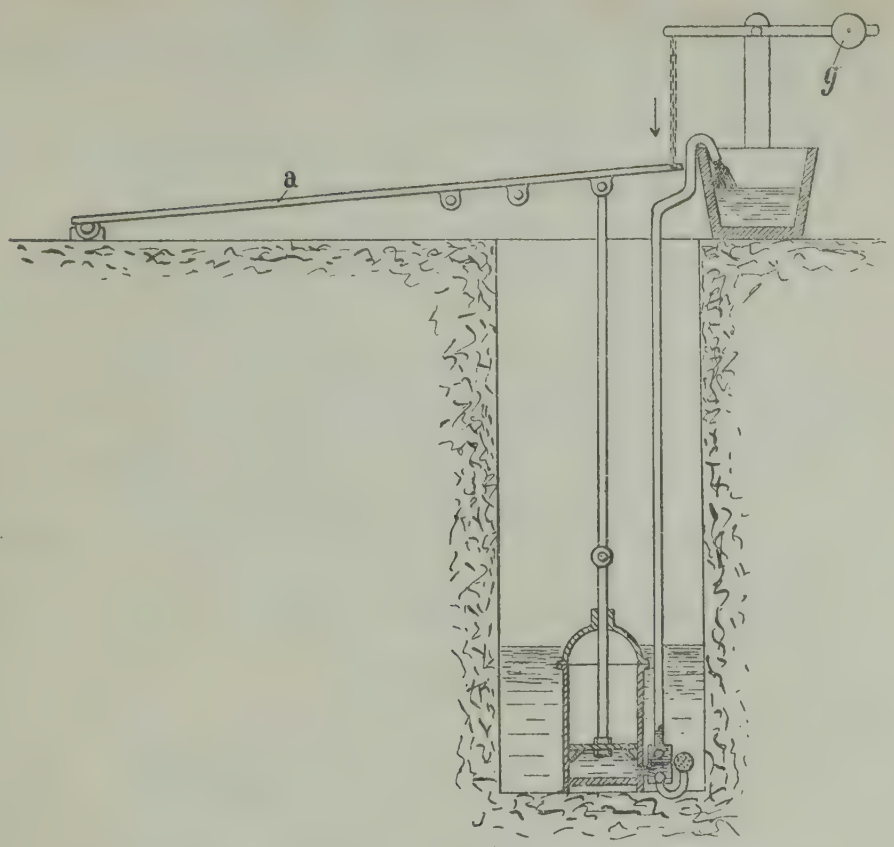
The accompanying figure is a sketch of an apparatus used for several years by the writer to remove dust while threshing. The screw-fan, *V*, rotating in front of the shakers, leads the dust into the pipes *a*, *b*, as shown by the arrows. The diameter of the fan and of the pipe *a* is about 40 inches, while that of the pipe *b* is only 24 inches. The moveable bent pipe, *c*, allows the action of the wind to be counteracted. The main pipe is about 15 ft. long and the dust can be driven a distance of 40 ft. The cost of the apparatus is from £16 to £20.



Apparatus for removing dust while threshing.

767 – **Pump for Watering Cattle worked by the Animals themselves.** — HINRICHS, in *Deutsche Landwirtschaftliche Presse*, Year XLI, No. 40, p. 500. Berlin, May 20, 1914.

This apparatus is designed with the object of saving the labour of pumping up water into the drinking troughs of pastures not provided with running water. The accompanying figure shows a section of the apparatus. The animal on mounting on the platform, *a*, starts the pump, which raises a certain amount of water. The counterweight, *g*, lifts the platform into its original position when the animal leaves it. A fence is placed round the apparatus to prevent its being used by more than one animal at a time.



Pump for watering cattle worked by the animals themselves.

768 – Review of Patents.

Tillage Machines and Implements.

Austria	65 192. Implement for removing weeds and the like from beet fields.
	65 386. Motorplough which can be used as a lorry or power engine.
	65 582. Clod-crusher.
	65 584. Turn wrest plough.
Belgium	264 420. Beetroot hoe.
Canada	152 930. Gang plough.
	152 969. Garden weeder.
	152 982. Motor plough.
	153 047. Land drag.
	153 079. Pulverizer, planter and weeder.
	153 081. Hoe and plough.
	153 103. Rolling drum plough.
	153 145. Land roller.
	153 165. Cultivator and weeder.
	153 180. Weeder for harrows.
	153 194. Plough beam.
	153 268. Weeder.
France	464 996. Motor plough.
	465 079. Machines for hoeing and singling beets.
	465 650. Rotary subsoil digger.
	466 103. System for fixing the moveable point of the plough.
	466 287. Apparatus for anchoring tillage machines, driven by portable engines, and advancing automatically as the work proceeds.

	466 490. Ploughshare with reversible edge.
	466 754. Hoeing and singling machine for horse or motor traction.
	466 841. Kneed cultivator tooth.
	466 855. Jointed ridging plough.
Germany	272 760. Motorplough, the front end of whose frame can be raised or lowered on the front wheel.
	272 819. Screw for ditching plough.
	272 844. Apparatus for driving ploughs by electromotor.
	272 787. Driving wheel with movable projecting cleats, for agricultural machines.
	272 877. Disk harrow with adjustable counter pressure disk.
	272 879. Plough with device for ploughing in green manure.
	272 947. Motorplough with one driving wheel.
	273 289. Two-furrow turnwrest plough with one plough on each side of the beam, thus balancing each other.
	273 377. Depth and inclination adjusting device for Flemish turnwrest ploughs.
Hungary	62 384. Motor rotary digging machine.
	62 399. New cultivator.
	62 448. Hoeing and ridging plough.
	62 470. Gang plough.
	62 503. Harrow.
	62 521. Motor gang plough with reversible motion.
	62 562. Self contained motor plough.
	62 604. Rotary cultivator.
	63 069. Rotary tilling machine.
	63 119. Driving wheel for agricultural machine, with cleats worked by an excentric.
	63 207. Device for raising or lowering plough shares.
	63 275. Weeding rake.
	63 341. Horse hoe.
	63 382. Steering gear for motor cultivator.
Italy	149 464. Device for balance ploughs to protect the headlands.
Switzerland	63 945. Toothed tilling machine.
	64 397. Ploughs.
	65 063. Motor fore carriage for ploughs in which the frame is beneath the axle of the side wheels.
	65 064 and 65 065. Machines for tilling the soil.
United Kingdom	28 234 and 28 288. Rotary power cultivators.
	28 391. Cultivator.
	28 861. Hoe blades for rotary hoe.
	29 210. Hand rakes.
	29 729. Agricultural ploughs.
	29 812. Digging machines.
	29 967. Cultivators.
	303. Motor cultivators.
United States	1 091 358. Cultivator.
	1 091 273. Revolving harrow.
	1 091 131. Zig-zag harrow.
	1 091 031. Subsoiler.
	1 090 935. Steering wheel for ploughs.
	1 091 681. Implement adjusting device for cultivators and the like.

1 091 712. Hand cultivator.
1 092 632. Rotary plough.
1 092 249. Disk harrow.
1 093 421. Steering device for cultivators.
1 093 786. Weed destroyer.
1 094 201. Land roller or pulverizer.
1 094 240. Plough.
1 094 277. Motor plough and planter.
1 094 196. Orchard plough.

Manure distributors.

Belgium 264 236. Mixing barrel for diluting and distributing cow dung.
Germany 272 948. Ratchet wheel and pawl drive for manure spreader.
Hungary 62 483. Manure distributor.
62 837. Liquid manure spreader.
Switzerland 65 293. Liquid manure cart.
United States 1 091 163. Fertilizer distributing attachment.
1 093 826 and 1 093 928. Fertilizer distributors.

Drills and sowing machines.

Austria 65 387. Potato planter.
65 581. Device for drills with sliding disks.
65 583. Dibbling mechanism.
Belgium 263 848. Beet drills.
Canada 153 280. Grain drill.
153 301. Corn-hill marker.
France 466 098. Sowing machine.
466 525. Drill.
Germany 273 171. Potato planter in which the potatoes are taken out of the hopper by revolving forks.
273 172. Sowing machine with unmoveable agitator wheels.
273 001. Tubes for potato planters.
273 291. Potato planter.
273 378. Potato planter with several tubes each with two slides.
Hungary 62 383. Improvements in dibbling machines.
62 441. Potato planter.
62 688. Seed pickling machine.
Italy 139 156. Drill.
Switzerland 65 469. Seeding apparatus with agitator wheels.
United Kingdom 28 290 and 29 967. Seed drills.
United States 1 091 068. Attachment for corn planters.
1 092 007. Marker mechanism for corn planters.
1 092 030. Corn planter.
1 092 358. Seeder attachment for gang and sulky ploughs.
1 093 991. Planting machine.
1 093 938. Transportable potato hole digging machine.

Reapers, mowers, etc.

Austria 65 774. Machine for hammering the blades of scythes.
Belgium 263 445 and 263 446. Attachment for mowers for arranging clover and other grasses in regular windrows.
263 684. Lawn mower with cutter-bar.

Canada	153 006-7 and 153 073. Harvester mechanisms.
	153 127. Harvester,
	153 132. Sheaf-loader.
	153 229. Harvester machine.
	153 250. Lawn trimmer.
	153 284. Lawn mower.
	153 302. Stacker mechanism.
	153 333. Grain carrier.
France	465 150. Improvement in the cutter-bar of mowers and reapers.
	466 298. Improvement in side delivery rakes convertible into tedders.
Hungary	62 496. Hay fork with wooden tines.
Italy	139 867. Device for mowers to prevent the knives from blocking.
Switzerland	63 947. Mower with reaping attachment.
	63 948. Cutter-bar for mowers.
	64 398. Machine for hammering scythes.
United Kingdom	28 578. Scythes.
	29 497. Harvesting machine.
United States	1 091 064. Hay rake and stacker.
	1 091 105. Knife arrester for mowers or binders.
	1 091 109. Corn topper.
	1 091 747. Corn harvester.
	1 091 779. Heading attachment for Kafir corn harvesters.
	1 092 721. Harvester.
	1 092 356. Grain stooker.
	1 092 722. Mowing attachment for motor vehicles.
	1 093 108. Harvesters for beans and the like.
	1 093 109. Kafir corn topper.
	1 093 742. Header and header binder.
	1 093 906. Shock-forming attachment for grain binders.

Machines for lifting root-crops.

Belgium	263 443. Improvements in toppers and lifters for beets and other roots grown in rows.
	263 480. Toppers for beets and other roots.
Canada	153 281. Potato digger.
France	464 872. Beet topper and lifter.
Germany	272 820. Potato harvester with tilting scoops.
Hungary	62 403. Beet topper.
	62 495. Steering gear for beet-root lifters.
	62 663. Potato lifter.
	62 950. Root lifting machine.
	63 377. Beet lifter.
United States	1 090 871. Beet harvesters.
	1 091 823. Beet topper and digger.
	1 092 216. Beet harvester.

Threshing and winnowing machines.

Austria	65 630. Device to prevent the straw from winding round the cylinder in threshing machines.
Belgium	263 042. Improved hand threshing machine for all cereals.
Canada	153 054. Threshing machine.
France	465 904. Straw elevator for threshing machine.

466 566. Group of machines for threshing and cleaning wheat.
467 058. Attachment for threshers to direct the straw or sheaf elevators.

Germany
273 198. Threshing machine with feed parallel to beater.
273 490. Self feeder for threshing machine.

Italy
134 812. Shaker with large screen for threshing machines.
139 357. Automatic device for counting sacks or measures for threshing, winnowing machines etc.
140 085. Straw elevator.

Switzerland
63 949. Dust-removing apparatus for agricultural machines and especially threshing machines.

United States
1 092 222. Threshing machine screen.
1 092 356. Grain stooker.
1 093 853. Grain separator.

Other agricultural machines and implements.

Austria
65 191. Tre felling and cutting machine.
65 269. Wheel especially for agricultural machines.
65 388. Turning and raking device for tedders and potato lifters.
65 772. Apparatus for watering live stock.

Belgium
263 285. Improved root-cutter.
263 491. Potato peeler.
263 572. Improvement in liquid manure pumps.
263 840. Centrifugal water purifier.
263 975. Filter for rain water.

Canada
153 091. Driving device for agricultural machines.
153 120. Device for extracting traction wheels from holes.
153 123. Stacker.
153 195. Well drilling machine.
153 252 and 153 290. Cattle guards.
153 286. Rake cleaner.

France
464 965. Fore-carriage for agricultural machines of all kinds.
464 983. Machine for composing buttons for marking animals.
464 999. Improvement in milking machines.
465 098. Double portable fodder press.
465 148. Device for untying animals in stables.
465 475. Traction sprayer.
465 867. Metal dismountable anti-hail rocket with safety device.
465 892. Apparatus for sulphuring vines and fruit trees.
466 249. Portable forcing bed built of reinforced concrete plates without angle uprights.
466 289. Leaf fender for beet root lifter.
466 579. Machine for removing outer bark for control of insects, etc.
466 770. Apparatus for destruction of injurious animals.

Germany
272 626. Appliance for use in manger.
273 003. Machine for shelling nuts.
273 005. Automatic lamp trap for insects with separate illuminating and catching surfaces.
273 151. Protective screen for chaff cutters.
272 999. Beet singling and potato lifting machine with throw wheel.
273 492. Vertical milk separator with vessel for skim milk.
273 199. Chaff cutting machine with device for automatic sharpening of knives while working.

	273 489. Cherry stoning machine.
Hungary	62 402. Agricultural tractor.
	62 527. Combined rake and elevator for straw, hay etc.
	62 577. Hay knife.
	62 606. Cleats for motor wheels.
	62 855. Wheel for raising and lowering agricultural machines.
	62 954. Chaff cutter.
	62 981. Ladder stay for fruit picking.
	62 982. Machine sprayer.
	63 030. Dust removing apparatus for agricultural machines especially threshers.
	63 093. Machine for untying sheaves.
	63 336. Appliance for cleaning fruit, seeds etc.
Italy	137 826. Device for untying animals.
	139 153. Sliding support for needle with elastic safety clutch for hay and straw balers.
	139 259. Wine pomace press with upward motion.
	139 261. Machine for extracting, at the same time, the essential oil and the juice of lemons, oranges etc.
	139 353. Pyramid-shaped continuous feed cereal esiccator.
	139 954. Improvement in hand sulphur dusting machines.
	139 961. Machine for husking dried chestnuts.
	139 719. Grape crusher.
	139 796. Fork for agricultural and industrial purposes.
	139 938. Soil injector.
	140 162. Double flower pot with compensating reservoir, porous inner wall and impermeable outside.
	140 254. System of protection against hail.
	139 598. Syringe for injecting liquids into cheeses while pickling.
	140 043. Machine for peeling chestnuts.
	140 171. Apparatus for peeling scalded almonds.
Switzerland	63 950. Apparatus for fumigating trees, etc. for control of pests.
	63 951. Process and apparatus for removing honey combs from hives.
	64 006. Apparatus for concentrating milk and other emulsions by filtration.
	64 007. Apparatus for washing and removing stones from wheat and other grain.
	64 008. Process and apparatus for grading and cleaning groats, grains, etc. by statical electricity.
	64 139. Grape cutting device.
	64 140. Honey separator.
	64 401. Sulphur duster.
	64 472. Milk separator.
	64 647. Window with device for catching insects.

1 093 862. Wind mill .
1 093 904. Silo.

RURAL ECONOMICS.

769 – **The Statistical Method and its Value for the Economics of Farming.** — SAGAWE, B. in *Archiv für exakte Wirtschaftsforschung*, Vol. 6, Part 1, pp. 116-136. Jena, 1914.

In the first part of his work the writer discusses the different ways of collecting and working up material in the statistical and in the monographical methods and their advantages and disadvantages for showing the connection between causes and effects in general; he then passes on to the question as to which method is to be preferred and comes to the conclusions that in the study of productive farms (Erwerbswirtschaften), only by a combination of the two methods can the connection between causes and effects be estimated quantitavely and qualitatively in a reliable way.

In the second part of his work the writer treats of the importance of statistics in rural economy and of their application to research in this field.

The writer attempts by means of an example, to find out how far the several methods of isolating any particular factor to be examined attain their object, and analyses the effect of increasing intensity of culture upon the net returns. In this connection he examines: 1) an individual farm which, in the course of several years, evolved from extensive to intensive cultivation; 2) several variously organized farms during the same periods of time; 3) abundant material arranged according to the statistical point of view.

With the first method the period of observation, considering the variability of the weather and the consequent oscillation in the crops, must be extended to about 20 years. Then the most important factors to be considered are: position as regards means of communication, condition of prices, quality of the soil, capacity of the manager, which by their variation in the course of time render it almost wholly impossible to isolate completely the influence of the intensity of cultivation. When such is the case the result cannot be utilized as a term of comparison. The direction of the effect of individual factors can be recognized by separate monographs, but as soon as their quantitative effect is to be determined the method fails. The comparative monographic method encounters first of all the difficulty of finding suitable objects of comparison, for if even the so-called involuntary factors of production are fairly equal and comparable with each other, on the other hand it is impossible to eliminate the influence of the voluntary factor, the manager of the farm. Consequently it will also be impossible to attain correct numerical conclusions. The comparison of individual farms may afford a general view of the effect of the various factors, but in order to calculate with precision their influence and to obtain comparable figures available in practice, the formation of groups must be resorted to, that is to say the statistical arrangement of the data.

The use of the statistical method presupposes the existence of abundant material. But even not very abundant material can be utilized statistically, because with suitable methods of compensation a relatively large number of groups can be formed. In conclusion, the writer shows by a practical example how the isolation of a factor can be carried out under some circumstances without forming sub-groups. He calculates the effect of the increasing intensity of cultivation on net returns in 88 farms affiliated to the book-keeping office of the D. L. G. (German Agricultural Society).

In the formation of groups connected with each other, according to the compensation method of Prof. Mitscherlich of Königsberg, all the factors are fairly compensated with the exception of that of soil quality. The writer calculates the effect of the varying quality of the soil upon net returns, and basing his calculations upon the difference between the net returns obtained in this way and those obtained by grouping the farms according to the increasing intensity of cultivation, he shows the influence of this factor upon net returns.

770 – **Principles of Exact Investigations in Agriculture.** — Von Koppen, Wilhelm in *Archiv für exacte Wirtschaftsforschung*, Supplement 13, 88 pp. Jena, 1914.

After giving some general information on the importance of agricultural bookkeeping and on the difference between the bookkeeping of financial institutions and of commercial firms, the writer treats with more detail the notion of " net returns ", about which a certain confusion has often been made between the means and the end ; in defining it also the technique of some particular method of bookkeeping has been too frequently used, instead of explaining the result of calculations. A general definition of net returns must satisfy all methods of bookeeping. The writer proposes the following : " Net returns are the numerical expression of the economic result of a farm free from debts. "

Every system of agricultural bookeeping which calculates net returns in such a way that they correspond to this definition must be considered systematic.

The most valuable system of bookkeeping is that which answers best to the requirement of the farm manager and to the character of the farm. The writer considers the systematic opening of accounts as the simplest and surest way of recognizing the direction and organisation of the farm. Systematic bookkeeping or bookkeeping by double entry must first of all show the various branches of the farm in such a way as to allow of the sufficient examination of each branch-organ and to recognize its function towards the other branches and towards the whole farm — the organism. Lastly bookkeeping by double entry must allow the cost of production to be exactly determined.

The system of bookkeeping introduced by the writer in his farm is called by him farm bookkeeping by groups. In his method the ledger is arranged under the form of accounts, with an auxiliary book in the form of tables.

The divisions of the whole farm into a small number of groups of accounts avoids the danger of totally separating the various production branches from the complex of the whole farm and renders the examination of each branch and of the reciprocal connection between them easier. On the other hand the decomposition of each group of accounts according to the system of tables by means of auxiliary annexes allows of a very detailed division of the farm and of the grouping together of the similar items of accounts, in view of a very minute control, of systematic calculations and of statistical observations, without causing the slightest perturbation in the whole of the farm.

In the bookeeping by groups adopted by the writer the agricultural production is divided into two groups only : crops and productive stock. The utilization of the soil (crops) is considered as a whole. It is the same with the maintenance of productive live stock, which includes milch cows, young cattle and foals, as well as pigs and sheep if kept. Against these two accounts of production are placed the expenditure accounts, chief among which is that for labour, comprising all the labour expenses. Among the items of outlay there are the produce that is consumed and

general expenses. The first contains all the stores bought in, so far as a control over the remaining stock appears necessary. All the other expenses are found together in the general expenses account, which may be subdivided again as required. Lastly there are the inventories and the closing accounts.

The prices given to the produce sold are the market prices, upon which are based those of the produce consumed in the farms itself. In order to take into due consideration the rise and fall of the market prices, the writer uses a table of calculations relating to the produce of all kinds consumed on the farm. This table is an indispensable auxiliary in bookkeeping by groups, and it must be posted up every four weeks so as to follow closely the changes in market prices. Besides the prices, the quantities also must be carefully determined.

Of course, as in all bookkeeping, the accounts begin by an inventory and balance-sheet containing all the necessary information on the assets and liabilities. The items concurring in an increase of capital are entered as follows : The cultivable soil, having a lasting value, is inventoried at its cost price ; permanent improvements likewise, while improvements possessing only a temporary duration are written off proportionately to their duration. The farm produce utilized in the farm itself, for instance timber for building purposes, is entered at the sale price obtainable at the farm. New plantations of trees are treated according to the same principle as cultivable land. The cost of the work of preparing the land for the crops, such as sowing, the seeds sown and the manures, must also appear in the inventory ; only when an inventory contains these data can the profitableness of the various crops and the cost of their production be ascertained.

Following upon this somewhat general discussion, the writer explains how he deals in the inventory with the various assets and liabilities, such as soil, forests, fruit plantations, improvements, roads, buildings, machinery, live and dead stock, cash, credits and debts, etc.

After entering these various values in the inventory, they are grouped together in the balance sheet and the total capital is worked out. The ledger is opened on the basis of the balance sheet. For technical reasons it is advisable to open the accounts of the ledger only at the end of the year. During the course of the year the farmer can limit himself to the entering of all business and farming events in chronological order in his memorandum book and to drawing up his table of stores every four weeks. The memorandum books must group the figures as they are to be used in the ledger.

The writer distinguishes two kinds of memorandum books :

A. Those referring to business transactions.

B. Those dealing with the work in the farm itself. The first group includes : the business journal with cash book, the labour book, the petty cash book, etc. as well as the current account book.

The second group includes the farm day book, with forage and milk tables as auxiliaires, the stores and livestock account, and the principal labour book.

At the end of the year the inventary has to be posted up to date and the closing balance sheet prepared, but it cannot be closed until the value of the stores and of the work put in the ground for the standing crops has been determined.

The next steps are to close the memorandum books, to start the ledger accounts and to close : 1) the auxiliary accounts, 2) the cash and inventory accounts, 3) the general expenses accounts, 4) the stores and 5) the labour accounts. After this, production accounts proper are closed. The first of these is the crop account, which must be divided into two parts : " production " and " utilization ". Then comes the productive stock account and last of all the forest account.

After this there remain the other auxiliary and closing accounts : 6) the household and personal expense account, 7) the profit and loss account, and 8) the capital account.

771 – **Giving Farm Labourers a Personal Interest in their Work.** — Schulze Georg, in *Landwirtschaftliche Jahrbücher*, Vol. XLVI, No. 1, pp. 44-88. Berlin, 1914.

An enquiry was made into the means adopted on a number of large farms for giving all hired labourers as well as managers a personal interest in their work. Such means will naturally differ according to the nature of the work involved, but take the general form of payment by piecework and of bonuses in the case of stockmen. The writer discusses the advantages of large holdings in many styles of farming and the possibilities of adding to these advantages that personal interest in the work which is such an important factor in obtaining the best results. A bibliography is appended, together with a copy of the question form sent to the farmers.

772 – **Piece-Work in German Farming.** — Esden-Tempski K., in *Landwirtschaftliche Jahrbücher*, Vol. XLVI, Part 3, pp. 455-498. Berlin, 1914.

The object of this paper is to illustrate the principles followed in fixing payment of piece-work in farms. For this purpose wages in kind must be considered as well as wages in cash.

Farms in Germany employ three kinds of labourers.

1. Labourers under permanent engagements.
2. Labourers under temporary engagements.
3. Casual labourers.

The first two classes get respectively two-thirds and one-third of their wages, in kind and the rest in cash, while the third class is paid only in cash. Assuming that for work of the same value the total wages are the same, the payment in cash is lowest for the permanent hands, somewhat higher for the temporary ones and highest of all for the casual labourers.

In practice this arrangement leads to the result that those labourers who should have the greatest interest in the prosperity of the farm get the least profit from piece-work, while the other two classes are better paid.

That such is the case is proved by a practical examples. On a farm in the province of Brandenburg the wages per day in summer are the following :

Permanent labourers	8*d*
Temporary »	1*s* 1*d*
Casual »	2*s* 0*d*

Usually the wages of the casual labourers or strangers are considered as the price of labour in the locality. Assuming such to be the case, namely that the men get a daily total wage of 2*s* then the value of the wages in kind per day is:

Permanent labourers	1*s* 4*d*
Temporary »	11*d*
Casual »	—

In this farm the payment of piece-work is fixed according to the wages in cash. Taking the daily wages at 8*d*, 1*s* 1*d* and 2*s* as the piece-work payment of one day's work, then the earnings of the three classes of labourers, 1) at daily wages, 2) at piece-work pay doing twice as much work, and 3) at piece-work doing three times as much work (all calculated for 140 summer days) work out as follows:

	I Daily wages			II Piece-work doing twice as much work			III Piece-work doing three times as much work		
	£	*s*	*d*	£	*s*	*d*	£	*s*	*d*
Permanent labourers:									
in cash	4	16	1	9	12	2	14	8	3
in kind	8	18	5	8	18	5	8	18	5
Total earnings	13	14	6	18	10	7	23	6	8
Temporary labourers:									
in cash	7	11	0	15	1	11	22	12	11
in kind	6	3	6	6	3	6	6	3	6
Total earnings	13	14	6	21	5	5	28	16	5
Casual labourers:									
in cash, total earnings	13	14	6	27	9	0	41	3	6

The casual labourer has thus an advantage over the permanent labourer in case II of £8 18*s* 4*d* and in case III of £17 16*s* 8*d*. His greater profit in case II is equal to the value of the payment in kind that the more permanent labourer receives and which is not considered in the piecework payment of the latter. Every further increase in the amount of work done is so much more profit to the casual labourer. This signifies that the piece-work wages of the permanent labourers, even when he is, as capable as the casual labourer, are always inferior to those of the latter and to a less extent to those of the temporary labourer.

If instead of taking only the wages in cash as a basis for the payment of piece-work, the total of cash and kind were taken, all three classes of labourers would be paid on the same basis of 2*s per diem* and the wages for all three would be :

I	II	III
Daily wages	Piece-work doingt wice as much of work	Piece-work doing three times as much work
£13 14*s* 6*d*	£27 9*s* 0*d*	£41 3 6

But as the permanent and temporary labourers also get payment in kind, this must be deducted, otherwise they would receive it twice. After this subtraction the three classes would be paid as follows :

	I Daily wage			II Piece-work doing three as much work			III Piece-work doing three times as much work		
	£	*s*	*d*	£	*s*	*d*	£	*s*	*d*
Permanent labourers:									
Total earniugs:	13	14	6	27	9	0	41	3	6
Wages in kind	8	18	5	8	18	5	8	18	5
Wages in cash.	4	16	1	18	10	7	32	5	1
Temporary labourers:									
Total earnings	13	14	6	27	9	0	41	3	6
Wages in kind	6	3	6	6	3	6	6	3	6
Wages in cash	7	11	0	21	5	6	35	0	0
Casual labourers:									
Wages in cash, total earnings . .	13	14	6	27	9	0	41	3	6

Thus the daily wages of the three labourers are the same in all cases. Only the amount in cash varies, and the difference is equal to the value of the wages in kind counted once.

From the above the conclusion may be drawn :

1) That the calculation of piece-work must not be based only on the cash wage but on the total wages in cash and kind.

2) That from the total wages the amount given in kind must be subtracted.

Only piece-work paid according to these principles will keep labourers in the country, whilst the system hitherto followed has done much to drive labourers away form the country, as it has been more unfavourable to the permanent hands than to the temporary and casual ones.

773 – **Reclamation and Improvements in the Roman Campagna** (1). — VERRATTI, S. in *L'Italia Agricola*, Year LI, No. 5. Piacenza, May 15, 1914.

A first Commission was appointed in 1870 to report on the measures necessary for reclaiming the Roman Campagna, and in December 1878 a law was passed declaring the proposed reclamation to be of public utility and that the State should undertake the draining of the principal marshes, while landowners should be compelled to do the subsidiary canalization; further, the law decreed that the zone of reclamation was to extend in a circle with a radius of 10 kilometres (6.3 miles) from the Milliarum Aureum in the Roman Forum. In July 1883 an additional law was passed enabling the Government to expropriate the owners of land in the given zone should they refuse to play their part in the scheme of reclamation, but as serious outlays were imposed on the landlords without a prospect of anything like adequate returns, and, further, as the expropriation would have involved the State in far too great an expense, the law was applied in three cases only and was then left aside. A new law was finally passed in December 1903 (No. 474), which, together with that of 1883, constitutes the combined law of November 10, 1905 (No. 647), which is still in force.

This law confirms the obligation to reclaim the land in the zone mentioned above, and in that part of the basin of the Aniene which is comprised in the Roman Campagna, with the provision that owners not wishing to conform should have their land sold by public auction, the purchaser undertaking to carry out the necessary improvements. Landlords or purchasers might receive, besides other pecuniary advantages, a loan from the Ministry of Agriculture at 2 ½ per cent, repayable in 45 annual instalments, beginning after the fifth year of the loan, such loans, which might amount to £80 000 per annum, to be furnished by State funds. Even if done by private initiative, three-tenths of the expense of making the subsidiary canalization was to be contributed by the State, the Province and the Commune. With regard to the construction of new roads required by the scheme, these were to be approved by the Ministry of Public Works, and the expense of construction shared equally by the Government and by the Commune, their upkeep being left to the Commune.

A special Commission made up of 11 members was formed to attend to the application of the law and to investigate technical and administrative questions to which it might give rise.

A further law dating from July 1910 (No. 491) comprises some addi-

(1) Throughout this article, "Roman Campagna" is used as a translation of "Agro Romano", that is the territory belonging to the Commune of Rome, and not in the more general sense of all the country round Rome. The Agro Romano includes two very distinct types of country: 1) a flat belt along the coast, originally marshy, including the reclaimed areas of Maccarese, the Isola Sacra, Ostia, etc.; 2) a plain at 200-400 ft., furrowed by streams which mostly only run in rainy weather, and largely under pasture (dry for three months in summer) or temporary grain cultivation: to this second part colonization rather than reclamation applies. (*Ed.*).

tional measures for reclaiming the Roman Campagna, which may be summarised as follows :

1) *Application of measures laid down in the law of* 1905 *to land situated beyond the zone originally fixed upon.* — By a Royal Decree it was made possible to extend the application of the measures to land outside the given zone in certain cases where the general condition of an area or the desire to encourage private enterprise made it expedient to do so.

2) *Necessity to encourage the formation and development of centres of habitation in the reclaimed area.* — To this end it was decided: *a*) that all centres of colonisation consisting of at least 25 families established within ten years of January 1, 1911, and at a distance of at least 5 kilometres (3.1 miles) from the boundaries of Rome, should be exempt from all rates and taxes, local or governmental, during a period of 20 years ; *b*) that anyone proposing to establish such a rural centre of habitation and not having the necessary building land, might apply to the Ministry in order to be supplied with the land by expropriation for the public good ; *c*) that all private or public enterprises, including those started by owners, with the object of establishing rural colonies should be assisted by a loan at 2 ½ per cent. repayable on the terms mentioned above ; and *d*) that the sum required for such loans should be provided by State funds, the total amount being limited to £40 000 per annum beginning from July 1, 1910.

3) *Encouragement of live stock* — The State associated itself with the Province of Rome for the establishment and upkeep of an Institute (Istituto zootecnico laziale) whose duty it is to distribute high class breeding stock suitable to the district, and to encourage the production of forage crops, dairying, etc.

4) *The provision of adequate financial means without creating new charges on the State.* — An independent fund was started known as the " Cassa di colonizzazione per l'Agro Romano " which draws its revenue from the following sources : *a*) one-tenth of its own net annual profits ; *b*) all sums become available by repayment of capital invested before 1910 or any balance left over in the special budget of the Ministry of Agriculture concerning the reclamation scheme ; *c*) other contributions.

With this fund the Minister of Agriculture will provide prizes and subsidies to encourage useful initiative and especially for making farm roads, providing water supplies for drinking and irrigation purposes, building cottages and other kinds of improvement.

5) *Modifications in certain articles of the law of* 1905. — The period fixed for obtaining the contribution of 30 per cent. from State, Province, or Commune towards canalization works was proroged to December 31, 1915. The Government was authorised to connect up the farm roads with train or railway stations, where necessary.

Some of the results obtained by the application of the law are given below :

Drainage works carried out by the State. — Of 34 600 acres which are estimated to require draining, about one half have already received attention; large drainage operations have been carried out at Ostia (4686 acres), Isola Sacra (637 acres), Maccarese (10 668 acres), and smaller ones at the Lake of Tartari, in the low ground of the Almone, in the marshes of Straccia-cappe, Baccano and Pantano, some of which have already been handed over to associations for management. Up to June 30, 1913, the State had spent about £260 000 on the enterprise. At that time it was estimated that another £80 000 would be required to complete the work, including the running expenses of the machinery for another five years and certain operations to be carried out on the coast between Pratica and Anzio.

The drainage of the Isola Sacra and Maccarese cannot be said to have had practical results in so far as cultivation is concerned, as they both

consist of grazing land over which cattle are allowed to range, and their hygienic condition is not very satisfactory. These areas have recently been brought into the zone of obligatory reclamation.

Drainage Associations. — In April 1912 the 91 Drainage Associations amalgamated to form one central society, which is to reorganize the whole system and undertake the management from a single centralized office, directing all the work and receiving all contributions. A committee made up of delegates from the various constituent societies has already drawn up a scheme of organization for the central office and another relating to the contributions to be paid by the various units. This has already been approved by the general meeting of the delegates and is now only waiting for the approbation of the Ministry of Public Works before being put into practice.

Contributions to subdidiary canalization. — The contribution of 30 per cent. from the State, Province and Commune towards expenses of making the subsidiary canals on the various estates has been granted in twenty holdings at a cost of about £12 800, while grants amounting to £12 000 are being made for six other holdings now carrying out similar work.

Road making. — The law of 1905 provided for the construction of 250 kilometers (156 miles) of roads, but of these only 30 km. (19 miles) have as yet been accomplished at a cost of £41 200, while another 10 km. (6 miles) are being built at a cost of £15 000 and 29 km. (18 miles) are planned at an estimated cost of £60 000.

As the city of Rome has extended, roads which were originally considered to form part of the reclamation zone have been taken over by the city, while the extension of the zone beyond the original limits has increased the number of roads fixed upon in the original plan approved by the Ministry of Public Works in 1905, and for these reasons a Commission has been appointed to modify the original plan. The revised plan is now being passed by the Ministry and provides for 250 kilometers of roads, and above those already in course of construction, at a cost of £460 000 over. Of this it is expected that £180 000 will be spent during the next four years for the building of 100 kilometres (62.5 miles) of road.

Agricultural improvements. — Of the 500 000 acres which constitute the whole Roman Campagna, 175 000 acres have been subjected to compulsory improvement, of which 112 000 acres excluding the suburbs make up the zone fixed by the law of 1903. Of this latter area, 6400 acres are already improved and 54 300 acres are in course of improvement, the remaining 51 000 acres being for the present almost untouched as the "Commissione di vigilanza per l'Agro Romano" admit the great difficulty of carrying the law into effect in all cases. Nothing has yet been done in those areas brought within the limits of the zone in 1910.

Loans. — The adjoining table shows the distribution of the annual grant of £80 000 from the central State bank for loans in connection with agricultural improvements; in ten years about £520 000 have been distributed.

Distribution of loans granted by the Ministry of Agriculture for improving the Roman Campagna.

774 – **Bookkeeping Results: Five-Year Averages obtained at the Accountants' Office of the German Agricultural Society.** — STIEGER. — *Arbeiten der Deutschen Landwirtschafts-Gesellschaft*, Part 255, pp. 87 + 4 tables. Berlin, 1914.

Two years ago Part 180 of the *Arbeiten der D. L. G.* gave the principal average results of five years of bookkeeping in the farms affiliated to the accountants' office of the German Agricultural Society (D. L. G.); these averages are now published annually.

The present work contains the average results of the books kept in 114 farms, classed according to the different regions of the country, for the years 1907-08 to 1911-12. In order to compare these data with each other and to exclude those of the abnormal year 1911-12, the writer adds the averages of the five years 1906-07 to 1910-11 for 103 farms which bear the same numbers in both synopses.

These data are given in the form of tables which contain 71 columns, as follows :

Column 1 : number given to each farm (repeated in column 71.).

Column 2 : group to which the farm belonged according to its extent.

Column 3 : distance of the farm from the nearest railway station.

Column 4 : net returns as ascertained for the purposes of the land tax, given as indications of the quality of the soil.

Column 5 : total value of the farm, which in 48 cases is the value of the farm as established in order to fix the amount of the complementary taxes, in 10 cases the net returns as per land register multiplied by 75, in 14 cases the real purchase price, in 2 cases the value estimated by the " Landschaft " (a Prussian credit institution), in 9 cases the rent capitalized at 3 per cent. plus the value of the live and dead stock, and in 27 cases the value as estimated by the owner himself.

Column 6 : capital invested in buildings
Column 7: capital in machinery and implements
Column 8 : live stock
} According to inventory

Column 9 : total live and dead stock in percentage of the whole value of the farm.

Column 10 : total live stock in head of large cattle per 100 hectares (247 acres) of cultivable area.

Column 11 : total draught animals in horse units.

Column 12: number of draught animals per 100 hectares (247 acres) of cultivable area.

Columns 13 to 20 : the various crops (13, meadows ; 14, permanent pastures, both in percentages of the whole cultivable area ; 15, winter cereals; 16, spring cereals ; 17, pulse crops ; 18, hoed crops ; 19, forage crops ; 20, bare fallow, (all in percentages of the arable land).

Columns 21-26 : yields in weight of the six most important crops (wheat, rye, barley, oats, sugar-beets, potatoes).

Column 27 : average milk yield per cow and per ration-day.

Column 28 : sale price of the milk.

Column 29 : total yield of the farm ; that is, besides the returns from the sale for cash or credit of the produce, also the value of those articles

supplied to the owner and the increase in value of the inventory at the end of the year.

Column 30 : total outlay ; that is the total working expenses wages, insurance, outlay other than in cash, such as wear and tear and depreciation of farm implements and other capital, and the decrease in value of the inventory at the end of the year as compared with that at the beginning.

Column 31 shows the difference between the items in columns 29 and 30, which represents the net returns of the farm free from debts, rent or other charges. The net returns per unit of area afford a clear expression of the absolute result of the farm ; but if this is to be estimated at its just and full value, it must be examined in connection with other data concerning the same farm. Thus, for instance, the best net return is that obtained with the least expense in the course of the year.

Column 32 : shows the amount of expense per unit of net returns. In comparing the results of several farms this figure is not sufficient measure of the success of the farm because it does not take into consideration the value of the farm, and of two farms which, with the same yearly outlay, get the same net returns, the one with the least capital value is to be considered the better managed of the two.

Column 33 shows the net returns expressed as percentage of the value of the farm, that is the interest on the total capital. This figure does not consider the year's expenses, and it is evident that of two farms the net returns of which give the same amount of interest on the total capital, the more successful one is that which obtains this result with the least expense. It thus becomes necessary to take into account the year's expenses as well as the interest on the value of the farm. The easiest way to do so is to add these two quantities together in order to get the total expenses and to obtain the ratio of the net returns to this sum.

Column 34 shows the actual amount of the 4 per cent. interest per unit of surface ; then, after having added together, for each farm, the figures contained in columns 30 and 34 in order to have the total amount of expenses, all that remains to be done is to divide by this number the net returns multiplied by one hundred, in order to get the desired number which shows the amount of net returns obtained per cent of total expenses. This figure is found in Column 35.

Column 35 : this figure affords the best possible base for judging the quality of the management of a farm from the point of view of profitableness. The writer calls it the " fundamental number " (Kernzahl).

Columns 36 -41 : amounts of the chief partial receipts in cash.

Column 42 : total amount of cash receipts.

Columns 49 - 60 : these give the farm expenses (60, the total amount, 49-59 the principal partial amounts).

In Columns 43-48 and 61-70 the quantities contained in columns 36-41 and 49-59 are repeated, but expressed respectively in percentages of the total amount of receipts and in percentages of the total amount of expenses.

The writer gives the averages of the interest obtained by these farms

during the years 1907-8 to 1911-12, first all together and then grouped according to provinces. He then endeavours to determine the influence of the quality of the soil, represented by the amount of the net returns according to the land register, on the economic results of 18 farms in the province of Silesia, and of 21 in the province of Brandeburg. The farms are arranged according to the land register net returns and the writer indicates for each farm: the yield of the crops per unit area, the net returns, the fundamental number (Kernzahl), the outlay for the purchase of artificial manures, the receipts from productive live stock, and the ratio between the areas under the various crops. If for the 21 Brandeburg farms, the first half with average land register net returns of 6*s* 3*d* per acre be compared with the other half with average land register net returns of 3*s* 5*d* per acre, higher effective net returns will be obtained for the first group than for the second (£ 1 0*s* 5*d* against 11*s* 5*d*), although the returns from the various farms taken separately differ considerably. The same result is obtained with the Silesian farms, the two groups of which show respectively land register net returns of 10*s* 7*d* and 4*s* 2*d*, and effective net returns of £ 1 9*s* 11*d* and 10*s* 10*d* per acre. In the same way the fundamental number of the Silesian farms, which is for the two groups 24.80 and 11.56, shows that the better quality of soil allows results to be obtained more economically. The difference between these two numbers is considerably less in Brandeburg (15.21 and 12.24).

At the end of his work, the writer calls attentions to the great importance of the value of the farm for all discussions on the management and organization on numerical bases, and on the necessity of a clear understanding as to this value and to the exact method of determining it.

AGRICULTURAL INDUSTRIES.

INDUSTRIES DEPENDING ON PLANT PRODUCTS

775 – **The Electric Field in the Maturation of Wine.** — NITESCU, MARCEL A. in *Revue de Viticulture*, Year XXI, No. 1068, pp. 621-624. Paris, June 4, 1914.

Wine is a good electrical conductor because of the acids and salts it contains, and it has been subjected to the influence of an electric field by CH. HENRY in order to bring about sterilization and maturation. The electric field employed is continuous and of high tension (100 000 volts) but of low intensity, so that the wine should be decomposed as little as possible, though suspended matter and colloids are sufficiently electrified to move towards one of the poles, where they can easily be eliminated. At the same time the invertion of sugar is prevented, and it is thus possible to treat wines attacked by injurious ferments such as "graisse" or "casse".

The Henry method makes it possible to control the process by stopping it as soon as the samples drawn from taps close to the poles have the same flavour as those drawn from the bung hole. The movement of the colloids in the liquid has the further function of constantly stirring the large reaction surface presented by them and thus accelerating their catalysing action.

The different wines, brandies and kirschs which have been treated, yield, besides an appreciable increase of volatile esthers, the various maturation indices which are usually observed as the result of the action of the more slowly working enzymes.

776 – **The Alcohol Content of Yeast.** — FOTH, G. in *Jahrbuch des Vereins der Spiritusfabrikanten in Deutschland*, Vol. XIV, p. 33. Berlin, 1914.

A series of determinations was carried out in the Laboratory of the Society of German Distillers in order to investigate the alcohol content of yeast under various conditions. The results are as follows :

1) The alcohol produced by the fermentation of sugar solutions is not all found in the solution; part is retained by the yeast. Moreover the amount of alcohol in both yeast and solution, stated as per cent. of alcohol + water in both cases, is practically the same and this fact holds good in both weak and strong sugar solutions (10 to 20 per cent.).

2) If yeast be washed to remove the alcohol it contains and then put into a solution containing alcohol, it will absorb alcohol until equilibrium is established between the yeast and the solution.

3) If yeast be left in alcohol solution, the alcohol content of both yeast and solution diminishes owing to assimilation of part of the alcohol.

4) The content of compressed yeast in both water and alcohol increases with the time of keeping, while glycogen disappears simultaneously, from which it would appear that the increase in water and alcohol is due to the decomposition of the glycogen. Moreover the amount of alcohol thus formed is considerably less than the amount expected by the fermentation equation.

777 – **The Use of "Phosphogelose" in Brazil.** — PELLET, H. in *Bulletin de l'Association des chimistes de sucrerie et de distillerie*, Vol. XXXI, No. 11, pp. 849-858. Paris, May 1914.

The "phosphogelose" process in the manufacture of sugar consists in the addition of a mixture of bicalcic phosphate and kieselguhr to the juice previously treated with lime, the object being to help clarification and to obtain a scum of manurial value. The composition of two such scums was as follows :

	Per cent.
Water	43.56 to 43.23
Organic matter	26.32 to 27.67
Total phosphoric acid	8.41 to 9.85

The process is at present in use in a few sugar factories in Bahia.

778 – **The Reduced Gluten Content of Flour.** — BALLAND, J. A. F., in *Comptes rendus des séances ds l'Académie des Sciences*, Vol. 158, No. 16, pp. 1103-1106. Paris, April 20, 1914.

For some time the Paris bakers have complained that flour requires less water than it did formerly to work up into dough. Analyses from the laboratory of the Bakers' Syndicate show that more than half of the flours examined during the month of February, 1914, contained less than

7.5 per cent. of dry gluten or 22.5 per cent. of moist gluten, a quantity which is considered insufficient to obtain the best results in breadmaking and which is generally attributed to degeneracy of the wheat owing to intensive culture.

From 1869 to 1880 the mean annual content of moist gluten in high class flours from twelve milling firms varied from 27.53 to 30.34, with an average of 29.1 per cent., or 9.7 per cent. of dry gluten. From 1881 to 1895 the figures range from 23.44 to 26.84, with an average of 25.1; during the last ten years (1905-1914) they were further reduced to 21.1, 26.8 and 24.7 respectively. Inferior quality flours frequently only contain 7.5 per cent. of dry gluten.

Although these data are not absolutely comparable owing to the introduction of foreign wheat, they would indicate that since roller mills have supplanted the grist mills, flour has reduced its dry gluten content by 2.2 per cent., that is, every kilog. of flour has lost 22 gms. of protein, which is equivalent to the amount contained in 110 gms. of butcher's meat. On examining the seasonal and regional yield, it was concluded that this loss of gluten is not due solely to degeneration of the wheat, but also to climatic variations and to the new methods of milling which eliminate the germ and those portions of the wheat grain which contain most nitrogen.

INDUSTRIES DEPENDING ON ANIMAL PRODUCTS

779 – **International Union of Municipal Dairies.** — *Molkerei Zeitung*, Year 28, No. 49, pp. 944-945. Hildesheim, June 26, 1914.

On the occasion of the Sixth International Dairy Congress, at Berne, was held the first general meeting of the recently founded International Union of Municipal Dairies, a large number of municipal dairy enterprises bring represented. Stockholm was selected by the meeting as the headquarters of the Union, which has for its object the general advancement of municipal dairying and the advising of its members as to methods of improving their business.

780 – **The Supply of Milk to Indian Cities.** — MANN. H. H. (Agricultural College, Poona) in *The Agricultural Journal of India*, Vol. IX, Part 2, pp. 160-177. Calcutta, April 1914.

An account is given of the milk supply of Poona, this being fairly representative of the conditions existing in several other Indian cities. The milk is produced partly in the city itself and partly in 47 neighbouring villages which send in about 550 galls. per day; of this :

21	per cent.	comes from	villages within a radius of less	than 3 miles
48	»	»	»	3 to 6 »
28.5	»	»	»	6 to 9 »
2.5	»	»	»	over 9 »

Practically the whole supply is brought in by hand in brass pots slung over the shoulders or carried on the heads of the milkmen, bullock carts or the train being only used in a few cases. Nine-tenths of the total consists of buffaloes' milk, whose content of fat and solids-non-fat amounts to 5 and 9 per cent. respectively, as against 3 1/2 and 8 1/2 per cent. in cows' milk.

Of 51 samples collected at the entrance of the city only 10 were pure, even when judged on a very conservative basis, the remainder being adulterated with more than ten per cent. of water. The price varies with the quality, there being a close connection between the price and the amount of water added; for instance all milk sold at less than six seers for one rupee (1s 1*d* per gallon) is almost certain to be adulterated. With regard to the amount of dirt it contains, this is not nearly so great as would be expected; of the 51 above samples:

56.7	per cent.	were	clean or nearly clean
33.3	»	»	fairly clean
7.8	»	»	distinctly dirty
1.9	»	»	very dirty

The milk produced in the city itself is a far more important contribution to the total supplies than that brought in from the surrounding country. The milking cattle of the city consist of 2 688 head, of which 1532, or 57 per cent., are kept for private use only and 1156, or 43 per cent., for sale of the milk. Among the former class about three-quarters consist of cows and the remainder of buffaloes, while in the latter class the proportions are reversed. The cattle kept for the sale of their milk are housed in small sheds distributed all over the city; 80 per cent. of these sheds contain less than ten animals, and their general conditions of hygiene are very bad. It is estimated that about 2 000 gallons are produced daily, of which about 1 400 gallons are buffaloes' milk and the rest cows' milk; the total daily consumption in the city therefore amounts to 2 550 gallons per day.

The writer discusses schemes of reform for the city milk supplies and advocates the establishment of large dairy farms outside the city, where the animals would be in cheap and natural surroundings, and the organisation of village production and export.

781 – **Experiments with the Biorisator** (1). — WEIGMANN, in *Molkerei Zeitung*, Year 28, No. 46, pp. 885-886; No. 47, pp. 899-901. Hildesheim, June 17 and 19, 1914.

The experiments made by passing several hundred gallons of milk through a Biorisator capable of dealing with 55 galls. of milk per hour have confirmed in the main the conclusions arrived at in former tests. They show further that cheeses made with biorized milk are richer in water and softer than cheeses made at the same time with exactly the same quantity of raw milk. Biorized milk kept good 2 ½ days, while raw milk turned after one day.

Altogether the writer is of opinion that the process is useful, but he recommends that care be taken to prevent new infection of the biorized milk.

(1) See also No. 743, *B.* June 1913; No. 1190, *B.* Oct. 1913; No. 1389, *B.* Dec. 1913 No. 570, *B.* June 1914. (*Ed.*).

782 – **The Action of the Enzymes due to Organisms on the Rind of Hard Cheeses.** — GRATZ, O. and SZANYI, ST. in *Biochemische Zeitschrift*, Vol. 63, Parts 4, 5 and 6, pp. 436-478. Berlin, June 6, 1914.

Careful examination of the various layers of cheese, starting from the outside and proceeding inwards, leads to the conclusion that in Trappist and Ovar cheeses the enzymes of the flora of the rind have no action on the decomposition of casein and fat in the inside of the cheeses. Further, on theoretical grounds, the possibility of the diffusion of the enzymes from the rind towards the interior must be rejected.

783 – **The Preparation of Buffalo Skins for Export from the French Colonies.** — BOULANGER, H. in *Bulletin de l'Office coloniale du Ministère des Colonies*, Year VII, No. 75, pp. 131-144. Melun, March 1914.

It is pointed out that the buffalo skins arriving on the European markets from the French colonies are frequently in a very unsatisfactory condition owing to faulty methods of preparation, and compare unfavourably with similar products from the Dutch Indies, Burma, India and Egypt ; certain reforms are advocated.

AGRICULTURAL PRODUCTS: PRESERVING, PACKING, STORAGE, TRANSPORT, TRADE.

784 – **Agricultural Storehouses in Bavaria (Financial Year 1912-13).** — *Landwirtschaftliches Jahrbuch für Bayern*, Year 4, No. 4, pp. 365-415. Munich, 1914.

The number of agricultural storehouses in Bavaria, in the year 1912-13, was 177, against 169 in the preceding year. The total cost of building and arranging them was in round numbers £193 000. The cereals delivered to the stores amounted to 119 920 tons and those sold to 115 560 tons. In 1900-01 the corresponding figures were 29 728 and 28 522 tons.

Out of these 177 storehouses only 35 are for the exclusive service of the members of the associations that work the storehouse, while the remaining 142 can be used by non-members also. In 135 stores the cereals must be bought at fixed prices, and 23 advance money on cereals. The amount of the loan varies from 33⅓ to 95 per cent. of the sale price. Some stores, besides purchasing at fixed prices, act as brokers for the sale of cereals, while 23 do not trade at all in cereals. In 32 of these storehouses, storage dues are levied ; these range from 2½*d* to 10*s* per ton. For cleaning and grading the grain 83 stores have a scale of charges somewhat higher for non-members than for members. The dues vary from 1*s* to 12*s* per ton. Fifty stores grind cereals, at charges ranging from 2*s* to 20*s* per ton.

Of the 177 storehouses, 93 are managed by loan banks, 40 by storehouse cooperatives and by purchase and sale associations, 27 by larger federations of associations, 10 by agricultural district associations, 4 by private enterprize and one each by a peasants' association and by a fruit-growers' association.

Besides dealing with the sale of agricultural produce, these storehouses purchase agricultural machines and implements, concentrated foods, seeds, coals and the like.

Eighty-nine of these stores showed a profit at the end of the year and 54 a loss. In the preceding year the figures were respectively 130 and 6.

In 1913 the State granted subventions amounting to £200, and loans bearing 2 per cent interest amounting to £956.

PLANT DISEASES.

DISEASES NOT DUE TO PARASITES AND OF UNKNOWN ORIGIN.

785 – **Leaf-Spot Disease of Sisal in German East Africa.** — BRAUN, K. in *Der Pflanzer*, Year X, Part 4, pp. 188-197, plate III. Daressalam, April 1914.

In 1913 leaves of Sisal were found to be more severely attacked than usual by a leaf-spot disease ; the spots were sunken and parti-coloured or white ; at the time of utilizing the leaves, these spots formed dark masses with difficulty separated from the fibres.

Experiments on the cause of this disease have shown that it may be produced by high temperatures. A temperature of 41° C. for 10 minutes may have a decidedly injurious action, and such temperatures frequently occur in the hot steppes. It is not yet known whether the susceptibility is increased by other factors unfavourable to the plant.

786 – **Researches on Gummosis and the Effects of Frost on Cherry Trees.** — SORAUER, P. in *Landwirtschaftliche Jahrbücher*, Vol. XLVI, Part 2, pp. 253-273 + 2 plates. Berlin, April 6, 1914.

In continuation of previous experiments and researches the writer in 1910 barked a few ungrafted sweet cherry trees (*Prunus avium*) about 20 to 30 years old. On some of the trunks the bark was removed all round, on others only on one side for a length of about 3 feet; in all of them the sap-wood was reached. The object of this was to determine whether the irritation caused by the wound was alone the cause of gummosis as is currently believed.

The experiments have proved that the irritation theory, according to which only wounds cause gummosis, is not correct in this form. A wound can certainly produce gummosis, but many wounds are not accompanied by gummosis. On the other hand this disease appears also on spots that have not been in any way wounded.

In the above experiments no centres of gummosis appeared in the wound-callus in the bark. On the other hand such centres appeared in the tissues (and precisely in the recently formed wood) of those portions

of the trunk which were not injured and which were formed, at the same time as the callus tissues, under the old bark. These diseased spots in the wood of recent formation and still in a parenchymatous state grow larger as the distance from the wound increases, but only up to a certain limit, beyond which none are found. In the older annual rings formed before the callus, the disease does not appear at all. The irritation caused by the wound may be considered the sole cause of this.

The wound, according to the writer's observation, causes a considerable afflux of protoplasmic matter towards the tissues that it has laid bare and to the neighbouring parts, which thus acquire the character of young growth necessary for the formation of callus tissue. This flow of protoplasm leads, however, at the same time to an accumulation of the enzymes present in all young tissues; of these, the cytases appear first, while the coagulases increase only gradually.

If these enzymes find their natural employment, as is the case in every young normally growing part of a plant, in which there is a sufficient formation of new cells, no anomalies are caused, and consequently no gummosis spots are produced on the new bark that is formed. In the adjoining parts of the trunk, which have not been deprived of their bark and where the normal pressure of the latter hinders the increase of new cells, an unfavourable ratio is established between the afflux of enzymes and their utilization in the formation of new tissue. The consequent excess of cytases causes outbreaks of gummosis. Near the wound these outbreaks are smaller, because the formation of wood and of new cells increases and the enzymes are utilized to a greater extent. At a certain distance from the wound these effects cease, because the irritation due to the wound is no longer felt. A wound thus causes gummosis only when an unfavourable ratio is set up between the quantities of enzymes flowing towards it and their utilization, thus causing an excess of cytases. This excess of dissolving enzymes prevents the formation of normal cell walls in the cambium tissues, or redissolves those already formed in the older tissues; in this case the cytases proceeding from the inside of the cell towards the outside cause the dissolution of the secondary membrane, and the result is gummosis.

This unfavourable ratio between the hydrolizing and coagulating enzymes appears not only in cases of traumatic origin but often in uninjured tissues. Thus the writer was able to prove the presence of gummosis in the vegetative cone of completely sound twigs. The contours of wounds are the spots on which these ruptures of enzyme equlibrium more frequently occur. It is not the wound in itself that determines gummosis.

BACTERIAL AND FUNGOID DISEASES.

GENERALITIES 787 – **New Fungi.** — SYDOW, H. and P., in *Annales Mycologici*, Vol. XII, No. 2, pp. 195-204. Berlin, 1914.

This (twelfth) report gives descriptions of one genus and 32 species of fungi new to Science, collected at various times and in various countries.

They include the following: *Hemileia Holarrhenae* on leaves of *Holarrhena antidysenterica* in Eastern India; *Aecidium parile* on leaves of *Loranthus* sp., which is itself parasitic on *Goniothalamus Elmeri*, in the Philippines; *Entyloma Oryzae* on rice leaves in the Philippines; *Meliola Memecyli* on leaves of *Memecylon edule* in Eastern India; *Cercospora Artocarpi* on leaves of *Artocarpus indica* in the Philippines; *C. Canavaliae* on leaves of *Canavalia ensiformis* in the Philippines; *C. pachyderma* on leaves of *Dioscorea alata* in the Philippines; *C. Puerariae* on leaves of *Pueraria phaseoloides* in the Philippines.

788 – **Contribution to the Mycological Flora of the Tyrol and Istria.** — BUBÁK, FR. in *Annales Mycologici*, Vol. XII, No. 2, pp. 205-220, plate VIII. Berlin, 1914.

Among fungi collected in the Tyrol and Istria in 1912 and 1913, the following occurrences are noteworthy:

Melampsora Lini (D. C.) Tul., which produces rust of cultivated flax, on *Linum angustifolium* in Istria.

Rehmiellopsis conigena Bubák (new) on the apophyses of the cone-scales of *Pinus halepensis* and *P. Pinea* in the Tyrol.

Ceuthospora phacidioides (Grev.) var. *Oleae* Scalia in olive groves in the Tyrol.

Cycloconium oleaginum Cast., so far only known from olive (on which it produces the leaf-spot disease known in Italy as "olive pox" or "peacock's-eye"), has now been found in the Tyrol on *Phillyrea latifolia* (Oleaceae).

Cladosporium episclerotiale Bubák (new) on sclerotia of *Sclerotinia cinerea* Schröt. (producing brown-rot of stone fruits) from mummified plums, in the Tyrol.

789 – **Parasitic Fungi from Northern Japan** (1). — SYDOW, H. and P., in *Annales Mycologici*, Vol. XII, No. 2, pp. 158-165, 1 fig. Berlin, 1914.

This second contribution to the parasitic fungus-flora of Northern Japan includes 55 species, *viz.* Uredineae, 33; Ustilagineae, 1; Phycomycetes, 2; Ascomycetes, 7; Fungi Imperfecti, 12. Most of these were collected in 1913; one genus and eight species are new.

The following are of special interest:

Puccinia triticina Eriks. on *Triticum vulgare* L.

Uropyxis Fraxini (Kom.) P. Magn., on *Fraxinus longicuspis* Sieb. et Zucc., new for Japan.

Gymnosporangium Yamadae Miyabe: aecidia on leaves of *Pyrus Malus* L., teleutospores on branches of *Juniperus chinensis* L. (2).

Phytophthora infestans (Mont.) De Bary, on *Solanum Melongena* L.

Mycosphaerella Yamadai Syd. (considered by Salmon as a variety of *M. Alni*), on leaves of *Hovenia dulcis* Thunb.

Cystotheca lanestris (Harkn.) Sacc., on *Quercus glandulifera* Bl.

(1) See also No. 608, *B.* Feb. 1911: No. 994, *B.* March 1911; No. 1529, *B.* May 1911. (*Ed.*).

(2) See No. 481, *B.* May 1914 and No. 578, *B.* June 1914. (*Ed.*).

Discosia maculiformis Syd. (new), on living leaves of *Fagus sylvatica* L. var. *Sieboldi* Maxim.

Clasterosporium degenerans Syd. (new), on living leaves of *Prunus Mume* Sieb. et Zucc. (1).

790 – **Parasitic Fungi from Formosa.** — SYDOW, H. and P., in *Annales Mycologici*, Vol. XII, No. 2, pp. 105-112. Berlin, 1914.

The fungus flora of Formosa was previously quite unknown. The writers now record 50 parasitic fungi collected there between 1905 and 1914; they include: Uredineae, 44 (13 new); Phycomycetes, 1; Ascomycetes, 2; Deuteromycetes, 3 (2 new).

The following species occurring on cultivated plants may be mentioned:

Kuehneola Fici (Cast.) Butl., on leaves of fig (*Ficus Carica* L.), *Broussonetia papyrifera* (L.) Vent. and white mulberry (*Morus alba* L.).

Ochropsora Sorbi Diet., on leaves of *Pyrus sinensis* Lindl.

Phleospora Mori (Lév.) Sacc., on leaves of *Morus alba*.

RESISTANT PLANTS

791 – **Resistance of Potatoes to Blight (*Phytophthora infestans*) in New Zealand.** — HILL, W. S., in *The Journal of Agriculture*, Vol. VIII, No. 4, pp. 370-371, 1 fig. Wellington, N. Z., 1914.

At the experimental farm at Moumahaki it has been observed that the potato Gamekeeper is very resistant to the disease (*Phytophthora infestans*), while Up-to-date growing beside it suffers severely. The former seems to be well adapted to the light soil and damp climate of the locality.

MEANS OF PREVENTION AND CONTROL

792 – **Commercial Sulphate of Copper and the Determination of the Copper in it.** — MACH, F. and LEDERLE, P. in *Die landwirtschaftlichen Versuchs-Stationen*, Vol. LXXXIV, Part 1-2, pp. 129-143. Berlin, April 14, 1914.

The writers examined five samples of sulphate of copper (one from Switzerland, two from Germany, one from Belgium and one from England) at the Agricultural Experiment Station of Augustenberg, Baden; they observed a difference in the behaviour of the samples when crystals of equal weight were dissolved in distilled water at room temperature. The crystals of two samples took 90 minutes to dissolve, two others 120 minutes and one 85. When these crystals were ground, no difference in the time required for their solution was observed. In the preparation of Bordeaux mixtures with these solutions, after standing one hour some differences were noticed, which on standing longer almost completely disappeared. On adding to 100 gallons of these mixtures 1 lb. of sugar they all behaved completely alike, precipitating but little and showing also after standing a length of time the same slimy consistence. The writers come to the conclusion that as far as their practical use is concerned the samples examined all have the same value.

As large well coloured crystals cannot, without further examination, be considered pure (they may, for instance, contain sulphate of manganese) the writers consider a qualitative analysis to be indispensable.

For the determination of the copper content they adopted R. Win-

(1) See No. 581, *B.* March 1912. (*Ed.*).

disch's method with sodium hypophosphite, and the method proposed by Rhead and recommended by Moser with titanium trichloride. The first method almost always gave somewhat too low values ; it is suitable only where the saving of time is a consideration, while the titanium trichloride method gives very reliable values.

793 – **Comparative Spraying Experiments with Several Fungicides against Vine Mildew.** — BRETSCHNEIDER, A. in *Zeitschrift für das landwirtschaftliche Versuchswesen in Oesterreich*, Year XVII, Part 3-4, pp. 106-118. Vienna, March-April 1914.

In 1913 experiments on the control of vine mildew (*Plasmopara viticola*) were made in various parts of Austria, Bordeaux mixture being compared with the following commercial fungicides : " Antiperonospora " (2 per cent.), " Cupran " (1, 2 and 3 per cent.), " Cuprosulfid " (½, 1 and 2 per cent.), " Forhin " (1 and 2 per cent.), " Kupferchlorid " (1, 2 and 3 per cent., apparently identical with the " Pasta Caffaro " long used with success in Italy) ", " Perocid " (" Cerdidyum sulfat ", 1, 2 and 3 per cent,), and lime-sulphur wash (1 : 30 and 1 : 40).

These fungicides have also been tried in some places against mildew of Cucurbitaceae (*Pseudoperonospora cubensis*) and certain fungi affecting fruit trees (*Fusicladium, Monilia, Sphaerotheca*, etc.).

The adhesiveness of the various mixtures was generally good ; as for the visibility of the sprayed foliage, it was best with " Perocid " and Bordeaux mixture and sufficiently good with the other mixtures, with the exception of " Cupran ". For rapidity of preparation, all the fungicides, with the exception of copper sulphate and " Perocid ", dissolve rapidly. " Cupran " and " Kupferchlorid " dissolve without leaving any residue, " Forhin " leaves a little and " Antiperonospora " rather more. " Cuprosulfid " settles very rapidly. " Cupran ", " Knpferchlorid " and " Perocid " have a neutral reaction, " Cuprosulfid " and " Antiperonospora " have a slightly acid one, and " Forhin " is very acid. With the exception of " Cupran " and " Antiperonospora " none of the mixtures clog the sprayers. " Cuprosulfid " and " Antiperonospora " cause considerable scorching of the foliage, " Cupran " and " Forhin " (one case) also, but in a lesser degree. The other fungicides, including the two sulphur preparations, are harmless.

As regards the fungicidal power of the several preparations, the writer observes that the results of the experiments have only a relative value, because in 1913 only few localities were visited by a severe attack of mildew. In the scale of efficiency the first place is held by Bordeaux mixture ; next in order of merit are : " Forhin " (which proved very good), " Perocid " (sufficiently effective in 3 per cent. solution), "Kupferchlorid " (effective but must be applied in 3 per cent. solution) ; then " Antiperonospora " (which did not completely prevent the appearance of mildew) and last of all " Cupran " and " Cuprosulfid ", which failed completely. It was not possible to judge the effect of the lime-sulphur wash, because where it was tried mildew had scarcely shown itself.

Against *Pseudoperonospora cubensis* all the fungicides that were tested proved unavailing.

The effect of the above fungicides in the control of the fungi of fruit trees could not be ascertained ; further experiments are necessary. "Antiperonospora ", " Cuprosulfid " and " Cupran " are not be taken into consideration, as they cause scorching even on apple trees.

The fungicides which deserve being considered in practical work for the control of mildew are : " Forhin " (which must be placed on the market with a more constant composition), " Kupferchlorid " (which is now sold in the form of paste, like the " Pasta Caffaro, " because under the form of powder it has not been satisfactory), and " Perocid ". The latter especially seems to have a future before it, because it costs much less than Bordeaux mixture ; the other two fungicides cost about the same and approach more the price of Bordeaux mixture.

BACTERIAL AND FUNGOID DISEASES OF VARIOUS CROPS

794 - **The Control of Damping-off Disease in Plant Beds.** — JOHNSON, JAMES, in *Agricultural Experiment Station of the University of Wisconsin, Research Bulletin* 31. pp. 29-61, figs. 1-12. Madison, Wis., March 1914.

Damping-off of tobacco seedlings in Wisconsin is generally produced by either *Pythium De Baryanum* Hesse or some species of *Rhizoctonia*. These two fungi can live on a great variety of hosts, as well as on organic matter in the soil.

The special points in the control of damping-off requiring further study were : 1) the strength of formalin sufficient to give complete control ; 2) the relative value of other fungicides ; 3) the value and practicability of steam sterilization of soils in the field.

In studying these points, tobacco and cress (*Lepidium sativum*) were grown in boxes in untreated soil, in sterilized soil inoculated with the organisms and in uninoculated sterilized soil, the various treatments being applied to the re-inoculated soils.

It was found that 1-100 formalin did not kill the fungus, though it kept it in check for some time. Treating the soil with 1-50 formalin, at the rate of two quarts per square foot of soil, will kill the fungi which cause damping-off, and hence will prevent the outbreak of the disease even under the weather conditions most favourable for its appearance. Formalin treatment has the further advantages of exerting a slight stimulating action on plant growth and of killing some weed seeds ; but the formalin costs a good deal and takes some time to act, while the soil dries out slowly after treatment.

Sterilization of the soil by heat has proved the most satisfactory method of preventing damping-off from all standpoints, except that under certain conditions it may be more expensive than formalin treatment. Where a steam traction-engine can be obtained, the sterilization is best performed by introducing steam under pressure from the engine below a galvanized iron pan inverted over the seedbed ; the edges of the pan should be driven into the soil an inch or so, and the steam applied for half an hour or an hour. Sterilization by heat has the further advantage of killing all weed seeds and insect pests, and of giving greatly increased vigor and growth of the plants sown afterwards.

795 – **The 1914 Outbreak of Rust on Winter Grain in Bavaria.** — HILTNER, L. in *Wochenblatt des Landwirtschaftlichen Vereins in Bayern*, 1914, No. 25.

In many parts of Bavaria rust on wheat and rye was so abundant in the summer as to cause general alarm. The attacks are almost all due to *Puccinia glumarum*, *P. triticina* being only occasionally associated with it.

As the ears were particularly badly attacked, total losses of crop were feared by the farmers ; but the writer points out that the experience of 1904 and 1911 shows that even a bad attack of yellow rust in the ears may result in nothing worse than some diminution of yield.

In previous outbreaks the following points were observed. In wheat, the local varieties are particularly subject to severe attacks of yellow rust (*P. glumarum*), whilst most other varieties, in particular the pedigree ones, remain nearly free. Many of the latter were, however, attacked by black rust (*P. triticina*), from about the middle of June, but without much damage being done. Yellow rust, which is often called spring rust, may appear as early as the end of April, as it did this year. In rye no marked distinctions between varieties as to rust-resistance have been observed.

There is a general consensus of opinion that rust is much favoured by one-sided nitrogenous manuring, especially with nitrate of soda ; this observation was, however, made before much care was taken to distinguish the different kinds of rust. In 1904 and this year (1914) it was found that yellow rust was less severe on fields properly manured, even when the dressing included sulphate of ammonia or nitrate, than on unmanured land ; also that thin crops were far more severely attacked than an even crop covering the ground properly. Unbalanced nitrogenous manuring is, however, favourable to yellow rust also, while dressings of phosphates have a marked effect in preventing rust ; cereals following a green manure crop are also very little subject to rust.

The true cause of severe outbreaks of rust is certainly the state of the weather. This year, just as in 1904, the outbreak was induced by the fact that in April a number of hot days were followed by frosts or heavy dews : then a spell of cool weather checked the growth of the crops, so making them very susceptible. The local varieties, which grow very quickly in spring, were the most severely attacked. Mists seem also very favourable to the spread of rust. The first reports of rust came from the same place each year, no doubt showing that the conditions there were suitable for an early outbreak, and confirming the importance of atmospheric conditions.

The writer suggests the advisability of making a comparative enquiry throughout Europe on the appearance of rust in its connection with varieties, soil, weather, etc., with a view to finding out the conditions leading to epidemics of this disease.

796 – **A Fungus Disease of Peppers (*Capsicum* spp.) : *Colletotrichum nigrum*.** — BANCROFT, C. K. in *The Journal of the Board of Agriculture in British Guiana*, Vol. VII, No. 3, pp. 139-140. Demerara, 1914.

In 1913 the fruits of various peppers (*Capsicum*) in the experiemental area of the Botanic Garden at Georgetown were attacked by a disease which spread so fast that some plants lost all their crop. The disease appears first in the form of spots at the apex or on the sides of the fruit ; these generally form when the fruit is half-grown. Concentric circles then form round the point of infection, and eventually the whole fruit may become involved, or may fall off. On the affected parts the fruit bodies of a fungus have been found : this has been identified as *Colletotrichum nigrum* Ellis et Halsted.

The fungus appears also to make its way down the stems for some distance.

Some varieties of pepper, such as Long White and Long Red, seem to be very subject to the disease, while others are less attacked ; Red Chilly and Long Bird seem to be quite immune.

The treatment adopted was to cut back the infected plants and spray with Bordeaux mixture : after the last spraying few fruits were attacked.

INSECT PESTS.

GENERALITIES

797 – **The Scale Insects of British Guiana.** — BODKIN, G. E., in *The Journal of the Board of Agriculture of British Guiana*, Vol. VII, No. 3, pp. 106-124. Demerara, 1914.

In British Guiana scale insects are the worst enemies of cultivated plants ; in general they are known as " blight ".

The following species, being widely distributed and attacking a great number of cultivated plants, are to be considered as highly injurious : *Aspidiotus destructor*, *Lepidosaphes beckii*, *Ischnaspis longirostris*, *Pseudococcus citri* and *Saissetia nigra*.

A number of species attack ornamental plants (in particular orchids and ferns) in sheltered places ; others, again, are constantly associated with certain crops, as *Aulacaspis rosæ* on mango and *Ripersia* sp. on sugarcane.

Many species are undoubtedly indigenous, while others have been introduced, especially from the West Indies, with fruits and provisions. A notable absence is that of *Diaspis* (*Aulacaspis*) *pentagona*, which is common throughout the West Indies. Certain well-known species, such as *Aspidiotus destructor* and *Vinsonia stellifera*, occur on trees and orchids in the virgin forests of the interior, while the most isolated native plantations are always found to harbour scales.

A number of natural enemies are known in the Colony. Besides some undetermined Hymenoptera, they include : *Blastobasis lecaniella* Busck, *Vitula bodkini* Dyar and *V. toboga* Dyar, Lepidoptera whose larvae feed on *Saissetia nigra*, *S. oleae*, *S. hemisphaerica* and *Ceroplastes floridensis* ; *Cryptognatha nodiceps* Mshl., *Azia trinitatis* Mshl. and *A. pontibrianti* Muls. (Coccinellidae), of which the first two attack *Aspidiotus destructor*

and the third *Saissetia hemisphaerica*; certain Neuroptera; and lastly two fungi — *Sphaerostilbe coccophila* (red-headed fungus) attacking chiefly *Chionaspis citri*, and *Cephalosporium Lecanii* (shield-scale fungus) attacking *Saissetia nigra*, *S. oleae*, *S. hemisphaerica*, *Coccus mangiferae* and *C. hesperidum*.

The following fifty-one species have so far been recorded from British Guiana:

Chionaspis citri Comstock (orange snow-scale), common on the trunks and branches of *Citrus* trees and on castor-oil.

Howardia biclavis Comstock, common on branches of jasmine (*Tabernaemontana Wallichiana*).

H. biclavis var. *detecta* Maskell, rare on branches of *Sapium Jenmanni*, a native rubber plant.

Diaspis boisduvalii Sign., frequent on shoots of plantains and on the orchid *Cattleya superba*.

D. echinocacti opuntiae Ckll., recorded in 1893 and 1899 on *Opuntia elongata*, but not observed since.

Aulacaspis rosae Bouché (mango snow-scale), common on leaves of mango and cinnamon.

Hemichionaspis minor Mask., not uncommon on cotton.

Pinnaspis buxi Bouché, common on leaves of ornamental palms and other plants.

Aspidiotus cydoniae Comstock, occasional on the stems of eggplants.

A. destructor Sign., abundant and injurious to coconut, banana, almond tree (*Terminalia Catappa*), avocado, etc.

A. diffinis Newstead, described from Demerara in 1893, but not found since in the Colony.

A. sacchari Ckll., sometimes common on sugarcane.

Morganella longispina Morgan, described from Demerara in 1889, on *Cupania sapida*, but not found since.

Selenaspidus articulatus Morgan (West Indian red scale), common on *Citrus* and leaves of Liberian coffee.

Chrysomphalus aonidum L. (red-spotted scale), frequent on leaves of *Citrus*.

C. aurantii Mask., rare on *Citrus*.

C. biformis Ckll., common on leaves of many orchids and on young sisal plants.

C. dictyospermi Morgan, described from Demerara in 1889, but not reported since.

C. dictyospermi var. *pinnulifera* Mask., recorded on crotons (*Cordiaeum*) at Demerara in 1893, but not found since.

C. dictyospermi var. *arecae* Newst., described from Demerara in 1893, but not found since.

C. personatus Comstock, common on leaves of star-apple (*Chrysophyllum Cainito*), ornamental palms and mangoes; occasional on leaves of Para rubber (*Hevea brasilensis*).

Lepidosaphes beckii Newm. (orange mussel-scale), one of the commonest

in British Guiana, occurring on *Citrus*, *Codiaeum*, Barbados cherry (*Malpighia glabra*), etc.

L. pinnaeformis Bouché, recorded from Demerara in 1892, but not reported since.

Ischnaspis longirostris Sign., frequent on leaves of Liberian coffee, to which it is very injurious, and on ornamental palms.

Parlatoria zizyphus Lucas, occasional on leaves of *Citrus*.

Orthezia insignis Douglas, common and very injurious on various Composites and *Citrus*.

O. praelonga Douglas (croton bug), fairly common on crotons (*Codiaeum* spp.), mango, Barbados cherry, sugarcane, *Sapium Jenmanni*, etc.

Asterolecanium bambusae Bdv., common on bamboos.

A. fimbriatum Fonsc., recorded from Demerara in 1889, but not found since.

A. pustulans Ckll., common on leaves of orchids and akee (*Blighia sapida*); occasionally damages Para rubber.

Lecaniodiaspis dendrobii Douglas, described from Demerara in 1892 on *Dendrobium* and *Codiaeum*, but not reported since.

Ceroputo barberi Ckll., reported on *Schinus terebinthifolius*.

Pseudococcus citri Risso (common mealy bug), very common on *Citrus*, cacao, ferns, *Codiaeum* and rice ; rare on sugarcane.

P. nipae Mask., occasional on coconut and other palms.

P. virgatus Ckll., occasional on egg-plant.

Ripersia sp. (sugarcane mealy bug), common on leaves of sugarcane.

Tachardia lacca Kerr. (the Indian scale producing lake), recorded in 1800 on *Erythroxylum Coca* in the Botanic Garden at Georgetown, but apparently now extinct.

Pulvinaria sp., rare on leaves of sugarcane.

P. pyriformis Ckll. (mealy shield-scale), common on guava, avocado and ornamental plants.

P. simulans Ckll., recorded on *Licuala grandis*.

Ceroplastes denudatus Ckll., recorded in 1893 on *Codiaeum*, but not found since.

C. dugesii Towns, recorded on *Schinus terebinthifolius*.

C. floridensis Comst. (Florida wax-scale), common on limes and various ferns.

Vinsonia stellifera Westw. (glassy star-scale), very common on leaves of coconut and other ornamental plants, on French cashew (*Eugenia Jambolana*), *Citrus*, and various forest trees of the interior.

Eucalymnatus perforatus Newst. (tesselated shield-scale), occasional on leaves of coconut and French cashew.

Coccus hesperidum L. (common shield-scale), common on *Citrus* and Liberian coffee.

C. mangiferae Green (mango shield-scale), common on leaves of jasmine (*Eugenia paniculata*) and mango.

Saissetia begoniae Douglas, described in 1802 on begonias, but not found since.

S. hemisphaerica Targ. (brown shield-scale), common on Liberian coffee, *Citrus*, guava, various ferns, etc.

S. nigra, Nietn. (hibiscus shield-scale), very common on *Sapium Jenmanni*, Para rubber, ochroe (*Hibiscus esculentus*), *Codiaeum* sp., egg-plant, cotton, sunflower and various ornamental plants.

S. oleae Bern., common on *Citrus*, *Duranta* and various ornamentalplants.

798 – **Injurious Scales from the Seychelles.** — GREEN, E. ERNEST, in *The Journal of Economic Biology*, Vol. 9, No 1, pp. 47-48. London, 1914.

In a small collection of injurious insects from the Seychelles, the following scales have been determined.

Aspidiotus ficus Ashm., on leaves of *Zamia* sp. (Cycadaceae), much grown for ornament in tropical countries.

A. bromeliae Newst., on leaves of pineapple. The discovery of this species is interesting, as it was previously only known from examples found on pineapples on sale in England, probably from the Canaries. The amount of infection appears to show that it may do a good deal of damage.

Lecanium hesperidum L. and *L. tessellatum* Sign., on leaves of water hyacinth (*Eichhornia crassipes* = *E. speciosa*). As this plant is very harmful in blocking canals and rivers (1), the scales must be considered useful in this case.

L. hemisphaericum Targ., on leaves of *Justicia Gendarussa*. Many species of the genus *Justicia* are shrubs with very ornamental flowers; they seem to be particularly subject to the attacks of scales, in Ceylon chiefly *Orthezia insignis*. *L. hemisphaericum* is a cosmopolitan species, attacking almost all plants except Coniferae and Gramineae.

799 – **Experimental Demonstration of a Difference in Biological Race between the Phylloxera of the South of France and that of Lorraine: *Perityмbia (Phylloxera) vitifolii pervastatrix.*** — BÖRNER, CARL, in *Zeitschrift für angewandte Entomologie*, Vol. I, Part I, pp. 59-67. Berlin, 1914.

As the writer had previously observed differences between the behaviour of the phylloxera of Villers l'Orme (Lorraine) and that of the South of France towards certain varieties and species of vines, he proposed to determine by means of experiments with both kinds of phylloxera whether the differences observed were due to a difference of race or to the different climate or nutrition of the insect. With this object in view, American vines and their hybrids with European vines were infected with phylloxera from Lorraine at Villers l'Orme, while in a French vineyard at Pagny-sur-Moselle (near the frontier) gall-producing phylloxera brought expressly from the south of France were used. The vines came from the same mother plants, were of the same age and had all been grown in Lorraine. Any difference in the susceptibility to attacks in vines of the same variety could thus be due only to some biological difference in the phylloxera used to infect them.

The experiments showed that biological differences really exist and

(1) See No. 333, *B.* April 1913. (*Ed.*)

reveal themselves in the repulsion shown by the phylloxera of Lorraine to certain vines which are attacked by the French phylloxera. The writer therefore considers the Lorraine phylloxera as a distinct race (the *Pervastatrix* race).

Among the results of the experiments the following are to be mentioned. At Villers l'Orme the following varieties inoculated with Lorraine phylloxera proved completely immune and showed no galls on the leaves or nodules on the roots : Riparia Gloire de Montpellier, Riparia × Rupestris 107 Geisenheim, Riparia × Rupestris 3306 and 3309 Couderc, Riparia × Chasselas 24 Laquenesey, Cordifolia × Rupestris 19 Geisenheim. Isolated small fertile galls together with sterile galls and punctures and occasionally small nodosities were found on Aramon × Rupestris Ganzin No. 1. A regular formation of larger or small nodosities, together with the absence of leaf galls, was shown by Riparia × Rupestris 175 Geisenheim, Riparia × Rupestris 101-14 Richter, and Riparia × Cunningham 535 Oberlin.

These varieties all showed normal formation of galls and root nodosities when inoculated with phylloxera from the South of France, with the exception of Aramon × Rupestris Gauzin No. 1, which behaved in the same way to both races (1).

Whether the *Pervastatrix* race has arisen through adaptation to European vines or already existed in America on the Labrusca vines so closely allied to European vines, has not yet been decided. Apparently climate has not had any noticeable influence on its development.

Notwithstanding the very numerous infection experiments made under varying conditions, it has never been possible to get the *Pervastatrix* race to adapt itself to one of the completely immune vines ; it may therefore be assumed that it is impossible for the *Pervastatrix* race to readapt itself from its usual host plants (European and Labrusca vines) to plants immune from its punctures, because on the latter it dies.

In the cross between immune and susceptible vines, immunity apparently behaves as a dominant character.

Inoculations of immune vines with root phylloxera coming from Alsace, Württemberg and Saxony have never led to infection, so it may be concluded that the *Pervastatrix* race has a wide distribution in Germany.

The writer divides the vines so far examined as to their behaviour towards the *Pervastatrix* race into the four following groups :

1. *Immune vines*, embracing many pure races of *Vitis riparia* (*vulpina*), as well as *V. rubra* and the races of *V. Berlandieri* ; then a number of hybrids, for instance Riparia × Rupestris Couderc 3306 and 3309, Geisenheim 107, Cabernet × Rupestris 33 a 1, Cordifolia × Rupestris Geisenheim 19 and 20, Hybrid Franc, Hybrid Dromois.

(1) Recently vines which had proved immune to the *pervastatrix* phylloxera after repeated inoculations (1912 and 1913), were inoculated with phylloxera from the South of France and immediately showed the formation of root nodosities.

(*Authors' note*).

2. *Vines subject to attack.*

a) Vines slightly attacked, generally quite free after the winter (resistant vines). To this group belong the following: Aramon × Rupestris Ganzin No. 1, Mourvèdre × Rupestris 1202, Aramon × Riparia Teleky 143 B, Riparia × Gamay Oberlin 595 and 604.

b) Vines which permanently show leaf galls (mostly sterile) and root nodosities, but which for the most part are resistant: Riparia × Rupestris 101-14, Riparia × Vinifera 44 Laquenesey, Madeleine royal × Riparia 33 Laquenesey.

c) Normally attacked vines (fertile galls and root nodosities), susceptible to permanent infection, and easily attacked: *Vitis vinifera* and *V. silvestris* (European vines); then *V. Labrusca* with its hybrids, and the American vines; *V. arizonica, V. Berlandieri, V. cordifolia, V. monticola, V. palmata, V. rupestris* and *V. Solonis*. This group also includes several Asiatic vines and numerous hybrids: Berlandieri × Riparia, Rupestris × Vinifera, Riparia × Labrusca, etc.

According to the writer it would be strongly advisable to impose the greatest limitation on the introduction of foreign vines into Germany, on account of the danger of introducing the phylloxera from the South of Europe.

MEANS OF PREVENTION AND CONTROL

800 – **Hymenoptera Parasitic on *Aphis euonymi*, the Beet Aphis** (1). — MALAQUIN, A., and MOITIÉ, A., in *Comptes rendus hebdomadaires des Séances de la Société de Biologie*, Vol. LXXVI, No. 16, pp. 803-805. Paris, 1914.

So far seventeen secies of Hymenoptera have been found to parasiti ze *Aphis euonymi*. They are as follows:

Aphidiidae: gen. *Praon* (one sp. near *P. abjectus* Halid.); gen. *Trioxys* (*T. auctus* Hald., *T. heraclei* Hald.); gen. *Aphidius* (*A. crepidis* Hald., *A. urticae* Hald. and two others).

Proctotrupidae: gen. *Lygocerus* (*L. antennalis* Kief., *L. rufipes* Thoms.); gen. *Sceliolina* (two undetermined species).

Cynipidae: gen. *Allotria* (*A. minuta* Hart. and two other spp. undetermined); gen. *Alloxysta* (*A. crassa* Cam.).

Chalcididae: gen. *Encyrtus* (one sp. undetermined); gen. *Pteromalus* (one sp. undetermined).

The two commonest species are *Trioxys auctus* and *Aphidius crepidis*. They attack chiefly apterous individuals of the aphis, laying one egg in each; the act of oviposition takes two or three seconds. The parasitized aphis shows no unusual symptoms for three or four days, and if not adult continues to grow and complete its metamorphosis; after this it becomes sluggish, turns from black to pale olive-green and finally to brown, swells up and dies. The dead body is almost spherical and adheres to the leaf by means of a sticky liquid, thus presenting a very characteristic appearance.

T. auctus takes three weeks to develop, while the aphis requires fifteen to eighteen days, according to the weather; other parasites (*Aphidius, Encyrtus*) take about as long as *Trioxys*.

(1) See also No. 296, *B.* March 1914.

In autumn, the latest Hymenoptera deposit their eggs in the sexual female aphids, then living on spindle (*Euonymus europaeus*). The females pass the winter on the twigs, and the Hymenoptera emerge from the parasitized ones towards the end of March or in early April ; the healthy *Aphis euonymi* appear early in March.

The pupa of *Trioxys* within the aphis is protected by a white silky covering, whereas that of *Allotria* is covered only by the empty skin of its host.

As showing the importance of these parasites, the writers refer to the two following cases of infection :

a) On the 9th and 19th of June, 1913, twenty individuals of *Trioxys auctus* of both sexes were liberated in a breeding-cage containing two beets whose leaves were infested by about a thousand aphids ; on the 2nd of July more than 500 showed the characteristic appearance of being parasitized.

b) In a small garden, plants of *Euonymus*, beets, *Lysimachia vulgaris*, *Epilobium angustifolium*, thistles, etc., were covered with aphids ; at the beginning of July some thousand individuals of *Trioxys auctus* and *Aphidius crepidis* were liberated : by the 15th of August it was almost impossible to find a living and healthy aphis ; some stems of beets for seed showed over 300 parasitized aphids.

801 – **New Species of *Aphelinus* Parasitic on Injurious Aphids in Russia** (1). — KURDJUMOV, N. B., in *Revue Russe d'Entomologie*, 1913, Vol. XIII, No. 2, pp. 266-270. St. Petersburg, 1913.

Four new species of *Aphelinus* (*Chalcididae*) have been bred from injurious aphids at the Poltava Experiment Station. They are as follows : *A. toxopteraphidis* and *A. flavipes* from *Toxoptera graminum* Rond. ; *A. hordei* from *Brachycolus noxius* Mordw. ; and *A. atriplicis* from *Aphis chenopodii* Schrank. (*A. atriplicis* L.).

802 – **Two New Genera of Hymenoptera Parasitic on *Ectoedemia*.** — ROHWER S. A., in *Psyche*, Vol, XXI, No. 2, pp. 79-81, figs. 1-2. Boston, Mass., 1914.

The writer describes two new genera of Hymenoptera, *Anomopterus* and *Centistidea*, each represented by a single species ; these genera belong to the sub-family *Liophroninae*, and come near *Centistes*.

Anomopterus fasciipennis is parasitic on *Ectœdemia phloeophaga* Busck, and *Centistidea ectoedemiae* on *E. castaneae* Busck, both of which are injurious to sweet chestnuts in Virginia.

INSECTS INJURIOUS TO VARIOUS CROPS

803 – ***Remigia repanda*** **(Lepidoptera), injurious to Crops in Sao Paulo, Brazil.** — HEMPEL, ADOLPHO, and D'UTRIA, GUSTAVO, in *O Fazendeiro*, Year VII, No. 3, pp. 110-111. São Paulo, 1914.

Remigia repanda is widely spread in the State of São Paulo ; its larvae are very voracious and feed chiefly on Gramineae, in particular maize, rice and sugarcane. The moth has a number of broods in the year.

(1) See also No. 294, *B.* March 1914. (*Ed.*).

To prevent attacks, one measure is to burn off the vegetation of waste places, in which the eggs are laid.

If a crop is attacked, aceto-arsenite of copper may be used as a spray (2 lbs. per 100 gallons of water, with the addition of 2 lbs. of soap and 4 lbs. of sugar, or 1 gallon of molasses, to make it stick). For grass crops 1 lb. per 100 galls. is enough. In some cases it may be worth while to burn off a crop and plough it under, so as to destroy the larvae and pupae and prevent subsequent attacks.

To stop the larvae spreading, trenches may be dug round the centres of infection. A belt of quicklime on the ground will also stop them.

Many birds are useful in destroying these larvae.

804 – **The Lesser Bud-Moth *(Recurvaria nanella)* on Apples in Michigan.** — Scott, E. W., and Paine, J. H., in *Journal of Agricultural Research*, Vol. II. No. 2, pp. 161-162. Washington, D. C., 1914.

In the spring of 1912, during spraying experiments on apples at Benton Harbour, Scott noticed serious damage caused by small larvae to the buds of unsprayed trees ; in one neglected plantation in the neighbourhood, the insect was largely responsible for a complete loss of crop. The damage was attributed at the time to the eye-spotted bud moth (*Tmetocera ocellana* Schiff.).

In 1913 the life-history was followed out ; various differences were found between the insect from Benton Harbour and *T. ocellana*. On examining the adults, A. C. Busck referred them to *Recurvaria crataegella*, described by him in 1903 ; further research by Busck and the writers has shown that this is identical with the European *R. nanella* Hübn. (known as the lesser bud-moth), so that *R. crataegella* is to be considered a synonym of this.

European authorities had recorded this species on apple, pear, apricot, peach, cherry and plum. According to Staudinger and Rebel (1901), the distribution in Europe is : C. Europe, Sweden, N. Spain, S. France, C. and N. Italy, Dalmatia and S. W. Russia.

805 – ***Coccus citricola*, a New Scale infesting Citrus Trees in California.** — Campbell, Roy E. in *Entomological News*, No. 5, pp. 222-224. Philadelphia, 1914.

In 1909 a scale was found on citrus trees at Claremont which appeared to differ from the common *Coccus hesperidum* L. ; it was first referred to *C. longulus* Dong. and then to *C. elongatus* Sign., but the writer has recently determined it to be a new species, which he names *C. citricola*.

It is so far known only from leaves and branches of *Citrus*. The young scales mostly settle down on the leaves, but when half grown they migrate to the twigs. None have been found on branches more than half an inch in diameter, and they are confined to the lower branches. When the scales are abundant, as often happens, they fit over one another in a characteristic way, like tiles.

The insect has recently become much more abundant, and has been found in many fresh localities in Southern California, in the Lower San Joaquin valley and to a slight extent in the Sacramento valley. It has probably existed for some time in California, and may very likely have been confused with *C. hesperidum*.

The writer gives the systematic and biological characters distinguishing *C. citricola* from *C. hesperidum* and *C. elongatus*.

ALFREDO RUGGERI, gerente responsabile.

THE INTERNATIONAL MOVEMENT OF FERTILIZERS.

No. 1. *September 1, 1914.*

SUMMARY. — Introduction (p. 1101). — World's production of fertilizers (p. 1103). — International trade in fertilizers (p. 1109). — Consumption of fertilizers in different countries (p. 1124). — Prices of mineral phosphates, potash salts and nitrogenous fertilizers (p. 1132). — Bibliography (p. 1138).

INTRODUCTION.

This review is the first number of a half-yearly periodical whose publication was decided upon at the last General Assembly held at the Institute (Inst. int. d'agr., 4ème Ass. gén., Décis. II, Rapport Pioda-Laur, 1913). The general plan of the review was established by the Permanent Committee; it will appear regularly in the official (French) edition on March 1st and September 1st, that is to say at those times of year when purchases are being made by consumers, and will form a continuation to *Production et consommation des engrais chimiques dans le monde,* already published by this Institute.

As regards the products to be considered, the scheme laid down in the above publication has been adhered to and the fertilizers limited to the following categories :

1. *Phosphatic fertilizers :* mineral phosphates, basic slag, superphosphates, guanos, bones.

2. *Potassic fertilizers :* Stassfurt salts, other potassic fertilizers.

3. *Nitrogenous fertilizers :* nitrate of soda, sulphate of ammonia, synthetic fertilizers, organic fertilizers.

In consideration of the similarity of their market conditions, sulphur and copper sulphate have been included in the Review as other products useful to agriculture.

The Review comprises five parts: production, imports and exports, consumption, prices, bibliography.

The figures given refer as far as possible to the whole year 1913 and to the first half-year of 1914; those referring to 1912 have also been reproduced for comparison. Prices are those of the first half of 1914 and of forward deliveries for the end of 1914 (1). The next number of the review, to appear on March 1, 1915, will contain final figures for 1913, and as far as possible all those for 1914, while prices will refer to the second half of 1914 and of forward deliveries for the beginning of 1915.

Production. — Each fertilizer forming a different category is tabulated according to its production in the different countries.

Imports and exports. — The principal products which are classified under separate headings in official returns are each tabulated to show the commercial movement in the different countries; an official statement of the international situation is thus obtained.

Consumption. — A few figures obtained by the Institute will be published under this heading; statistical information on this point is very difficult to obtain and should form the object of future development.

Prices. — Wholesale market prices from certain important markets are selected for reproduction and where necessary a distinction will be drawn between nominal quotations and actual selling price. This part of the Review will be further developed as time goes on in order that it should prove of the greatest possible practical value.

Prices of mineral phosphates are given both in America and c. i. f. in Europe. Potash salts are quoted at the German official prices and at New York, the latter as representative of the most important independent market.

Official quotations from the principal markets are compared for nitrate of soda, sulphate of ammonia and synthetic manures during the first six months of 1914, the figures referring to prices at the end of each month.

Bibliography. — Discoveries of new beds or the adoption of new manufacturing processes for dealing with chemical products used in agriculture will be notified in this part of the Review, as well as new methods of applying such products or legislative measures in connection with them.

(1) Quotations for forward deliveries have become invalid owing to the present international situation.

The figures for the United States refer to amounts mined; amounts sold were 3 146 573 m. tons in 1912 and 3 020 905 m. tons in 1913. The figures for Tunis also refer to amounts mined, while amounts despatched were 1 923 007 m. tons in 1912 and 1 984 880 m. tons in 1913. The figures for Algeria on the other hand refer to exports and should be increased by the amount consumed internally for the manufacture of superphosphate, which is in part exported (see Part 2, table III, p. 1111).

(1) Metric ton = 0.9931 long ton.

II. — World's Production of Basis Slag.

Potassic Fertilizers.

With regard to the Stassfurt potash salts, figures are given which have been supplied by the German Potash Syndicate and it should be noted that these differ slightly from those published later by the German Imperial Office of Statistics (see *Vierteljahrshefte zur Statistik des Deutschen Reichs*).

III. — Production of Potash Salts in Germany.

Nature of salts	1912	1913	1st half-year 1914
	metric tons	metric tons	metric tons

Other countries	(75 000)	(75 000)	.....
Total	(1 306 600)	(1 448 400)	.....

The figures for the United Kingdom refer to the total amount of ammonia produced stated as sulphate ; according to the Board of Trade the sulphate of ammonia actually produced would only be a little over 84.34 per cent. of these figures. The amount of ammonia produced in Italy in the first half-year of 1914 refers only to sulphate formed by the conversion of calcium cyanamide.

VII. — World's Production of Calcium Cyanamide.

Country	1912	1913	1st half-year 1914
	metric tons	metric tons	metric tons
Germany	(25 000)	(25 000)	.....

Germany	5 942	5 682	.....
Other countries (Sweden, etc.)	1 000	1 000	.....
Total...	203 862	178 785	.....

The figures given for the United Kingdom are those of exports, which are approximately equal to the production. For Ireland the following figures have been obtained :

	Imports		Exports	
1912	2 899	metric tons	14.2	metric tons
1913	4 780	"	3	"

INTERNATIONAL TRADE.

The data given below are drawn from the customs returns of imports and exports for each country and represent what is commonly termed the special trade of imports and exports (see : Inst. Int. d'Agr., Publications du Bureau de la Statistique Générale, No. 4, *Notes sur les Statistiques du Commerce extérieur dans les différents pays*, 1914). The figures referring to similar or almost similar classes of material in the returns have been collected into tables with various headings, qualifying notes being made where necessary.

The fiscal year in Canada ending in March, the figures for the two years ending in March 1913 and 1914 are given under 1912 and 1913 respectively. The same applies to British India.

Phosphatic Manures.

I. — Imports and Exports of Natural Phosphates.

Switzerland	112	72	.....	.....	.....	.....

The first set of figures for Germany refer to natural guano, the second to artificial guano and similar products. The exports from the Argentine consist of meat guano, while those from British India, Norway and the greater part from Sweden are fish guano. South Africa, over and above its official imports, received 6 993 and 4 830 metric tons of guano from the coastal islands during 1913 and the first half of 1914 respectively.

V. — Imports and Exports of Bones and Bone Manures.

The sets of figures classified as *a* refer to substances designated as "potash manure salts"; those under *b* to substances designated as "sulphate of potash"; those under *c* to substances designated as "muriate of potash". This classification is not, however, always very exact; for example in Italy kainite and other manure salts are included under *b*. The exports for Germany for 1913 are rather high, as they include a part of those for 1912.

The only potassic fertilizer classified separately in the United Kingdom is nitrate of potash (see Part 2, Table VIII, p. 1116) the rest are returned under the heading of unenumerated manures.

VII. — Imports and Exports of Other Potash Manures.

Country	Imports			Exports		
	1912	1913	1st half-year 1914	1912	1913	1st half-year 1914

The official figures given above do not agree with those published by the Nitrate Association, which are based on commercial data and therefore do not represent exactly exports and imports (see Bertrand, A., Circular No. 60 de la Asociacion Salitrera, p. 206).

For many countries no figures can be given as special returns for nitrate are not made, or are published with too great a delay.

IX. — Imports and Exports of Sulphate of Ammonia.

Country	Imports			Exports		
	1912	1913	1st half-year 1914	1912	1913	1st half-year 1914

This table is incomplete, especially with regard to imports in the colonies. Such data may be found in the export returns of the United Kingdom, Belgium (Antwerp), Netherlands (Rotterdam), and now also in those of Germany which has started a considerable export trade to Italy, the Dutch Indies, etc. (see Inst. Int. d'Agr. *Production et Consommation des Engrais Chimiques dans le Monde*).

X. — Imports and Exports of Synthetic Nitrogenous Fertilizers.

Country	Imports			Exports		
	1912	1913	1st half-year 1914	1912	1913	1st half-year 1914
	mteric tons	metric tons	metric tons	metric tons	metric tons	metric tons

	176	.....	.....	0.4	.....	.....
	0.2	.....	.....	4 058	.....	.....

The imports of Egypt consist only of calcium cyanamide, those of the United States only of nitrate of lime and those of Canada only of nitrate of ammonia, but the latter are probably not put to agricultural use.

The first, second and third sets of figures for Norway and Sweden refer to nitrate of ammonia, nitrate of lime and calcium cyanamide respectively. Figures for the exports of Norway during the first quarter of 1914 are as follows:

2 771 metric tons of nitrate of ammonia
19 636 „ „ „ „ „ lime
9 838 „ „ „ calcium cyanamide.

XI. — Exports and Imports of Organic Nitrogenous Fertilizers.

Country	Imports			Exports		
	1912	1913	1st half-year 1914	1912	1913	1st half-year 1914
	metric tons	metric tons	metric tons	metric tons	metric tons	metric tons
Germany	3 261	2 899	1 373	5 307	6 704	3 941
	57 930	64 421	35 636	12 022	15 781	9 866

Austria-Hungary	893	560	217	3 647	3 444	1 589
	1 237	1 667	963	777	654	388
China	140 307	.....	.....	51 066	.....	.....
	.....	.....	.....	493 477	.....	.....
Egypt	.....	.....	.....	.....	75	.....
	.....	.....	.....	80 778	62 977	.....
France	72 573	82 072	33 835	31 365	30 728	15 079
British India	19	464	.....	164 380	178 126	.....
Japan	623 471	373 800	.....	.....	.....	.....
Norway	.....	.....	.....	14 548	8 929	.....
Switzerland	145	136	.....	652	1 626	.....
	2 190	2 053	.....	1 354	1 579	.....
Uruguay	.....	.....	.....	137 559	.....	.....

The first set of figures for Germany, Austria-Hungary and Switzerland refer exclusively to horns and hoofs for manurial use; the second set refer to other animal residues, blood, etc. The figures for the Argentine Republic and Uruguay represent the total slaughterhouse residues excluding meat guanos and bones, which are given elsewhere.

The exports and imports for China, Egypt and India consist entirely of oil cakes with the exception of a small export of other material from Egypt shown in the first figure for 1913. Soya bean exports from China are classified separately in the second set of figures for 1912. It should be noted that oil cakes are largely but by no means exclusively used for manure in India.

Other Fertilizers and Chemical Products used in Agriculture.

XII. — IMPORTS AND EXPORTS OF UNENUMERATED CHEMICAL FERTILIZERS.

Country	Imports			Exports		
	1912	1913	1st half-year 1914	1912	1913	1st half-year 1914

Servia	18	.....	.....	.....	.....	.....
Switzerland.....	25 926	26 309	.....	7 487	10 994	.....

The nature of the products varies with the different countries. In France, up to 1914, they included ground basic slag. In Italy the greater part of the superphosphate is included. In the United States the figures refer almost exclusively to compound manures exported more especially to other countries on the American continent (Canada, Mexico, etc.).

XIII. — Imports and Exports of Other Unclassified Manures.

Country	Imports			Exports		
	1912	1913	1st half-year 1914	1912	1913	1st half-year 1914
	metric tons	metric tons	metric tons	metric tons	metric tons	metric tons

Netherlands	1 579 332	1 635 566	.....	109 497	62 215	.....
Russia	15 168	.....	.....	.....	.....	.....

This last class of manures is still more heterogenous. In Great Britain and Spain it includes potash salts, while the Netherlands include all fertilizers except guano and nitrate of soda under the one heading in their monthly returns, though further classifications occur in their annual returns. In Italy the figures refer exclusively to organic manures amongst which olive and wine pomace have recently assumed some importance.

XIV. — Imports and Exports of Sulphur.

Country	Imports			Exports		
	1912	1913	1st half-year 1914	1912	1913	1st half-year 1914

Kainite, ground fine, special type for the destruction of weeds	.....		5 (extra)	0

The above prices (Tables X and XI) refer to fertilizers consumed in Germany. For other countries the prices are fixed each year at the beginning of the season and are reckoned as at Stassfurt, always at higher prices than the same fertilizers intended for home use.

XII. — Prices of Potash Salts at New York, January-June, 1914.

Nature of salts	Potash content	Price per long ton			
	per cent.	$	£	s	d
Kainite	12.4	8.36	1	14	4
Hartsalz	16	10.87	2	4	8

Agricultural Education in Hungary

by

JÁNOS NYÁRÁDY.

Agricultural instruction in Hungary is given in the following special educational establishments :

Royal Veterinary College at Budapest.
Royal Agricultural College.
Agricultural Training Colleges for primary school teachers.
Schools of Practical Agriculture.
Royal Dairy School.
School for Dairymen.
Other schools for special branches.

There are further 28 lecturers from the Training Colleges acting as district organisers and advisors.

Royal Veterinary College at Budapest. — This institute : *a*) provides a course of instruction and training in veterinary science ; *b*) grants licenses to veterinary surgeons ; *c*) furthers the interests of veterinary science by observations and experiments ; *d*) provides expert opinion for questions of veterinary science and hygiene ; and *e*) obtains information for Government purposes or for the Law Courts on veterinary questions. The course lasts four years (eight terms) and students to be admitted require to have taken the school leaving examination of the middle schools ; terms kept in a foreign veterinary school of similar standard are recognised and the course leads to graduation with a doctor's degree. The staff consists of a director, twenty lecturers and 25 assistants and clerks. During the session 1912-1913, 190 students were in attendance.

Royal Agricultural Colleges. — Students having been through the middle schools and requiring a higher agricultural education, both practical and theoretical, go to one of the five Royal Colleges at Debreczen, Kassa, Keszthely, Koloszvár and Magyaróvár respectively. These institu-

tions take both full-time students and those who only wish to follow certain lectures. The course lasts three years (6 terms) and during the first year the instruction chiefly takes the form of practical work. The following subjects are taught at the Colleges: natural history, physics, plant production, rural economics, social economics, and practical agriculture including special branches.

Each College has a farm of 640 to 1100 acres attached to it for instruction in the actual practical work. Besides teaching, the staff carries on a certain amount of experimental work and advises on agricultural questions, for which purpose an agricultural consulting committee has been organised in each institution. During the session 1912-1913, 452 full-time and 9 part-time students were in attendance. The capital involved in these institutions amounts to £267 808, while the returns from the farms in 1913 were £3 144 (1).

Training Colleges for Elementary School Teachers. — Two training colleges have been established, one at Kecskemét for men and the other at Komárom for women (2) in connection with the Schools of Practical Agriculture in those places. Students who have taken the college diploma may become teachers in the rural complementary schools and some of the women students take up posts in the schools of domestic economy. The course lasts two years and only those candidates are admitted who already have their teacher's certificate and are under certain age limits, *viz.* twenty-two and twenty-four years old for men and women respectively. Forty students can be taken at Kecskemét and thirty at Komárom; the teaching staff amounts to seven and five lecturers respectively. Instruction is both practical and theoretical, the performance of a certain amount of practical work being compulsory. Women students are given general instruction in domestic economy as well as in agricultural subjects. Excursions are arranged to visit model farms in districts where poultry farming and market gardening are important industries, in order to provide the students with good object lessons in those branches. The students are further called upon to give popular lectures and demonstrations as part of their training.

Schools of Practical Agriculture. — These are the most elementary agricultural schools in Hungary and provide technical instruction to the sons of small farmers and under-managers on large estates. They are under Government administration and their organisation varies with the requirements of the district in which they are situated: for instance those at Ada, Békéscsaba, Hodmezövásárhely, Jászberény, Karczag, Kecskemét and Nagykálló have a six-months course for farmers and small landowners in the general management of holdings, while the schools at Kisszeben, Lugos, Pápa, Rimaszombat, Somogyszentimre, Algyógy, Breznóbánya, Csák, Csikszereda, Komárom, Nagyszentmiklós and Szilágysomlyó have

(1) See also No. 453, B. May 1913.

(2) See No. 402, B. May 1914. (*Ed.*).

a two-year course and give more advanced instruction adapted to the training of farmers, under-managers and inspectors.

In all these schools the instruction is chiefly of a practical nature and much stress is laid on the satisfactory performance of the various kinds of manual work; on the theoretical side, only the most fundamental and indispensable facts are treated, the object being to keep the whole scheme of education at a popular level. Schools which are destined solely for the training of under-managers take pupils of twenty-two years of age, preferably after they have finished their military training; other schools admit pupils of seventeen years old and upwards. At Algyógy there is accommodation for sixty internal students, who do all the practical work in both the fields and the garden.

Short elementary courses, lasting two months, are organised at these schools during the winter for adults who cannot leave their farms for a longer period of time. Besides these, short summer courses lasting four weeks are held for elementary school teachers who wish to qualify as complementary school teachers, and popular lectures are given to the farmers of the district on the use of farm implements and the cultivation of special crops. During the winter the regular students receive instruction in the domestic industries. All teaching is done in the simplest language and illustrated with practical experiment and demonstration; for this reason, special importance is laid on the organisation and equipment of the model farms, which cover altogether an area of 11 700 acres, part of which is State owned while the rest is either let or given rent-free by landowners. The returns on these farms for 1913 amounted to £4873.

The staff of each school consists of a director, an agricultural demonstrator, a gardener and a practical assistant

Besides these State schools there is an Agricultural School belonging to the town of Szabadka staffed by Government teachers. Private Agricultural Schools receiving State grants are also to be found at Csákvár, Bezstercze, Földvár and Medgyes; they are organised on similar lines to the State schools.

Royal Dairy School at Sárvár. — This institution provides suitable training for managers or skilled workmen of milk and cheese factories. Though all students receive both practical and theoretical instruction they are divided into two classes according as they are preparing to become managers or skilled workmen. The former class have to be over twenty years of age and to have already been through a course at a school of practical agriculture; the latter class are admitted at seventeen and only require to be able to read and write; during the session 1912-1913 attendances numbered 4 students of the former class and 17 of the latter. The course lasts one year.

Schools for Dairymen. — There are two of these, at Kisbér and Csák. The course is essentially practical and lasts one year.

The State Lecturers who teach agriculture in the agricultural colleges also act as advisors and organisers in the various districts, write agricultural articles for the local papers, give lectures and

supervise model farms. Besides these twenty-eight lecturers there are two lecturers in secondary boys' schools to help with the general organising and advisory work and four specialists to advise more particularly on the cultivation of potatoes, hops, hemp and flax, and on the improvement of pastures.

A School of Domestic Economy has been created at Putnok for the daughters of farmers, while seven travelling schools each under the control of two teachers give courses lasting six weeks in other parts of the country. They receive State grants amounting to £1666 annually.

During the winter popular agricultural lectures are given, towards which the State makes an annual grant of £4170.

Special schools also exist for the various branches of agriculture, such as poultry keeping, bee keeping, viticulture, horticulture, forestry, etc.

In conclusion the following figures summarise the annual expenditure by the Hungarian Government on agricultural education, which is almost entirely directly dependent on the State.

	Ordinary expenditure	Extraordinary expenditure
	£	£
Royal Veterinary College	21 846	4 417
Agricultural Colleges	48 929	9 792
Lower agricultural education, including advisory and organising work	84 047	22 000
Totals	154 822	36 209

Reclamation in the Province of Ferrara

by

Prof. VITTORIO PEGLION,

Formerly Director of the Travelling Lectureship in Agriculture at Ferrara, Professor of Agriculture in the University of Bologna.

The agricultural awakening of the Province of Ferrara has been closely connected with the carrying out of the projects of reclamation ; this work was begun under the rule of the Este family, but reached its greatest development in the second half of last century, when, with the help of modern engineering methods, human activity was able to attack and conquer the problems entailed in the definite and permanent reclamation of the marshes and lagoons.

The traces of the work carried out by the organizations formed to deal with these problems as far as the then existing means would allow will never be effaced : the division of the Ferrara territory into four drainage districts still exists, and it may truly be said that the colossal work of mechanical drainage performed on the second and third of these forms one of the most imposing monuments to the civilization of the third Italy.

Out of the 655 000 acres forming the territory of the Province, one may reckon 155 000 as still occupied by bracks used for fishing (115 000 acres) or by rivers, canals, buildings, etc.; the remaining half a million acres represent the raw material of agricultural and forest production. The last-named may be left out of consideration, as the woods occupy hardly as much as 6 500 acres, mostly in the territory of Mesola, — a poor remnant, which, with the classical pinetum of Ravenna, serves to recall the vast forests of holm-oak and pine which in ancient times clothed the further margins of the lagoons of Venice and the Romagna.

The survey of 1835 divided this area of 500 000 acres into 204 020 acres of field crops, 172 080 acres of natural meadows and pastures, and 105 953 acres of reed-beds; the data for the agricultural survey of 1906 show 399 608 acres of crops and 80 015 acres of meadow, leaving some 15 000 acres for woods and vineyards.

These figures give a clear idea of the scope of the reclamation work: the arable area has been *doubled* as a result of draining the marshes and the " meadows and pastures " — a euphemistic way of referring to swamps, nearly or quite unproductive; these have been turned into highly fertile plains on which wheat, hemp, beets and leys extend yearly and give such enormous crops that this land must be considered as among the most productive in the whole of Italy.

At the present time the agricultural land of Ferrara consists of a complex patchwork of newly-reclaimed plots with the ancient holdings and " old lands " under cultivation for centuries. Although the contemporary period of this story contains many unfortunate episodes, so that with the names of the successful men must be mentioned others who have spent their labour and means in vain, yet the impetus to further conquests shows no diminution. There are already 215 000 acres from which the drainage-water is drawn off by 18 pumping-stations, and projects are on foot for two further areas, each of some 20 000 acres: one belonging to the northern levels (" valli ") of Comacchio, and the other in the salt levels of Argenta and Porto Maggiore, which will form the so-called Mantello innings (" bonifica del Mantello ").

In contrast with this land drained mechanically by pumps — that is the typical Ferrarese type of undertaking — should be considered the land in the commune of Bondeno which has a natural outlet, the water flowing off by means of the great canal of Burana or Volano, which passes under the ruver Panaro by means of the famous " Botte Napoleonica ". This vast zone of reclaimed land consists of 26 690 acres in the Province of Ferrara, 54 750 acres in the Province of Modena and 47 060 acres in the Province of Mantua. With the drainage water from this great basin and the possibility of receiving water from the main stream of the Po through the Pilastresi sluices, the old Volano course of the Po has again become a river rather than a canal, and indeed for a considerable distance has a natural fall; it has also become the principal waterway of the Ferrara district, as well as a source of water for agricultural purposes.

The particulars of these reclaimed lands have been given in detail in various publications, to which we would refer readers who wish to study the question more in detail. In this short account it seems best to confine our attention to certain features of a general character.

From the purely technical point of view reference should first be made to the great difference in the problems presented according as the land has been reclaimed from freshwater or from saline marshes (" valli dolci " or " valli salse ").

The low-lying parts of the *freshwater marshes*, prior to drainage, were occupied by a more or less vigorous growth of reeds or other marsh plants. The succession of generations of such rhizomatous plants for centuries has given rise to strata of peat (" cuora "), in some places reaching a sufficient depth to allow of utilization for burning or as raw material for certain industries. But even these marshes rest on a distinctly saline subsoil, as can be seen at once from the nature of the water at some depth. Except for the markedly peaty areas, which require quite special treatment, one may say that these soils present no special obstacles to opening up for cultivation. With systematic treatment they may in a short time be put under highly paying crops. The fact that sufficient care has not always been taken in dividing up these lands is due to difficulties of a different character (to which we shall refer shortly) and not to the physical characters of the soil.

The behaviour of the land obtained by reclaiming *salt areas*, or *bracks*, is totally different, and as the new schemes refer to the inning of land covered by salt water it seems advisable to go more into detail on this point. Anyone familiar with the " Gallare " — typical of innings of this kind — or similar farms, such as what was once the Tassoni brack (reclaimed by Cav. M. Marini), knows that considerable areas may remain refractory to the usual methods of cultivation for several decades after the completion of the engineering works freeing them from water. Soils impregnated with saline matter, such as those inned from the lagoon, require special treatment to deal with the sterility resulting from the accumulation and continual change of level of these salts in the arable layer. We may here mention one or two fundamental points of such treatment not always remembered by the promoters of the reclamation of the bracks : owing to the position of these soils, their physical and chemical composition and their structure, and owing to the enormous quantity of salt contained in the mass, the possibility of profitable cultivation — when the engineering work is finished — is not only dependent on a period of absolute unproductivity, much longer than is generally admitted, but even later is subject to variations which cannot be foreseen and which are due to the special behaviour of the saline matter.

We have already given prominence to these considerations, though fully aware that they cannot outbalance the reasons of a social nature and especially of convenience which have created an opinion decidedly favourable to the carrying out of the reclamation of the stretches of lagoon in question. It would be well that the example of the practical results

furnished by the reclamations already accomplished should not be taken as the only criterion for the opening up and improvement of the neighbouring land, which is not always in a suitable condition for reclamation with a view to agricultural use. The planning, the execution and the completion of the past, present and future reclamations should not be effected entirely to the detriment of the " water farming " (vallicoltura) ; an investigation should be undertaken with a view to establishing once for all the productive capacity of this land under water and the best means of encouraging a reasonable and intensive " farming " of it ; such " farming " requires far less sinking of capital and at the same time lends itself to the natural tendencies of the local inhabitants concerned, so that it might well hold its own in comparison with the arable land to be inned from these inlets of the lagoon.

The fundamental work of reclamation for both freshwater and salt lands consists in drying, that is in the mechanical drawing-off of the ground water. There is not the slightest doubt as to the perfection with which this is now carried out by the engineers, who are thoroughly versed in the setting up of the necessary plant and in the maintenance of the scheme of drainage ; in all the operations so far carried out the removal of the water was obtained in the most perfect and simple manner possible ; though the methodical evacuation of the water is the primary necessity for these tracts lying at such a very low level, it is only one side of the complex problem entailed in opening them up for agricultural use.

This drying is naturally only relative, allowing a certain depth of free soil above the water-table. For this reason the individual characteristics of the different soils, especially as regards water-holding capacity, should be taken into account ; evidently sandy and clay lands cannot have the same treatment. The possibility of cultivating these reclaimed lands properly depends in particular on the reserves of water which the crops find at their disposal, and obviously an excessive drying may be as injurious as a condition of stagnation leading to swamp formation.

The working of the pumping engines is so regulated as to avoid any danger in this direction. In some of the very large sections covering something like 100 000 acres there are considerable differences in level ; in such cases it is now the rule to keep the so-called high-level water separate from the low-level water, the two being dealt with by different pumping stations. As an example of this may be mentioned the system adopted by the Association for the " Grande Bonifica " ; for the completion of this area, carried out between 1905 and 1910, they rearranged the old station at Codigoro to dispose of the high-level water (from an area of 39 929 acres), while the low-level water (from 89 875 acres) runs off by means of a new station put up close to the old one.

Although the drying is carried out in accordance with the needs of the crops, these are subject to the same risks as those on the neighbouring old lands as regards water supply. Indeed seasons in which the yield of these artificially dried soils is seriously reduced by drought are by no means rare.

In fact drought makes itself felt more severely on these soils, as the water is liable to take up mineral matter from the subsoil, constantly impregnated with salt, and may thus become too saline for the ordinary crops. We have elsewhere had occasion to refer to the difficulties attendant upon the excess of saline matter in the water taken up by the arable layer, which may provoke a special condition of " physiological drought " ; the same point has been referred to by Tacke in his masterly advice on the water economy of moor and fen soils : " The drawing-off of the water must be done with great care, as organic soils retain large quantities of water with such tenacity that the roots of the plants growing in them cannot make use of it; in such soils plants may suffer from lack of water in presence of considerable quantities of it.... ; once the stagnant water has been dealt with and the land brought under cultivation, only small amounts of water should be drained off ".

Pure sandy soils require similar treatment, as their productivity depends entirely on the presence of the water-table near enough to the surface to be within reach of the roots. The vineyards of Comacchio and parts of the cultivated land of the Mesola are in a flourishing condition solely because the water conditions have not been disturbed ; they form a marked contrast to certain old sandhills wedged in between low-lying reclaimed zones and consequently subject to excessive drainage: the careful running-off of the rainwater and the lowering of the water-level in the soil have led inevitably to absolute sterility in the higher sandhill tracts. In the modern work of completion of the Grande Bonifica it was recognized that this area would have to be isolated from the remainder and submitted to special treatment suitable for sandy land.

So far no plans have been made for correcting any possible deficiencies in the drainage schemes by means of irrigation. It is certainly very exasperating in some years to have to watch the crops daily drying up owing to continued drought, while up above the Grande Bonifica rises the great bank holding in the water of the Po on its way to the sea ; the Po water is, however, coming to be used for hygienic and agricultural purposes, as the need has become more acute with tl e yearly increase of the permanent population of the reclaimed lands.

It should be recognized that while the removal of the water — the main scope of the *engineering reclamation* — presents great difficulties, the difficulties encountered in the *agricultural reclamation* — that is opening up the land for cultivation and colonization — are equally serious, if not more so. The water from the ditches and main drains, as well as the ordinary well water, is absolutely unfit for watering cattle or for household and agricultural purposes; it is charged with saline and organic matter and becomes putrid in summer. Petitions for a supply of drinking water used frequently to be made by the people of the reclaimed areas and it was owing to the initiative of the Commune of Iolanda di Savoia that the legislation in vigour was altered, so that by the law of June 25 and July 13, 1911, communes in reclamation areas were added to the list of those allowed special facilities for the provision of drinking water. " If our

Commune, planned and founded contemporaneously with the carrying out of the reclamation scheme, cannot boast a past, it may well be proud of its present work " : so said Comm. A. Marangoni, who has been intimately connected with the Grande Bonifica of Ferrara, on the 15th of June, 1913, in opening the communal aqueduct, by means of which Iolanda di Savoia " has no longer fetid and stagnant water spreading fever and death, but pure and healthy water shooting up to many feet above the ground and bringing healthy and vigorous life to these redeemed lands. "

In the vast area of the Grande Bonifica (133 000 acres) provision has been made for obtaining water from the Po by means of four syphons, planned and constructed under the direction of Ing. Pasini. All the farms in the area feel the benefits of this work in completion of the reclamation, as they can provide water for the watering of live stock, for household use and for retting hemp. A logical finishing touch would have been the carrying out of Ing. O. Balduzzi's scheme for a Po valley aqueduct, to provide drinking water to the 103 200 inhabitants of 11 communes lacking it. As this remained in the condition of a project, the Ferrarese Reclamation Society — whose land makes up the greater part of the Commune of Iolanda di Savoia — with its usual enterprise, took up the construction of the communal aqueduct under the provisions of the law mentioned ; the Po water is filtered and purified on the Puech-Chatal system and brought into the area by a steel conduit 18 miles long ; finally it is distributed to the chief farms and groups of houses in the territory of the commune at the rate of 14 000 cu. ft. per day.

The Volano Po, or Burana, which runs from west to east through the province of Ferrara, has also been laid under contribution for water for agricultural purposes. Its value has been increased since the construction of the Pilastresi sluices has allowed water from the main Po to be run into it, but unfortunately the Burana is, and will continue to be, chiefly a drainage canal into which are run the waters from the 3rd, 4th, and 6th sections of the Burana innings : it also receives the water from the hemp-retting and in particular the refuse water from the sugar factories along its course. For these reasons water from it has a very limited use, and one of the associations most concerned is now making plans for obtaining water direct from the Po for the needs of its vast territory.

While the provision of water for agricultural purposes in this 3rd drainage section is difficult and costly, the provision of drinking water is equally so and sometimes not economically possible : we do not here refer to ordinary wells, as with rare exceptions the water they give is scanty and bad. So far the best results have been obtained by deep tubular wells, of which there are a certain number here and there in the Ferrarerse territory. Their depth varies from 80 to 600 ft. ; some only lasted for a very short time, while the use of the water from some others was prohibited for preposterous hygienic reasons about the quality. Special mention should be made of the well bored at the Bastioni farm on the Val Gallare property ; this is nearly 600 ft. deep and for over thirty years has given a constant supply of about 1 ½ gallon per second. Last year this source was covered

in, and after filtration it is now distributed through 12 miles of steel tubing to 40 fountains at the numerous farms round.

Yet another vital problem of the reclaimed zones remains to be mentioned, namely the question of means of communication : there are still large areas inaccessible for several months in the year owing to lack of roads ; the laying of good roads to connect the reclaimed lands with the nearest centres requires a great outlay. Happily the most economic means of transport of agriculturial produce, namely by water, can to some extent be substituted for roads, which in these one-time bracks are yet to come. The chief canals have indeed been arranged so as to be navigable, but access to the wharves or landing-stages must be provided and the farms must be joined up one to another and to the nearest centres. There is no need to go deeply into the question, as the above will suffice to call attention to one of the causes which has contributed and still contributes to retard colonization of the reclaimed areas.

These considerations indicate that it would be very instructive to make an investigation into the real cost of reclaimed land, especially so as to be able to make proper comparisons as to the utility of continuing the inning at the expense of the lagoon. There is a fundamental difference between schemes which have in view the reclamation of land at present more or less completely and constantly submerged under salt water, and such schemes as the great Rhine reclamation, now being carried out, in which it is a question of laying out permanent drainage for vast stretches of land whose productive power is paralized by the lack of a proper outlet for their waters. Probably, however, the calculation of the true total cost of such reclamation can never be made : it would show up the perseverance and strong spirit of initiative possessed by the past generation of farmers, who selected this extreme corner of the Po Valley for their operations. The names of Count Francesco Aventi, Count Luigi Gulinelli and Ing. Gerolamo Chizzolini — to mention only some of those no longer living — will always be remembered as among the numerous band of pioneers who devoted brains and money to carrying through this reclamation work. It should be repeated here that the fundamental work of engineering reclamation was performed on private initiative and with private capital, at a time when the Government seemed almost ignorant of the existence of any such important problems. It was only after the passing of the law of 1882, modified in 1901, that the State took a part in the completion of the work.

It will still be possible to calculate what has been spent by the State and by local bodies in completion of the work, at any rate where such expenditure was undertaken to satisfy collective needs. But the total sum sunk by private persons defies all attempts at estimation, whether it be that expended on the large properties organized on industrial lines or that due to large, medium or small landowners.

Among the large organizations for intensive cultivation or industrialized agriculture, special mention should be made of the Ferrara Land Reclamation Society and its derivatives — the Immobiliare Lodigiana, the Immo-

biliare Veneta and the Amministrazione Mazzotti, besides other smaller ones comprised in the Association for the Grande Bonifica — and of the Val Gallare and Valle Volta Societies, comprised in the 2nd section ; all these have been the subject of numerous publications and serve as object lessons for all engineers and agriculturists. No less worthy of mention are the numerous farms whose present prosperity is the fruit of the labours and faith in the agricultural industry of the much abused class of large and small Ferrarese landowners.

The fertility of the redeemed land, after it has been properly laid out, has often been referred to : yields per acre exceeding 37 bushels for wheat, 16 tons of beets and 12 cwt. of hemp lint are by no means exceptional. There are still a few pieces of land, which as Prof. Munerati wrote some time ago, have not yet been awakened by phosphatic manuring, the foundation-stone of scientific agriculture ; such lands require an enormous expenditure of capital to bring them under cultivation, and they have absorbed and continue to absorb a large part of the returns given by the crops on them.

In the early years of cultivation these lands were robbed by excessive grain-growing : they form another example of the specialized agriculture which is started wherever virgin land is suddenly opened up for farming, as shown by the agricultural history of all countries. But this extensive cultivation had a short life ; these reclaimed lands gradually came to resemble the densely populated old lands surrounding them, as regards the working plan, the arrangement of the farms and the means of production.

The tendency is to form farms of about 75 acres — the old-fashioned " versuro " — which, at any rate in the early stages, are run on the " boarico " (1) contract system. Many private estates have already reached this condition, and modern necessities incline to still further reduction of the holdings, so as to make them suitable for farming on the métayer system or for letting to colonizing families. On the larger estates such division exists only in theory, as the complex circumstances already mentioned prevent its being carried into practice.

We may finish up with a few statistics, which refer to the whole province of Ferrara and not only to the reclaimed areas. The following table

Crop	Average 1862-1871		Average 1909-1913	
	Per acre	Total	Per acre	Total
Wheat . . . . . bushels	16.26	1 875 335	29.13	4 323 935
Hemp . . . . . cwt. .	6.3	294 375	9.0	619 900
Beets . . . . . tons . .	—	—	14.9	226 966

(1) The " boarico " contract is one in which a head ploughman is put in charge of a certain number of teams of oxen; he is housed and receives part money wages and part wages in kind. (*Ed.*)

gives the average yields of certain crops for the decade 1862-71 in comparison with the agricultural statistics for the 5-year period 1909-13.

The cattle numbered 70 000 in the 1869 census and 110 320 in the 1908 census.

The Swine Raising Industry in Canada

by

J. B. SPENCER, B. S. A.

Editor and Chief, Publications Branch, Department of Agriculture for Canada.

The swine raising industry in Canada is closely allied with what may be termed general agriculture or mixed farming. Even the early settlers raised a few hogs to supply themselves with meat and to provide a product acceptable to the local merchant in exchange for products of commerce. With the development of urban populations and the growth of the lumbering industry, there grew up a demand for pork products. In the case of beef, the butcher very early became a necessary factor, while in the swine industry, the farm continued to combine the breeding and feeding operations with the slaughtering and curing of meat. Then there arose a more or less extensive fresh pork trade, but it was not until the packing houses were established about 1860 that an export trade began.

Of the early years of the industry, Mr. William Davies of Toronto, the pioneer pork packer of Canada, writes :

> Fifty years ago or even more, large numbers of dressed hogs were brought by farmers to Toronto. Besides the few that were bought by local dealers many were bought by commission men in the city for local operators in Montreal. These carcases were chopped up and packed in barrels with a certain amount of salt, then coopered up tight and filled with water and brine. These barrels were then shipped by boat to the consignees in Montreal. In a few instances they were taken down by local Toronto men. Arrived in Montreal these barrels of pork were taken to a Government Inspection Warehouse. The inspectors were sworn Government Officials and they made out a bill for each owner specifying so many barrels of mess pork, so many of prime mess, etc., and armed with this certified bill the products could be sold to Montreal merchants, from whom the stuff found its way into the pineries to feed the lumbermen. At that day there was positively no export trade. Soon

after that a reciprocity treaty with the United States was enacted and as hogs were much more plentiful in the United States than in Canada, and mess pork in barrels was put up in the United States on a very large scele, it came to Canada duty free and thus there was a considerable surplus available for export, especially as the kind of hogs desiderable for the lumbermen's use were "mammoths" while the sort desirable for export were "light weights". From that time the export business increased largely.

While the market for Canadian pork products was confined principally to a home demand, there was no incentive to change from the customs that had become well established, but so soon as there was an appreciable quantity for export, the requirements of the importing country had to be reckoned with.

It was, as it is today, the business of the farmer to raise the hogs, but to find a market depended upon the commercial man, who, in this case, was the pork packer. Fortunately for the industry, which expanded very rapidly, there were in Canada farseeing men engaged in the packing business, and on these the swine raising industry depended more than upon any other agency. They set about developing the right kind of hogs for the best trade.

The English market demanded medium weight hams and "Wiltshire sides" full of lean meat. Experience taught the packers that the Yorkshire and Tamworth breeds excelled in these particulars. To encourage farmers to raise hogs of these breeds, leading packers imported boars and distributed them in hog raising sections. This was done in sections of Ontario about 1890. The result was very pronounced and in the desired direction, for in a few years Canadian hog meats became very popular on the British market.

The possibilities of the bacon industry appealed to Provincial and Dominion Governments perhaps more especially at the beginning. The Ontario Department of Agriculture during several years in the nineties conducted a most effective campaign on behalf of the "bacon" hog. By means of Winter Fairs and Farmer's Institute meetings, Ontario farmers were shown conclusively that the "bacon" hog was the most profitable to raise and the most readily sold in the best markets of the world. The correctness of the teaching in those days is amply borne out by the report of the Swine Commissioner who visited Denmark and found that the Danish pig, from which the highest-priced bacon in England is made, corresponds exactly with the pigs advocated for Canadian farmers and at the present time raised by them in every province. The results of this campaign of education were so pronounced that within a few years the railroads leading to the large packing houses were loading hogs at almost every country station once or oftener weekly with stock that came well up to the standard for the export trade.

Nor were the other provinces asleep in regard to the swine breeding industry, as in each one of them excellent progress has been made, more especially in the matter of quality. In each and every province the "bacon" hog is the Standard and the pigs that win the best awards in the Eastern provinces are of the same general type, age and weight as those that take the best awards in Ontario and in the Western provinces.

The Federal Department of Agriculture has done much to uplift the industry, more especially in the provinces outside of Ontario. Through the Branch of the Live Stock Commissioner the teaching commenced in Ontario has been extended to other parts of the Dominion both at Institute meetings and Winter Fairs, while these latter organizations have been induced to frame their prize lists so as to encourage only breeds of the "bacon" type. The Federal Department of Agriculture, in conjunction with other agencies, has also distributed by means of section sales and through Farmer's Clubs breeding swine of superior quality. Then the Experimental Farms have rendered and continue to render a highly valuable service in experiments carried on more especially at the Central Farm, where the questions of economical feeding and sanitary housing have been very largely solved.

The Export Trade.

From small beginnings in the early nineties, the export bacon trade with Great Britain grew by rapid strides until in 1905 Canada supplied the Mother Country with about 20 per cent of her imported bacon. For a number of years a highly satisfactory export trade was maintained, but since 1907, a decline has been in operation until Canadian supplies to the Old Land have fallen to about one-third what they were when the trade was at its height.

It must be noted that up to about 1884 much of the export pork was made from United States hogs. Soon after that time Canadian hogs were raised in sufficient number to keep the packing houses supplied.

The following table shows the exports of bacon, hams and pork from 1868 to the fall of 1913.

Exports of Bacon from Canada.

Fiscal Year	Bacon	Hams	Pork	Total
	lbs.	lbs.	lbs.	lbs.
1868	—	10 580 528	3 506 048	14 086 576
1870	—	19 627 216	6 544 384	26 171 600
1880	8 616 739	955 603	1 281 391	10 853 733

* April-October.

The falling off in exports does not indicate a serious decline in the raising of hogs. According to the Census of 1891 there were that year on Canadian farms 1 733 850 hogs, which number had increased ten years later to 2 353 828, and in 1911 to 3 610 428.

Federal meat inspection in Canada, which is confined to establishments doing an export or inter-provincial trade, was inaugurated in September, 1907. The following table shows the number of hogs slaughtered in inspected establishments in Canada year by year since that time :

Swine Slaughtered in Canada at Inspected Establishments (1).

The decline in exports must, in large measure, be attributed to increasing consumption in Canada. During the years of heavy export the supplies shipped out were produced almost entirely in the Province of Ontario. The western provinces, while filling with people, were slow to produce hogs until the past two or three years, when a great increase in production has taken place. Up to 1913 packing houses in Ontario and Quebec had a large market west of the great lakes, but the tide has turned. Prairie province farmers, owing to continued high prices for pork, have turned their attention more and more to the feeding of hogs on their low grade and damaged grain, and since the fall of 1913 have been shipping hogs east in large numbers. During 1913 the slaughtering of hogs in Canada showed a very slight increase over that for 1912. The killings in eastern houses showed a decrease which was slightly more than met by an increase in the west. This is borne out by statistics supplied by the Meat Inspection Division of the Department of Agriculture in the following table.

Hogs Slaughtered in Inspected Houses.

	1913	1912	Increase or Decrease
Eastern Canada	923 908	1 058 486	— 134 578
Western Canada	336 147	145 064	+ 191 083

The exports of hog products from Canada have, until quite recently, been almost entirely to Great Britain. With the coming into force of the "Wilson-Underwood" Tariff in September, 1913, the markets of the United

(1) A large number of swine are slaughtered in Canada in places other than those under federal inspection.

States of America were thrown open to meat products on a free basis. Since that time increasing quantities of Canadian bacon, hams and pork have been finding their way over this international boundary.

Pedigree Registration.

The registration of swine in Canada commenced with the Berkshire breed in 1875, but it was not until 1882 that other breeds commenced to be recorded. That year, a record was opened for Suffolks, Yorkshires and Tamworths, and at various periods up to 1892 practically all of the present breeds in Canada, with the exception of the Hampshires, were being recorded ; Hampshire records were opened in 1910. The work of registration was carried on by the Agriculture and Arts Association of Ontario until about the year 1900, when that body ceased to exist. From that time until the National Live Stock Records were formed in 1905 (under the Live Stock Pedigree Act of 1901) the work of registration was done by the late Henry Wade, Secretary of Live Stock Associations in Ontario.

Since 1905 the registration of swine in Canada has been carried on under the National Live Stock Records System at Ottawa.

The development of a Canadian " bacon " hog is strikingly reflected in pedigree registration. During the past thirteen years hogs of breeds of the " bacon " type have increased by leaps and bounds, those approaching that form have more than held their own, while certain breeds of the short, thick type have passed off the stage so far as registration in Canada is concerned. The following table shows the number of pedigrees of each of the several breeds that have been recorded up to 1900, the number of each recorded up to the beginning of 1914 and the number of each recorded since the beginning of the present century:

SECOND PART.

ABSTRACTS

AGRICULTURAL INTELLIGENCE

GENERAL INFORMATION.

AGRICULTURAL EDUCATION

806 – **Courses of Instruction for Teachers in Rural Continuation Schools in Prussia.** — *Zeitschrift für das ländliche Fortbildungsschulwesen in Preussen*, Year 5, Part 9, pp. 397-398. Berlin, June 1914.

Special courses were to be held this year in 19 places in Prussia for the instrction of teachers in rural continuation schools.

ORGANIZATION OF EXPERIMENTAL AND ANALYTICAL WORK

807 – **Recent Experience in Farming on Moors.** — *Communication from* DR. HJ. VON FEILITZEN, *Director of the Experimcnt Station of the Swedish Moor Cultivation Association.*

Among the recent works which deal with the nature of humic substances those of BAUMANN and GULLY, TACKE and SÜCHTING, RINDELL, ODEN, SCHREINER (1), and SHOREY deserve to be mentioned, and on the chemistry of the nitrogen of moor soils the works of JODIDI, SUZUKI and VALMARI.

The formation of limonite and its explanation by AD. MAYER and RINDELL led to a closer discussion of HAGLUND'S so-called fire theory and to the explanation of the origin of sphagnum moors through the destruction of the moor forests by fire (2).

On the growth of peat, recent investigations in Sweden have shown that in a moor 36 inches of peat have been formed since 1540. J. AF ZELLÉN measured in one locality a yearly increase of 1 inch of light sphagnum peat. According to TOLF this increase of peat on the surface of diggings has no practical importance.

Concerning the chemical composition of various kinds of peat the following works may be mentioned: ZAILER and WILK on pure sedge peat; GULLY on species of sphagnum and sphagnum peat; PAUL on the

(1) See No. 343, *B.* April 1913; also No. 311, *B.* April 1914.
(2) See No. 312, *B.* April 1914. (*Ed.*).

calciphobe nature of sphagnum; and MINSSEN on the various kinds of peat.

The writer's own investigations have shown that the moor water in untouched moors contains nearly one part of potash per 100 000.

As regards the microbiological properties of moor soils, KARSTEN at Helsingfors has recently made experiments on the low power of conducting heat of moor soils in a dry and moist state. Interesting also are the minimum temperature readings which have been taken during the last five years at Flahult 4 inches above the surface of the soil on different spots near each other, over sandy soils, fens, and cultivated and uncultivated moors, in the months from May to October. They show what considerable differences of temperature different irradiation of the soil causes in places quite close to each other.

Of great practical importance is the question of the draining of moor land. On the moor at Flahult shallow drainage with ditches 2 feet deep and 66 ft. apart, during five years, gave an average yield of hay 25 per cent. higher than that obtained from land drained by ditches 4 ft. deep. With shallow drainage the water-table stood, during the period of vegetation (May to October), at an average of 22 inches below the surface of the middle of the land between the ditches, while with the deeper drainage it stood at 26 inches. The fluctuations of the water-table were in general greater with shallow than with deep drainage.

In experiments made in concrete basins in the experiment garden, with constant heights of water-table (8, 16, 24, 32 and 44 inches), the grass crop in the first two years on sphagnum moor soil was highest when the water-table stood at 8 and 16 in. and decreased rapidly with the lowering of the water-table. On the fen land the crop was heaviest with the water-table at 16 and 24 inches.

In the second experiment farm at Torestorp, experiments have been in course for the last five years on the effect of varying distances (26, 40, 66 and 80 feet) between drains at equal depths (4 ft.). Hitherto no noticeable difference in the vegetation has been observed. The water-table stood everywhere about 36 inches below the surface. In this direction observations have recently been made also in Norway (Maeresmyren), Bavaria (Bernau) and Esthonia (Thoma).

On the importance of damming up the water in the ditches on moors American farmers in Michigan have collected evidence, and the Bremen Station recommends the practice in moor drains. Count BERG, at Sagnitz (Livonia), on the contrary, does not approve of it and recommends instead the use of heavy rollers to prevent the excessive drying of the surface of moor soil which has been rendered too loose by deep tillage.

The percolation of rainwater through well decomposed fen was found in lysimeter experiments at Jönköping to be 90 per cent. on bare soil in the winter half-year, and from 50 to 60 per cent on soil under vegetation. The corresponding figures were 40 and 10 to 30 per cent during the summer half-year.

For many years past a system of drainage has been practised in Sweden much resembling Butz' wooden pipe drainage (1); this latter system also has been used at Flahult with satisfactory results.

Experiments have been made during five years with lysimeters at Jönköping on the quantities of plant food carried away from moor soils by drainage water ; they have shown that the losses on good fen land are much greater in uncultivated than in cultivated soil, and in arable soil than under meadows. More lime and nitrogen are lost by unmanured than by manured soils. In the case of potash the losses were about the same; only traces of phosphoric acid were found. The losses of potash caused by manuring amounted to from 2.23 lbs. to a maximum of 12.49 lbs. per acre per annum. The losses of lime reached 256 lbs. on arable land and 164 lbs. on meadows. A normal dressing of potash salts (38 per cent.) showed no increase of lime washed out over land without potash ; this agrees with the Bromberg results.

The question of liming moors has been very exhaustively treated by DENSCH (2) at Bremen and by SJOLLEMA and HUDIG (3). Dr. NILSSON-EHLE, of the Swedish Seed-breeding Station at Svalöf, has demonstrated that dry-spot disease (*Scolecotrichum*) (4) attacks the various kinds of oats with different intensity and that greater or less resistance is hereditary; of the varieties tested Improved Roslag and Mesdag were the most resistant, while Tartar Flag and Improved Dala were very susceptible. According to Dr. HEDLUND, *Scolecotrichum* does not attack oats, and probably a saprophytic *Cladosporium* has been mistaken for it. The dry-spot disease, or " Kalimangelkrankheit " (disease due to lack of potash) as Dr. Hedlund calls it, is probably caused by soil bacteria, as the plants are not attacked by it when the soil has been sterilized, for instance with carbon disulphide.

That lime must be finely powdered in order to produce the best effects, has again been shown by recent experiments at Jönköping with powdered lime of several sizes of grain, in the course of which experiments the finest powder (passing through a sieve of less than 0.2 millimetre mesh) gave the heaviest yields (5).

Silicate of lime in Martin's slag proved almost equal to the carbonate.

Among new implements for use on moors (6), the most important are heavy cement rollers (7), motor ploughs, Banke's new Swedish meadow plough, Wassis and Hankmo Finnish harrows, the moor ploughs built by the Norrahammer factory and Faxe's moor shoes for horses.

Concerning manures it has been observed at Flahult that farmyard manure has a very feeble action during the first years of cultivation on

(1) See No. 229, *B.* March 1913 and No. 1324, *B.* Dec. 1913.

(4) See No. 575, *B.* June 1914.
(5) See also No. 17, *B.* Jan. 1914.
(6) See also No. 760, *B.* Aug. 1914.
(7) See No. 1067, *B.* Sept. 1913. (*Ed.*).

moor soils; after some years its effect was decidedly better, but much inferior to that of artificials. On the peat soils of a better class the effect of farmyard manure was more marked. A shallow ploughing in to a depth of two to four inches was better than to a depth of six inches. It was found that for turnips it was better to apply farmyard manure in spring than in autumn. The spreading of road sweepings is recommended by SCHREIBER, and in Ontario, Canada, very good results appear to have been obtained by a cartload of garden earth to the acre. Green manuring with blue lupins gave very good results at Flahult; the residual effect was, however, very slight.

Among the bacterial cultures on the market, Azotogen and Kühn's Nitragin in earth cultures have been beneficial on moor soils; on the contrary liquid Nitragin proved uncertain. Earp-Thomas' Farmogerm (from Bloomfield, N. Y.) had very little effect on yellow lupins. Inoculation earth had a good and certain action.

The question of the effect of Leguminosae on Gramineae in mixed crops has been especially studied by TACKE, HILTNER, KASERER, LIPMAN, LYON, and BIZZELL.

The investigations of BOTTOMLEY on *Myrica Gale* deserve to be mentioned here.

HAGLUND, at the Jönköping Moor Experiment Station, tested the effects of artificials and lime on sphagnum and found that lime destroyed it; basic slag acted like lime but less energetically. Superphosphate kills sphagnum. Kainit was somewhat caustic, but without any special effect, and nitrate of soda also acted weakly. The two latter, however, had an indirect action, as they encouraged growth of algae and lichens and thus hindered the formation of new shoots of sphagnum.

It is generally admitted that sedges dislike manuring, because the manuring of meadows causes them to disappear; this is, however, not the case and the apparent destruction of sedges is only due to their being smothered by the other plants. GÈZE, at Villefranche-de-Rouergue (Aveyron, France), has shown by direct manuring experiments, that sedges growing alone respond readily to phosphoric acid, nitrogen and potash.

At the Jönköping Moor Experiment Station experiments have been made for several years on the crops raised on the moors and on the quantities of plant food removed by them from the various moor soils; two years ago the results were published in a voluminous report. There are some deviations from WOLFF's figures respecting certain plants, but in the main the values agree well with the revised figures given by STUTZER in *Mentzel & von Lengerkes landw. Kalender*. The writer's investigations did not allow him to confirm the high figures found by WAGNER and TACKE for the amount of phosphoric acid contained in hay; the figures found by CHRISTENSEN in Denmark, LENDE NJAS in Norway, and KRÜGER and STUTZER in Germany, agree with those of the writer.

Among the different phosphates Palmaer phosphate proved equal to superphosphate. Basic slag was tested in two series of experiments,

and its total effect, lasting three or four years, turned out clearly superior to that of superphosphate. In the Danish field experiments superphosphate and basic slag proved of equal value on field crops, but on meadows the former was somewhat superior. The after effects of basic slag were better than those of superphosphate. In moist years basic slag acted better than in dry ones. Bone meal behaved almost as well as superphosphate on acid moor soils, but badly on alkaline soils. Tunis phosphates, on newly cultivated moor land at Flahult, in two years of experiment, gave only one half the effect of basic slag. Vivianite proved almost as good as basic slag.

As for potash manures, the effect of phonolite (1) was only half that of Stassfurt salts.

Among recent experiments those with "Elektrokali" (2) and Jungner's carbonate of potash, as well as those on the substitution of potash by soda, and the works of WHEELER, SCHULTZE, WOHLTMANN and SÖDERBAUM on the effects of common salt deserve to be mentioned.

CROPS AND CULTIVATION.

AGRICULTURAL METEOROLOGY

808 – **An Improved CO_2 Psychrometer.** — SHAW, H. B. (Bureau of Plant Industry, U. S. Dep. of Agr.) in *The Plant World*, Vol. XVII, No. 6, pp. 183-185. Baltimore, Md., June 1914.

A psychrometer (*i. e.* an instrument used by the U. S. Weather Bureau for measuring the relative humidity in given localities) is described which is designed for use amongst foliage and differs from other psychrometers in being provided with a protecting device preventing entanglement with the foliage while the thermometers are being whirled.

SOIL PHYSICS, CHEMISTRY AND MICROBIOLOGY

809 – **Distribution of Soil Particles.** — BEDFORD, DUKE OF, and PICKERING, S. U., in *Fourteenth Report of the Woburn Experimental Fruit Farm*. London, 1914.

The distribution of the clay particles in a soil was determined in a series of experiments, carried out during a period of 14 months, in order to estimate the influence of the rainfall on such distribution. From a plot of ground 4 yards square which had received moderate dressings of artificial manures for the last 18 years, samples were drawn once a month in three layers of 6 in. each down to a depth of 18 in. The samples were air-dried, sifted, and dried at 100° C.; then 40 gms. were shaken up with 400 cc. of water for 24 hours; after being allowed to settle, 200 cc. of the solution were syphoned off and its clay content was estimated. The results obtained for the top 6 in. of soil are given below, together with the rainfall for the 20-day period preceding each sampling:

(1) See Prof. LEMMERMANN'S article, in *B.* Oct. 1913, pp. 1486-1489; also No. 253, *B.* March 1913 and No. 500, *B.* June 1914.

(2) See No. 420, *B.* May 1914. (*Ed.*).

Aug.	0.46	18	2.65

The fluctuations in the "relative" clay content of the top layer of soil follow closely those of the rainfall except during the month of February when the land is in an abnormally wet condition owing to the accumulation of the winter rainfall. If the "relative" proportion of clay in the top 6 in. of soil be calculated on the two topmost layers alone, instead of on the whole depth of 18 in., then the figures, though following the rainfall fairly well, do not do so as well as when the proportion of clay in the topmost 6 in. of soil is considered in relation to the three layers; and from this it would appear that the effect of the rain on the clay particles extends below the top 12 in.

The total "absolute" amount of clay in the 18 in. is by no means constant; this would indicate that the alteration in the proportion of the clay in the uppermost layer is not due to differences of distribution, but rather to deflocculation and flocculation caused by the rain ; on the other hand, as the "absolute" amounts of clay in the top layer do not follow the fluctuation of the rainfall as closely as the "relative" amounts, it would seem that though the flocculation and deflocculation are perhaps the most important effects of the rainfall, they are not the sole ones, and that some redistribution of the particles also occurs.

810 – **The Number and Growth of Protozoa in Soil.** — SHERMAN, J. M. (University of Wisconsin), in *Centralblatt für Bakteriologie, etc. II Abt,*. Vol. 41, No. 18/23. pp. 625-630. Jena, July 22, 1914.

Sixteen soils from Wisconsin, Virginia and Tennessee were examined for protozoa by the dilution method, soil extract being used as the growing medium. It appeared from the results that all the soils contained at least

1000 protozoa per gram and that most probably even 10 000 per gram would still be a conservative estimate. Nearly all the organisms found were flagellates, but *Colpoda cucullus* and *C. steinii* occurred in two of the $^1/_{1000}$ dilutions and *Balantiophorus elongatus* in one of them. No amoebae were found.

Sterilized soils were also inoculated with normal soil, proving good culture media even with a somewhat subnormal moisture content. After 15 days flagellates had multiplied in some cases to the extent of 100 000 per gram of sterilized soil ; ciliates on the other hand made no growth.

811 – **Relation of Bacterial Transformations of Soil Nitrogen to Nutrition of Citrus Plants.** — KELLERMAN, K. F., and WRIGHT, R. C. (Bureau of Plant Industry, U. S. Dep. of Agr.) in *Journal of Agricultural Research*, Vol. II, No. 2, pp. 101-113. Washington, D. C., May 1914.

The writers analysed the soils of certain citrus groves suffering from chlorosis in California and carried out greenhouse experiments in Washington, D. C., from which they obtained evidence that the falling off in yield of the citrus groves may be due to the toxic effects of superabundant nitrates.

OPENING UP LAND FOR CULTIVATION

812 – **Improvement of Waste Land in the Netherlands.** — MÜLLER, A., in *Deutsche Landwirtschaftliche Presse*, Year XXXI, No. 57, pp. 701-702. Berlin, July 1914.

1. *Generalities.* — In the Netherlands the improvement of waste lands commenced in the first few decades of last century with the afforestation of heaths by individual landlords ; some of these now form groups of fine closed woods. The growing interest in the improvement of unproductive lands led the parties concerned to the foundation of the Heath Improvement Society in 1888. At first the State limited its action to the encouragement of private undertakings and to the fixation of certain shifting dunes which were a menace to the community. It was only in 1899, after the institution of a special Forest Service, that the State began to purchase large extents of waste land and to put them under cultivation. It dealt chiefly with lands the improvement of which was important for the neighbouring cultivated areas but not suitable for private enterprise. At present the State Forest Service possesses 46400 acres of waste land and 12850 acres of cultivated land against 26 000 and 6600 in the year 1899. Further, the State assists the Communes in their work of improvement of waste lands by granting loans free of interest and by the technical direction of the work ; the Heath Improvement Society also receives yearly State grants for the promotion of drainage schemes and for holding public courses in forestry.

2. *Treatment of heaths.* — *a) For permanent agricultural utilization.* — The first operation generally consists in working with a steam plough to a depth of 6 to 12 inches ; occasionally in uneven soils the spade is used. Then follows manuring, for instance with 6 to 8 cwt. per acre of basic slag and kainit, and yellow lupins and serradella are sown for a year or two. According to position and soil, oats and rye or potatoes and even beets or peas are then grown. If the heath is suitable for meadow or pasture

the ploughing is only 6 or 8 inches deep and is followed by harrowing. After due drainage and levelling of the inequalities of the surface the soil is manured ; moor soils are frequently covered with a layer of sand 2 to 4 inches deep ; grass and clover are then sown, often under oats or rye, but sometimes after potatoes.

b) *For reafforestation.* — The areas suitable for forests are ploughed to a depth of about 16 inches, and where necessary drained by open ditches and manured with artificials and green manure crops (yellow lupins). They are then mostly put under rye for one or two years (sometimes serradella is taken with it) or, on low-lying land, under oats. After this preparation one-year-old pines are planted at distances of 24 to 30 inches each way. If the locality is suitable, oak, elm, alder and other trees are also planted in clumps or as borders.

3. *Fixation of shifting sands.* — While the heaths occupy about a million acres, the sands cover only about 125 000 acres. About seven-tenths of these are maritime dunes. Considering the importance of this area for agriculture, the State has taken possessions of four-tenths of the coast dunes and three-tenths of the inland ones. In the districts of Haarlem and the Hague some large dune areas have been afforested by private owners.

a) *Inland shifting sands.* — After roughly levelling the greatest inequalities of the surface of the sandhills the ground is partially or wholly ploughed to a depth of 12 to 20 inches. Then the soil is covered with cut heath, marram grass, peat or the like, on which a shovelful of sand is thrown at every step. Recently the areas to be afforested have been treated with various fertilizers, as well as with lupins, the straw of which has proved very useful for covering the soil. Two-year-old pines are then planted by means of iron planting-spades provided with a long and heavy blade which ensures the long pine roots reaching to the moist subsoil.

b) *Dunes.* — For fixing the dunes the Dutch use chiefly marram grass (*Ammophila arenaria*) ; plants preferably one or two years old are carefully dug out and planted in clumps at distances of 20 in. × 20 in. (on slopes 12 in. × 12 in.). As soon as the condition of the soil allows it, Austrian, Corsican and mountain pine are planted. In sheltered spots Scots pine is used with success, as well as pitch pine (*Pinus rigida*) and in some moist places oaks and alders. Where conditions are favourable the possibility of agricultural work is not neglected. Thus, for instance, on the island of Texel, where for a long time sheep breeding has been practised on a large scale (about 30 000 lambs are exported every year), the most sheltered dunes have been devoted to grazing purposes.

813 – **A New Way of Utilizing the Energy of Peat Beds.** — ZAILER, V. in *Zeitschrift für Moorkultur und Torfverwertung*, Year XII, Part 3, pp. 89-91. Vienna, 1914.

In order to utilise the quantities of energy latent in peat beds, the construction of large central electric stations has been undertaken. These works burn only dried peat. This is done in two different ways : the peat is either burnt directly in the fire-box of steam boilers and the steam is used to drive turbine dynamos, or it is burnt in gas generators and the gas used

in motors which transform the energy into electricity. Some of these generators obtain sulphate of ammonia as a by-product.

Of late another method has been adopted, to a certain extent combining the advantages of the two systems, and giving a still better utilisation of the energy contained in the fuel. This is the flameless surface combustion of generator gas under steam boilers. The process was invented at the same time in England and in Germany. It consists in leading a mixture of gas and air under low pressure through a certain mass of fuel which melts only at an exceedingly high temperature. In the interior of the mass an incandescent nucleus is formed which irradiates heat without forming flames. In England some boilers fired with this system have worked uninterruptedly for upwards of nine months, using water gas or coke gas. Any other similar gas can be used equally well. Whilst formerly it was considered satisfactory to produce 8 to 9 lbs. of steam from 1 sq. ft. of heating surface, with this method as much as 21.5 lbs. of steam can be produced from the same surface.

From the point of view of the exploitation of moors it is of great importance that no other fuel need be brought to heat the boilers.

The writer is of opinion that if this invention fulfils its promises a great step will have been made towards the solution of the problem of utilizing the energy latent in peat beds.

MANURES AND MANURING

814 – **Influence of Lime on Soil Bacteria**. — MILLER, F., in *Zeitschrift für Gärungsphysiolo ie*, Vol. IV, Part 3, pp. 194-206. Berlin, April 1914.

The writer contributes to the discussion of the question already examined in various quarters as to the influence of the compounds of lime upon the multiplication and the vital activity of soil bacteria. In the experiments the rather heavy soil of the experiment field of the Agricultural and Bacteriological Institute of the University of Göttingen was used. The soil was taken from the field when it was damp ; it was then sifted and thoroughly mixed. The additions were calculated on the dry earth. The quicklime was added in a finely pulverized state and well mixed with the soil. It contained only 4.16 per cent. of CO_2. The soil under examination contained 2.02 per cent. of CaO and 1.19 per cent. of CO_2. An addition of 5 per cent. CaO made the soil noticeably warmer and additions of 1 and 5 per cent. increased the loss of water from the soil. The experiments led to the following principal results :

1. Additions of 0.3, 0.5 and 1 per cent. CaO caused at first a striking decrease in the numbers of bacteria and later an immense increase. The greater the addition of lime the longer the duration of the decrease, but also all the more intense the increase when it finally set in.

2. The addition of 5 per cent. CaO hindered completely the growth of bacteria.

3. Quicklime in doses of more than 0.05 per cent. on loam rich in lime caused a reduction of nitrification. Doses of 0.01-0.06 per cent. in Bunter sandstone poor in lime have a stimulating effect in this direction.

4. Additions of quicklime up to 0.1 per cent. on sandy soils rich or

poor in lime diminished the formation of nitrate from ammonium sulphate, and doses of 0.5 per cent. CaO stopped this process altogether.

815 – **Experiments on the Value of Nitrate of Guanidin and Nitrate of Urea in comparison with Nitrate of Soda and Nitrate of Ammonia.** — WAGNER, P., in *Mitteilungen der Deutschen Landwirtschafts-Gesellschaft*, Year XXIX, Part 29, pp. 417-421. Berlin, July 18, 1914.

At the request of the German Agricultural Society's Committee on Manures the writer has tested the manurial value of nitrate of guanidin and of nitrate of urea, two new products derived from calcium cyanamide, which it is hoped can be placed upon the market at suitable prices. Samples of the two salts, the former containing 40.20 per cent. and the latter 30.54 per cent. of nitrogen, were obtained by the writer from the " Oesterreichischer Verein für chemische und metallurgische Produktion" of Aussig on the Elbe. The experiments were made on oats and French ryegrass.

1. *Experiments on oats.* — Fifty-two pots were used, each of them containing 46 lbs. of sandy soil of the following composition :

	per cent		per cent
Silt and clay	20.6	Carbonate of lime	0.02
Fine sand	19.4	Phosphoric acid	0.148
Coarse sand	50.1	Potash	0.076
Gravel	9.9	Nitrogen	0.079

TABLE I

No.	Manure	Dates of manuring			Total grams of nitrogen
		April 17, grams of nitrogen mixed with soil on sowing	May 21, grams of nitrogen dissolved in 1 litre of water and poured on soil	May 28, grams of nitrogen dissolved in 1 litre of water and poured on soil	
1	—	—	—	—	—
2	Nitrate of Guanidin	1.0	—	—	1.0
3		1.0	—	—	1.0
4		1.0	—	—	1.0
5	Nitrate of Urea	1.0	—	—	1.0
6		1.0	0.5	—	1.5
7		1.0	0.5	0.5	2.0
8	Nitrate of Soda	1.0	—	—	1.0
9		1.0	0.5	—	1.5
10		1.0	0.5	0.5	2.0
11	Nitrate of Ammonia	1.0	—	—	1.0
12		1.0	0.5	—	1.5
13		1.0	0.5	0.5	2.0

The four manures were given in doses of 1.0, 1.5 and 2.0 grams of nitrogen per pot. Each pot also received 5 grams of phosphoric acid under the form of basic slag, and 2 grams of potash as silicate of potash.

Table I gives the scheme of the experiment; Table II shows the results, expressed as average increase in dry matter over the average of the control pots, which was 20.2 gms. of straw and 6.2 gms. of grain.

TABLE II.

Nitrogen given under the form of:	Increase in yield of straw due to manuring with			Increase in yield of grain due to manuring with		
	1 gr N	1.5 gr N	2.0 gr N	1 gr N	1.5 gr N	2.0 gr N
Nitrate of soda . . .	86.9	104.1	113.4	46.3	70.8	76.7
» of ammonia .	85.7	101.9	100.0	42.1	64.7	71.8
» of urea . . .	62.2	81.8	97.1	37.8	54.8	67.2
» of guanidin. .	33.6	—	—	26.8	—	—

Taking the yields obtained with nitrate of soda as 100, the following relative values are found :

	grain	straw
Nitrate of guanidin.	39	58
» urea.	72	82
» ammonia	99	91
» soda.	100	100

2. *Experiments with French ryegrass.* — For these experiments also 52 pots were used. The soil was the same as that for the experiments on oats. As basal manure 5 gms. of phosphoric acid as basic slag and 2 gms. of potash as silicate were mixed with the soil. To these amounts some more potash was added for the second cut and some phosphoric acid and potash for the third cut, so as to keep pace with the development of the plants. Three cuts were made. The manures under comparison were given as in the preceding experiment, but only to the two first cuts, the third getting no nitrogen.

The injurious effect of nitrate of guanidin observed in the experiment with oats was not noticeable in these tests. The sum of the average increases given by the three series (2,3 and 4 gms.), expressed as dry matter in the three cuts, was as follows (control 18.3 gms.) ;

	gms
Nitrate of guanidin.	312.0
» urea.	350.9
» soda.	358.8
» ammonia.	365.1

If the increase obtained with nitrate of soda be taken as 100, the following relative values are obtained :

Nitrate of guanidin.	87
» urea.	98
» soda	100
» ammonia	102

The writer concludes from these experiments that nitrate of urea can be recommended to farmers as a useful manure, provided the nitrogen in it is sold at about 20 per cent. cheaper than the nitrogen in nitrate of soda. It does not seem advisable to produce nitrate of guanidin as a commercial nitrogenous manure, as its effect was inferior to that of the other three nitrates and in the experiments with oats it was observed that this nitrogen compound was not favourable to plant growth.

816 – **The Relation of Atmospheric Evaporating Power to Soil Moisture Content at Permanent Wilting in Plants.** — SHIVE, J. W, and LIVINGSTONE, B. E. (Botanical contribution from the John Hopkins University, No 37) in *The Plant World*, Vol. XVII, No. 4, pp. 81-121. Baltimore, Md., April 1914.

In their investigations on the point of permanent wilting in plants, BRIGGS and SHANTZ (1) showed that the moisture content of soils where this point had been reached was the same when the experiments were carried out in a damp chamber or in an unshaded green-house. CALDWELL, on the other hand, only obtained moisture residues similar to those calculated from the Briggs and Shantz formula when he grew his plants in a moist chamber. The present investigations were undertaken to determine the effect of the evaporative power of the atmosphere on the soil moisture content at the permanent wilting point. To this end plants were tested under five different conditions of atmospheric humidity : *a*) in the open air, exposure I ; *b*) in a cheese-cloth shelter, exposure II ; *c*) in a lath shelter made of laths 3 cm. wide with 3 cm. spaces between the laths, exposure III ; *d*) in a cheese-cloth shelter placed inside the lath shelter, exposure IV ; and *e*) in a glass chamber protected from direct sunlight and kept saturated by wet cloths, exposure V. The evaporation rate in each exposure was determined by means of a porous cup atmometer. The experiments were carried out at the Desert Laboratory of the Carnegie Institute, at Tucson, Arizona, in July-September 1913. Maize, *Phaseolus vulgaris* and *Capsicum annuum* were used as test plants ; the soils employed consisted of a mixture 25 or of 50 per cent. of a local clay loam with a coarse river sand, or of the clay loam used alone.

The results are summarised in the table on the next page.

These results confirm those of Caldwell in that the higher the rate of evaporation, the higher the water content of the soil at the wilting point. Where the soil employed consisted of a mixture of sand and loam the values actually obtained for soil moisture were all higher than those calculated from the Briggs and Shantz formula, but where the pure loam

(1) See No. 20, *B.* Jan. 1914. (*Ed.*).

Test Plant	Exposure	Evaporation from atmometer cc. p. hour.	Soil used	Water content of soil at the permanent wilting point

	I	3.9		13.13	—	1.05

was employed the ratio actual: calculated started well below unity and only rose with increasing evaporation to a maximum of 1.05.

The writers discuss the interpretation of their results by means of a formula.

817 – **The Distribution of Stomata in the Seedlings of Some Gramineae.** — ZAEPFEL, EDGAR, in *Comptes Rendus hebdomadaires des Séances de l'Académie des Sciences*, Vol. 159, No. 2, pp. 205-207. Paris, July 13, 1914.

The writer has observed that in oats (*Avena sativa*) and in wheat (*Triticum vulgare*) the stomata are most numerous at the apex of the cotyledon, less numerous in the subapical belt and absent at the base of the cotyledon, while in *Panicum altissimum* and *Paspalum stoloniferum* stomata exist throughout the length of the cotyledon and are not more numerous towards the apex.

Summarizing, in the Graminee examined, stomata are absent in the hypocotylous belt, which is incapable of heliotropic perception. In the cotyledon of oats and wheat stomata abound at the apex, where the heliotropic sensibility is great. Stomata exist also, though in much smaller numbers, in the subapical belt, which possesses only a weak capacity of perception. In the cotyledon of *Panicum* and *Paspalum* the stomata exist throughout the whole length, and the cotyledon is wholly sensible to light. The conclusion may therefore be drawn that in the Gramineae examined the abundance of stomata in young plants corresponds to their degree of heliotropic sensibility.

818 – **The Resistance of Wheats to Winter** (1). — HITIER, H., in *Journal d'Agriculture pratique*, Year 78, Vol. II, No. 29, pp. 82-84. Paris, July 16, 1914.

Last winter M. Schribaux made observations on the resistance to cold of various wheats at the Paris Seed Trial Station and in the field devoted to collections belonging to the Agricultural Institute. The following points were noted.

The varieties from Algeria and the extreme south of France and the hard wheats (Touzelle de Provence and Richelle of Naples) were completely destroyed. Then follow in increasing order of resistance: wheat from the Gironde, Rieti, Belótourka, Polish wheat, Black Russian Petanielle, Japhet, Bordeaux, Autumn Saumur, Saint Laud, Noé, Gros-Bleu and Pithivier (derived from Bordeaux). The hybrids Rieti × Japhet obtained by Schribaux proved decidedly less sensitive to the cold than their parents. Among the English wheats (which stood the winter well) Hunter's was the most resistant.

Among the riveits, Nonette de Lausanne showed great resistance, but of all the wheats examined, Alsatian wheat and the hybrids obtained from it by M. Schribaux (Red Alsatian × Bordeaux and Red Alsatian × Dekat, varieties which are now well fixed) are those that stood the cold best.

According to observations in several parts of France, M. Hitier believes that the damage done to the wheat by frost depends more upon the nature and physical condition of the soil than upon the varieties of wheat used. In heavy soils which had been beaten down by rain all the varieties suffered, while they resisted in permeable soils and in those that had not been compressed.

The greater susceptibility to damage by frost cannot always be attri-

(1) See also No. 620, *B.* July 1914. (*Ed.*).

buted to late sowing, because in several cases the last wheats sown resisted much better than those sown first. On one farm in the department of Aisne and on another in Seine-et-Oise, it was observed that wheat overtaken by frost before it had completely sprouted out of the soil, grew very vigorously as soon as the thaw set in and did not suffer any further injury from the winter. Similar observations were made by M. Schribaux in 1891 and by others also.

It seems that there is a critical period in which wheat is specially susceptible; it is when the radicle is ceasing activity and the adventitious roots have not yet had time to develop; the result is a want of moisture in the leaves.

It may be said, in conclusion, that a whole series of causes exists, which we do not yet know completely and which render a wheat resistant or not to cold.

819 – **Report on the Field Trials with Barleys organized in 1913 by the Barley-growing Station of the Brewers' Institute of Berlin.** — Von Eckenbrecher, C., in *Deutsche Landwirtschaftliche Presse*, Year XXXXI, No. 50, pp. 625-628. Berlin, June 24, 1914.

The comparative trials carried out in 1913 by the Barley-growing Station of the "Versuchs- und Lehranstalt für Brauerei" were intended to test the cultural value of various barleys for brewing purposes. They were made on 14 farms in North Germany, with the six following varieties:

1. Bethge's No. 2.
2. Mahndorf Improved Hanna (Strain C 8).
3. Heil's Improved Franconia.
4. Zeiner's Improved Franconia.
5. Ackermann's Improved Lower Bavarian "Danubia".
6. Ackermann's Improved Lower Bavarian "Bavaria".

Each variety was grown on at least two plots separated by plots under other varieties. No special manure was prescribed; in general, however, abundant quantities of potash and phosphoric acid were used with more moderate dressings of nitrogen. The seeds used were obtained direct from the breeders.

The examination of the product was restricted to the following points: protein content of the dry matter, thousand-grain weight, and grading of the grain. The judges adopted the scoring usually followed in the Berlin barley shows: protein content, weight and uniformity, ranging from 1 point (bad) to 18 (superfine). The nature of the husk and the colour of the grain were also judged, 9 points being the maximum for the former and 5 for the latter.

The results of nine complete trials may be summarized as follows:

The highest average yield of grain was given by Zeiner's Improved Franconia, with 3130 lbs. per acre, but it was rather subject to smut and liable to lodge. It was followed by Ackermann's Danubia (very resistant to smut, but liable to lodge) with 3105 lbs. per acre, and by Bethge's No. 2 (little subject to smut but a little inclined to lodge) with 3095 lbs. per acre. The fourth place was taken by Heil's Improved Franconia with 3040 lbs. per

acre ; this suffered much from smut but stood up well. Ackermann's Bavaria, with 3030 lbs. per acre, possessed great resistance to smut and did not lodge. Last of all was Mahndorf Hanna, which yielded 2945 lbs. per acre ; it was fairly resistant to smut but liable to be badly laid.

The points awarded to the above varieties for brewing quality were as follows :

Zeiner's Improved Franconia	60.1
Mahndorf Hanna	58.9
Heil's Improved Franconia	58.4
Ackermann's Bavaria	57.3
Ackermann's Danubia	54.4
Bethge's No. 2	54.3

820 – **Field Trials of Vegetables: Four Years' Trials of Green Peas, 1909 to 1912.** — SCHULTZE, W. — *Arbeiten der Deutschen Landwirtschafts-Gesellschaft*, Part 253, 69 pp. Berlin, 1914.

The four years' field trials of green peas (1909-12), carried out on several experiment fields in the most important vegetable-growing districts in Germany, were intended to test the respective merits of the various kinds of peas as raw material for the canning industry, especially from the farmer's point of view. Special importance was attached to the time of ripening, to its duration, and to the stature of the plants, as dwarf varieties that do not require staking are to be preferred for the smaller amount of labour and material they require. Consequently early-maturing dwarf varieties were tried side by side with late-maturing tall ones. The preparation of the soil, sowing and cultivation were in every case carried out according to local practice.

Results. — The yields of green peas are subject to much greater variations than those of cereals or hoed crops. These variations are due partly to differences in soil and weather conditions and partly to the varieties of peas grown. In the eleven varieties tried there were striking differences in stature, time of ripening and quality of the crop, so that in certain cases it was difficult to decide which to prefer, as frequently a drawback in one point was compensated for by an advantage in another. Some varieties, however, possess a decided superiority, as may be seen from the following :

1. *Monopol*: plant of low growth (does not require staking), early ripening ; yield barely medium; ratio of the weight of the seeds to that of the hulls good; size of the peas good (the peas are sorted by two sieves, one of 7 mm. and the other of 8 ½ mm. mesh; the larger peas are not esteemed for canning purposes).

2. *Stanley* : a marrowfat pea of low growth, very late ; yield and ratio of peas to hulls low ; small peas too numerous.

3. *Express* : medium growth, very early, medium to good yield; satisfactory ratio of peas to hulls; size of peas satisfactory.

4. *Ueberreich* : medium to tall growth, early, low yield; medium ratio of peas to hulls; size of peas unsatisfactory.

5. *Canning* : marrowfat pea, medium growth, late, low yield; good ratio of peas to hulls; small peas too numerous.

6. *Buchsbaum-Schnabel*: dwarf, very late, good yield, medium to good ratio, very good size.

7. *William Hurst;* marrowfat pea, low growth, early, low yield, good ratio, unsatisfactory size.

8. *Moringia White* (*Teutonia*) : marrowfat pea, low growth, very late, good yield, medium to good ratio, size poor ; very good for drying.

9. *Moringia Green* : marrowfat, medium growth, late, medium yield, good ratio, poor size.

10. *Grünbleibende Folger*: tall, mid-season, good ratio, average size.

11. *Improved Schnabel*; tall, mid-season; yield, ratio, and size all very good.

From the above it is evident that there are dwarf varieties that yield well and possess a good ratio and well formed peas. In general the early varieties have lower yields than the mid-season and late ones, but they are less exacting as to soil and moisture. Owing to their shorter life the moisture they require when sown early is generally provided by the winter rainfall, which is not the case with later varieties, the yield of which is often endangered by dry weather, especially on light soils. The chief aims of practical plant breeding are thus seen to lie in the direction of combining early maturity with satisfactory yield.

The flavour of the peas is less dependent upon the variety grown than upon the weather and perhaps the soil and its state of cultivation.

FORAGE CROPS. MEADOWS AND PASTURES

821 – **Physiological Correlations and Climatic Reactions in Alfalfa Breeding.** — FREEMAN, G. F. (Agricultural Experiment Station, Phoenix, Arizona) in *The American Naturalist*, Vol. XLVIII, No. 570, pp. 353-368. Lancaster, Pa., June 1914.

During the season of 1910, 44 varieties of alfalfa were grown at the Arizona Experiment Station Farm; they were irrigated at the rate of over 6 in. of water for each cutting, and 6 cuttings were obtained during the season ; these were studied with regard to yield and character of the hay and other points.

The correlation between the yield obtained at the first and subsequent cuttings takes the form of a curve beginning and ending high with a sag in the middle, which indicates the presence of some disturbing factor specially noticeable at the fourth and fifth cuttings, and which appears to be the high temperature together with a slight deficiency of water. The presence of this factor is again evident in the disturbance of the normal correlation between the yield and the stand (number of plants on a unit area) at the fourth and fifth cuttings.

The 44 varieties are classified according to their morphological characters and geographical origin into the following groups : Mediterranean, Peruvian, European, American and Turkestan. The reaction of the different groups to the climatic conditions of Arizona is shown by plotting the differences between the average yield of each group and the total average yield at each cutting. The curves thus obtained show that there is a marked similarity between the European and Mediterranean alfalfas, though the better stand of the European varieties makes thes yield always better than the yield of the Mediterranean ones ; European varieties yield

their largest relative crops at the fourth cut and then go off rapidly. The curves of the American and Turkestan groups are again much alike, the Turkestan being slightly above the American strains ; the yields of both groups decrease earlier than the European varieties. The Peruvian group on the other hand are by far the best croppers at the end of the season.

Other correlations show how the nitrogen content of the hay is dependent on the high proportion of leaves in the hay and on the composition of the leaves, but that the stand of the plant has no effect on the proportion of leaves in the hay, though this is always low when the plants are tall or when the total yield of hay is high. Negative correlation was also shown to exist between the height of plants and their stooling capacity (average number of stems per acre).

822 – **The Value of Turkestan Lucerne.** — Bohutinsky, G., in *Monatsheft für Landwirtschaft*, Year VII, Part 3-4, pp. 73-81. Vienna and Leipzig, 1914.

Owing to the increasing importation of Turkestan lucerne seed into Croatia, comparative tests were made in the experiment field of the Royal Agricultural College at Krizevci between this seed and the Hungarian, which is the most important in Croatia. The soil is a heavy loam, containing from 0.4 to 0.9 per cent. of lime ; owing to its tenacity and capacity for water and to the abundant rainfall it is not the most suitable for growing lucerne. Nevertheless lucerne persists for five or six years, yielding from three to five cuts per year on land subjected to garden cultivation during the few preceding years, as was the case with the area on which the experiment was conducted.

Each variety of seed was examined as to its germinating capacity and then sown at the rate of 45 lbs. per acre on two plots each measuring 459 sq. yds. As a cover crop a thin sowing of four-rowed barley was made. The barley was sown first ; then the land was thoroughly harrowed and on April 8,1909, the lucerne was sown. It came up well on the 14th. The growth of both kinds was normal and when the barley was harvested on July 18 they did not differ from each other in appearance. Only later, on both plots, the Hungarian lucerne grew more rapidly and intensely and already in the first year yielded a considerably heavier crop than the other variety.

The experiment was continued during the three following years. Owing to the slower growth of the Turkestan lucerne the plots under this variety showed the very first year many more weeds than the other ones. The two varieties passed the winters 1909-10 and 1910-11 equally well, but during the winter 1911-12 the Turkestan lucerne, which was already very thin towards the end of 1911, fell off further. In the spring of 1913 it was so thin that the plants could have been counted. On the other hand the Hungarian lucerne presented a completely closed surface.

In 1910 the first cut was made on both varieties at the same time, the succeeding two cuts when each variety was in bloom. The yield was about equal, especially because the weeds also contributed to increase the bulk of the Turkestan plots, and also because the first cut was somewhat

too late for the Hungarian variety. In 1911 the cuts were made when this lucerne began to bloom; the result was that it gave five cuts with a considerably heavier yield than the Turkestan, which allowed of only four cuts. In 1912 both varieties were cut four times. The first cut of Turkestan, owing to the grass and weeds it contained, was more abundant than the Hungarian. In the other three cuts only the lucerne plants were weighed; in the second cut the grasses and weeds made nearly half. On the whole the yield of the Hungarian lucerne during the four years exceeded that of the Turkestan by 53 cwt. per acre, notwithstanding the fact that in the latter grasses and weeds were included except for the last three cuts of 1912.

The chief result of the experiment was the demonstration of the much slower aftergrowth of the Asiatic variety. The writer does not draw any conclusion regarding its shorter duration, as its slower growth favours the development of other grasses and this fact alone may lead to the earlier disappearance of the lucerne. Its slowness of growth is alone enough to condemn it as unsuitable for leys.

In order to prevent the trade in this variety, the writer proposes that the seller should be always obliged to declare the origin of certain inferior varieties and that the seed control stations should no longer seal the sacks containing it : the Hungarian stations have since 1909 stopped sealing the packages of this variety and have succeeded in the object aimed at.

SUGAR CROPS

823 – **Connection between Available Space, Weight and Sugar Content of Beets and Mangolds.** — MUNERATI, O., MEZZADROLI, T., and ZAPPAROLI, F. V., in *Bollettino dell'Associazione italiana delle Industrie dello Zucchero e dell'Alcool*, Year III, No. 1, pp. 6-12. Bologna, April 1914.

In the experiments conducted during 1912 and 1913 three groups were formed : one consisted exclusively of sugar beets, the second of mangolds and the third of a mixture of the two. They were sown in a field and in boxes 6 ft. 6 in. square by 3 ft. 3 in. deep containing different kinds of soil. The seeds were all of the same kind, and were sown on the same day. The results are summarised as follows :

1. Between the available space for each plant and the weight of individual beets there is no constant connection. While usually beets with plenty of available space are larger, yet very fine beets are also found where the plants are close together, and the reverse also is often the case.

2. The weight which some beets attain depends markedly upon the soil and, in equal soils, upon the season.

3. Exceptionally large beets occur much more seldom when they have much available space upon poor soil than upon a rich one.

The above observations are equally true for beets, mangolds, and semi-sugar beets.

4. Mangolds growing near beets do not affect the development of the latter.

5. Even in the most uniform soil imaginable (such as that in the boxes) and with the same treatment, the same variations and differences occur.

6. The differences between individual plants growing in the same

conditions of soil appear also in the shape of the roots and behaviour of the tap-root.

7. Even in sugar content noticeable differences are observed in beets growing in the same soil. Not only does the percentage of sugar vary according to the weight and form of the roots, but beets of the same weight and form and growing in the same soil during the same period may present very remarkable differences in the percentage of sugar they contain.

824 – **Coffee Cultivation in Uganda.** — SMALL, W. (Department of Agriculture, Uganda) in *Bulletin of the Imperial Institute*, Vol. XII, No. 2, pp. 242-250. London, April-June 1914.

STIMULANT, AROMATIC, NARCOTIC AND MEDICINAL CROPS.

Coffee is the staple crop of European planters in Uganda ; exports have risen from about 10 tons in 1908 to 167 tons in 1912-1913, and are still rising as the estates gradually come into bearing ; the exports for the 9 months ending December 31, 1913, were double those for the whole preceding year. There were 4 568 acres under coffee and 2 659 acres under rubber and coffee in March 1913.

The indigenous coffee plant is *Coffea robusta*, but this is only cultivated by the natives and consumed locally ; Europeans plant the so-called Nyasaland and Bourbon varieties, said to have been imported from Jamaica and Aden respectively and both derived from *C. arabica*. Little care has been taken so far with seed selection, but both these varieties thrive well and yield heavy crops the fourth year. The outbreak of coffee leaf disease at the end of 1912 and the epidemic in 1913 led planters to give some attention to other forms of coffee, and experiments are now being carried out with *C. liberica*, *C. stenophylla* and *C. robusta*. With regard to climate, soil and altitude, Uganda is eminently adapted to the production of coffee.

The question of permanent shade in coffee plantations is still in the experimental stage ; results obtained up to the present have not been favourable to permanent shading, but the matter has not yet been given a sufficiently extensive trial. The silky oak (*Grevillea robusta* A. Cunn.) is being tested for this purpose and various species of Leguminous trees, also para rubber trees which have the advantage of being profitable and the disadvantage of being subject to a root disease which also attacks coffee. The question of cover crops is also being investigated.

The strong, steady winds which occur periodically in certain parts of the country have to be guarded against, and high or low wind belts can be made with various trees, bananas being a favourite subject as they provide food for the native population at the same time.

Hemileia disease is endemic in Uganda and its apperance in the form of an epidemic in 1913 may be attributed to the fact that it was suddenly provided with a new host plant ; despite the prevalence of this disease, the outlook is favourable, for the indications are that its virulence will be less in the future than in the past ; the fungus, being endemic in Uganda, cannot be expected to work the havoc that it has wrought in other countries into which it was introduced. Planters are recognising that much depends on their efforts to eradicate it, and the Department of Agriculture is alive

to the situation. In dealing with white ants (termites), exterminators have been used with success. The ravages of these pests are unequal, and in some parts they have caused little or no damage to growing plants.

825 – **Production of Vanilla in the French Colonies.** — *Ministère des Colonies, Bulletin de l'Office Colonial*, Year 7, No. 77, pp. 209-249. Melun, May 1914.

Martinique. — Vanilla was introduced into this colony a long time ago (about 1697), but its cultivation has not spread much and it seems at present to remain stationary. During the four years from 1908 to 1911 the greatest exportation took place in 1909 (4 590 lbs., worth about £1520), the least in 1911 (2536 lbs., worth about £955).

Guadeloupe. — *Vanilla planifolia* was introduced in 1701 ; artificial pollination was begun in 1839, and a few years later the exportation of vanilla began ; in 1911 it amounted to 39 267 lbs., of the value of £13 352. The greatest quantity was exported in 1908 : 68 242 lbs., worth £10 871. Besides Mexican vanilla (*V. planifolia*), the native vanilla (*V. pompona*) is also grown to some extent.

Guiana. — *Vanilla planifolia* was introduced about the year 1870 by the Administration of the penal settlement, but it dit not gain a footing and its cultivation is now abandoned.

Gaboon. — The cultivation of *V. planifolia* has developed gradually during the last fifteen years. The vanilla exported in 1911 was 891 lbs., worth about £1102. Vanilla has often been found wild in both the French and Belgian Congo.

Mayotte and dependencies. — Vanilla has been cultivated in the Comoro Islands since 1875. At present it is the principal crop of the archipelago ; in 1909 the crop amounted to 91 525 lbs. The greatest quantity is produced by the island of Anjouan (1 200 000 plants) ; the quantity harvested in 1908 was 59 342 lbs., worth £32 031 ; the island of Mohéli gives the best quality. Mayotte possesses about half a million plants.

Madagascar and neighbouring islands (1). — Vanilla is not native to the island, but it is now widely spread, especially along the east coast. The neighbourhood of Tamatave seems to be too moist for *V. planifolia*, but might perhaps be suitable for other species. In 1891 there were already at and round Vatomandry about 181 000 plants, and during the last twenty years this crop has attained real importance in the island, especially in the provinces of Vohemar and Antananarivo, in the districts between Andevoranto and Mananyari. In Madagascar it does not encounter any serious natural obstacles, but the market is limited and the island is near other competing centres of production, such as Réunion and the Comoro Islands, the plantations of which are in full bearing and producing a vanilla which enjoys great repute. The exports began to be important in 1896 ; in 1911 they reached 115 589 lbs., worth £87 452. The vanilla of Nossi-Bé is especially renowned, but, like all Madagascar vanillas, is somewhat lacking in perfume.

Réunion. — Vanilla has been grown in this island for about a century,

(1) See also No. 635, *B.* July 1914. (*Ed.*)

and it has also been exported for a long time, but it was only after 1862 that exportation became considerable. The so-called "vanillon" (the exportation of which began in 1884) is not *V. pompona* but the pods of *V. planifolia* less than 5 ½ inches in length. The cultivation of vanilla is somewhat decreasing in Réunion, but the island still occupies one of the foremost positions among the countries producing this commodity. Almost the whole of the crop is exported. The graph of the exports from 1896 to 1911 presents two maxima, in 1898 and in 1902, respectively 442 046 lbs., worth £273 057, and 439 526 lbs., worth £107 196 ; in 1911 it was 146 610 lbs., worth £73 606.

Bourbon. — Vanilla is grown almost everywhere up to 100 ft. above sea-level ; it thrives better, however, in the windward part of the island than in the leeward. Bourbon vanilla ranks in the trade as a vanilla having a strong perfume, while in Mexican vanilla the perfume is delicate and sweet.

New Caledonia. — It appears that vanilla was introduced about 1861 and that only parts of the island are suitable to its cultivation. Experiments carried out on medium soils in the neighbourhood of Nouméa gave good results, but then the introduction of coffee raised more interest and vanilla was abandoned. In 1901 234 lbs., worth £127, were exported, but in 1911 only 2 lbs.

Tahiti. — *V. aromatica* was introduced in 1848 and is now widely spread. It is grown chiefly by the natives ; the pods are picked too soon and their preparation leaves a good deal to be desired ; the result is that the produce is sold at a low price, chiefly to Germany and the United States. In 1902, 318 525 lbs. were exported, representing a value of £47 493 ; in 1903, 289 761 lbs,, worth £23 461. After 1904 the exports from Tahiti are included in those from Oceania, which comprises Tahiti and Moorea. In 1911 it amounted to 467 567 lbs., worth £95 944.

French establishments in India. — At Pondicherry vanilla was introduced into the botanic gardens of the colony about 1879. The production began to be regular after 1888 ; it reached a maximum in 1901, with 280 lbs., worth £175. The soil and climate of the French establishments in India are not suitable to this crop, and the prices realized are not sufficiently remunerative.

Indo-China. — Vanilla was introduced about 1865 to the botanic gardens of Saïgon, but it has not gained a footing in the country.

The exportation of vanilla from all the French colonies amounted in 1911 to 948 988 lbs., worth £389 832. The French colonies produce about two-thirds of the vanilla produced in the whole world. Its consumption in France between 1907 and 1912 was about 132 300 lbs. per annum.

826 – **Nicotine in the By-products of the Cultivation of Tobacco** (1). — CHUARD, E., and MELLET, R., in *Compte-rendus hebdomadaires des Séances de l'Académie des Sciences*, Vol. 159, No. 2, pp. 208-209. Paris, July 13, 1914.

Through the investigations carried out by the writers, in 1911, into the variation of the proportion of nicotine in the several organs of the

(1) See No. 1424, *B.* Oct. 1912. (*Ed.*).

tobacco plant during the course of development, it was ascertained that the offal of the crop as it is raised in Switzerland contains considerable quantities of the alkaloid. This waste consists of tips and axillary shoots before the leaves are gathered ; stems, roots and shoots after the leaves are gathered. This waste, when used green, in order to avoid the loss of nicotine due to esiccation, is an important raw material for the preparation of the titrated solutions used as insecticides.

Experiments were undertaken in 1913 with a view to ascertaining the possibility of increasing the yield of nicotine in these waste products by suitably modifying the methods of cultivation of the plants and their treatment after the leaves had been gathered, without damaging the quality and the quantity of the chief product ; the following methods were tried : 1) allowing the axillary shoots to grow instead of removing them as they appeared ; 2) at harvest time gathering only the largest leaves, leaving in the ground all the stems provided with the recently formed shoots ; 3) treating with nitrate of soda the plants thus partially deprived of their leaves.

From the analysis of the plants thus treated the writers draw the following conclusions :

1. The plants not deprived of their shoots are on the whole less abundant producers of the alkaloid (1.305 gm. nicotine per untouched plant against 1.891 gm. in the others), and this independently of the serious harm done, by not removing the shoots, to the quantity and quality of the main crop.

2. The yield of nicotine of the plants left in the field after the harvest with the small shoots recently formed in the axils of the large leaves is much superior (0.942 gm. nicotine per whole plant against 0.432 gm.) to that of the plants completely stripped.

3. Treating with nitrate of soda does not regularly modify the relative content of the different organs of the plant, but increases the absolute production of alkaloid per individual by favouring its growth (with nitrate 0.739 gm. nicotine per completely stripped plant and 1.288 gm. per partially stripped one). Thus nitrate is not a direct producer of nicotine (A. Mayer).

The writers conclude that it would not be advantageous, even from the point of view of the production of nicotine, to allow the growth of the axillary shoots which are formed before picking, instead of removing them as they appear, but that the returns from the utilizable by-products (according to the method of cultivation adopted in Switzerland) may be considerably increased by giving nitrate of soda to the plants that are left standing after the harvest, during which they are deprived only of their large leaves.

827 – **Experiments in Growing Medicinal Plants at Korneuburg in 1913** (1). — (Communication of the National Committee for the Encouragement of the Cultivation of Medicinal Plants in Austria, No. 17). SENFT, E. in *Zeitschrift für das Landwirtschaftliche Versuchswesen in Oesterreich*, Year XVII, Part 3-4, pp. 129-182. Vienna, March-April 1914.

After some general observations on the cultivation of medicinal plants in Austria and on their disposal, the writer enumerates the chief pests which attacked them in 1913. Thus it is remarkable that white grubs attacked almost all the poisonous and aromatic plants, such as *Atropa, Hyoscyamus, Datura, Angelica, Valeriana, Anacyclus, Pyrethrum* and others, and respected only *Conium* and *Levisticum*. He then gives detailed information on the sowing, manuring (in some cases), development, pests, harvest and yield of the following plants : marsh mallow (*Althaea officinalis*), hollyhock (*Althaea rosea*), pyrethrum (*Anacyclus officinarum* and *Anacyclus pyrethrum*), annual and biennial angelica (*Angelica archangelica*), *Anthemis nobilis*, wormwood (*Artemisia Absynthium*), estragon (*A. Dracunculus*), deadly nightshade (*Atropa Belladonna*), blessed thistle (*Cnicus benedictus*), Caucasian pyrethrum (*Chrysanthemum* [*Pyrethrum*] *carneum*), Dalmatian pyrethrum (*Chrysanthemum cinerariaefolium*), scurvy-grass (*Cochlearia officinalis*), foxglove (*Digitalis purpurea*), yellow gentian (*Gentiana lutea*), *Grindelia robusta, Gypsophila paniculata, Hydrastis canadensis*, henbane (*Hyoscyamus niger*), hyssop (*Hyssopus vulgaris*), elecampane (*Inula Helenium*), German iris (*Iris germanica*), lavender (*Lavandula Spica*), lovage (*Levisticum*), liquorice (*Liquiritia*), mallow (*Malva sylvestris*), balm (*Melissa officinalis*), mints (*Mentha canadensis, M. crispa, M. viridis*), peppermint (*M. Piperita*), marjoram (*Origanum vulgare*), *Panax quinquefoliuum*, opium poppy (*Papaver somniferum*), parsley (*Petroselinum sativum*), rhubarb (*Rheum*), rue (*Ruta graveolens*), sage (*Salvia officinalis*), sclary (*Salvia Sclarea*), soapwort (*Saponaria officinalis*), comfrey (*Symphytum officinale*), tansy (*Tanacetum vulgare*), thyme (*Thymus vulgaris*), valerian (*Valeriana officinalis*), mullein (*Verbascum phlomoides*).

The number of species planted in the botanical garden during the year 1913 was 140. Among them there are some North American medicinal plants which thrive well, especially *Spigelia marylandica, Asarum canadense, Hamamelis virginiana, Grindelia robusta* and *Hydrastis canadensis*.

828 – **The Influence of Soil and Manures on the Yield, Chemical Composition, Size and Quality of Strawberries.** — VERCIER, J., in *Journal de la Société Nationale d'Horticulture de France*, Vol. XV (4th Series), pp. 349-375. Paris, May 1914. FRUIT GROWING

Plant food removed by strawberries. — This was estimated not only in the fruit harvested during one season but also in the vegetative organs of the plant representing one year's growth ; the following results were obtained (Table I) :

(1) See also No. 1155, *B.* Oct. 1913 ; No. 1345, *B.* Dec. 1913 ; and pp. 26-30, *B.* Jan. 1914, article by Dr. BÉLA PÁTER: Cultivation of Medicinal Plants in Hungary. (*Ed.*)

TABLE I. — *Removal of plant food from the soil by strawberries (lbs. per acre).*

	Total crop		Nitrogen	Phosphoric acid	Potash	Lime and Magnesia
	Green	Dry				
Removed by fruit, including calyxes and peduncles:						
in 10 English varieties . . .	13 400	4 800	45.32	41.46	43.40	22.18
(composition per 100 parts green weight).			(0.338)	(0.310)	(0.324)	(0.166)
in Alpine varieties	10 700	5 600	86.36	51.26	85.80	35.10
(composition per 100 parts green weight)			(0.806)	(0.478)	(0.801)	(0.328)
in 3 perpetual-fruiting varieties	13 800	7 200	90.00	46.78	93.55	34.55
(composition per 100 parts green weight)			(0.650)	(0.338)	(0.676)	(0.250)
Removed by vegetative organs:						
in 10 English varieties . . .	3 200	1 200	13.91	11.80	13.67	45.98
(composition per 100 parts dry weight)			(1.17)	(1.00)	(1.15)	(3.87)
in Alpine varieties	1 200	500	9.28	5.46	4.81	12.70
(composition per 100 parts dry weight)			(1.83)	(1.08)	(0.95)	(2.51)
in 3 perpetual-fruiting varieties)	2 400	1 060	13.90	0.90	7.54	29.46

» perp. fruiting »			103.90	47.68	101.09	64.01

The figures for phosphoric acid are relatively high, as the soils of the experimental fields were rich in this element.

The effect of manures. — The effect of different manures on the size of the fruit was investigated on various soils; the results are given in Table II.

TABLE II. — *Average weight of strawberries (Sharples) in grams.*

Soil	Control	Complete manuring	No potash	No nitrogen	No phosphoric acid	Slag alone	Potash alone	Organic manures
A	10.5	10.7	—	10.5	—	—	—	—
B	10.4	—	—	—	—	10.6	—	—
C	6.4	9.2	—	—	—	—	7.5	—
D	9.5	9.6	11.8	9.4	10.1	—	—	12.5
E	—	—	—	—	—	—	9.4	9.7
F	8.3	8.6	—	—	—	8.3	8.9	9.3

The influence of manures on the period of ripening was also examined, but though manured plots in general may be said to ripen earlier than unmanured plots, the various manures produced very irregular effects in this connection.

The influence of manures on the flavour of the fruit is given in Table III:

TABLE III. — *Influence of manuring on flavour of strawberries.*

Manurial treatment	Points	Remarks
I Unmanured	80	Typical flavour.
II No nitrogen, but slag and sulphate of potash	60	Flavour reduced, not so sweet.
III Complete manuring, slag, sulphate of potash and nitrate	63	Flavour reduced, very slight acidity.
IV No potash, but slag and nitrate	93.5	Very fine flavour, large fruits.
V No phosphoric acid, but sulphate of potash and nitrate	75.5	Fairly sweet and with a pleasant taste.
VI Organic manure: compost, blood and cake residues	79	Fruit well filled and with a pleasant taste.

Though the absence of potash raises the quality of the fruit, it also decreases the total amount of the crop.

The influence of manures on the chemical composition of the fruit is given in Table IV.

TABLE IV. — *Influence of manuring on chemical composition of strawberries.*

Soil	Manurial treatment	Yield of juice, per cent.	Sugar, in gms. per litre	Acidity, in gms. of H_2SO_4 per litre
A	Unmanured	54	63	6
	Dung	57	65	5.2
	Complete fertilizers and dung	56	73	5.9
	Slag and sulphate of potash	59	65	5.6
B	Unmanured	77	56	4.7
	Slag	68	67	5.0
C	Unmanured	54	63	6.0
	Potash	58	68	6.2
	Complete fertilizers and dung	56	56	5.5
D	Dung	86	86	6.4
	Slag and sulphate of potash	85.5	81	6.4
	Complete fertilizers	79.7	83	6.3
	Slag and nitrate	75.1	80	6.3
	Sulphate of potash and nitrate	81.3	80	6.3
	Compost, blood and cake residues	80.2	78	6.2

Influence of the soil on the fruit. — The following points for flavour were awarded by expert tasters to samples of fruit grown on different soils ; the two trials were carried out separately (see Table V).

TABLE V.

Variety	Soil	Points	Remarks
1st *trial* : Sharples	containing a fair amount of organic matter	80	typical.
	light sandy loam	109	best flavoured.
	low-lying sand	53	rather watery.
2nd *trial* : Vicomtesse Héricart de Thury	rich wheat land in good condition	30	slightly acid.
	very light, non calcareous	39	full flavoured, firm and dense.
	poor gravel	38	full flavoured.
	marly	26	flavour less good.
	gravelly sand with 9 per cent. carbonate and iron salts	30	full flavoured.

Analyses of the fruit from different soils are given in Table VI.

TABLE VI.

Soil	Yield of juice per cent.	Gms. of sugar per litre	Acidity in gms. of H_2SO_4 per litre
Slightly sandy	57	65	5.2
Low-lying sand	77	56	4.7
Sandy hillside, unmanured for 5 years	54	63	6.0
Garden	86	86	6.4

In another set of experiments the changes taking place during the maturation of the fruit were investigated and it was found that the acidity gradually diminished, while the amount of reducing sugars increased.

The chemical composition of 16 varieties is given and various schemes of manuring are discussed in the paper.

829 – **Fruit and Vine Growing in Central Asia.** — BARSACQ, JOS., in "*Zapiski*" *Simferopólskavs Otdiéla I. R. obschtchestva Sadovodatva*, No 142, 1914.

I. *Fruit growing.* — In Russian Turkestan there are 29 123 dessiatines (78 632 acres) under fruit, mostly in the form of small native orchards, though of late years there has been a distinct tendency towards the establishment of larger orchards, up to 250 acres or more in extent, by the Russian colonists.

Of all fruits, *apricots* are the most common and are not only consumed locally in enormous quantities but also exported to Siberia ; a succession of varieties assures a constant supply from May to August. The next most common fruit is the *peach* ; a flat-fruited variety known as "Cheftalé injir" is very popular, while the local varieties of nectarines are better than the European varieties. *Mulberries* are an important crop not only for the sake of their fruit but also as food for silkworms ; the large fruited seedless varieties are eaten raw, or made into a kind of sirup which is used as a sugar substitute, or even dried and made into a kind of flour which is used as a substitute for bread in very out-of-the-way districts. *Walnut* trees are common in the forests of Ferghana, which, according to the most recent statistics, extend over 35 000 dessiatines (94 500 acres); walnuts are represented chiefly by a large fruited and by an early dwarf variety. Local varieties of *apples* and *pears* are few and worthless, but European varieties, more particularly those cultivated in Crimea, have been introduced by Russian colonists and excellent results have been obtained in the Vierny district with Aport or Grand Alexandre ; in the neighbourhood of the large Turkestan cities, especially Tashkent where fruit growing is developing with rapid strides, satisfactory varieties have yet to be selected, for shallow rooted stocks such as paradise or quince yield poor

specimens of trees and probably suffer from the great summer heat (up to 122° F.) and the drought.

As regards management, in order to keep down weeds, which are a serious pest, lucerne is sown in the orchards with excellent results; pruning is only practised in a very primitive fashion ; the orchards are irrigated four or five times during the course of the summer. Flowering takes place about one month before it does in the Crimea, and late spring frosts are liable to cause very extensive damage, especially to the hard fruits.

With regard to diseases, codling moth (*Carpocapsa pomonella*) is by far the most destructive and affects up to 80 and 100 per cent. of the apples ; this insect, though native, has few natural enemies and an attempt was made to introduce *Oophthora semblidis* and other of its internal parasites, but without success. As the moth has three broods in a season, the late varieties of apples suffer most and 75 per cent. of their fruits are attacked as against 20 per cent. of the early varieties. Preventive and remedial measures employed successfully in other parts of the world, such as spraying, trapping, grease-banding, seem useless in Turkestan, but certain large growers have adopted the method of bagging their fruit and the practice seems to be spreading. *Tingis piri*, apple sucker (*Psylla*) and its allies, *Polyphylla adspersa* var. *pulverea*, *Melolontha afflicata*, *Rhizotrogus solstitialis*, *Tropinota turanica*, *Oxythyrea cinetella*, *Cetonia margicollis* also cause serious damage. Owing to the almost complete rainlessness of the summers fungoid pests are rare. Certain choice varieties of apples are frequently affected by so-called "Stippigkeit", which is thought to be of physiological origin though its cause is at present unknown ; the disease is characterised by corky filaments under the epidermis which appear usually after picking, and it is spreading in a somewhat alarming manner.

Turkestan apples are inferior in quality to Crimean apples and the writer does not consider that the country will ever be capable of producing any but lower grade fruit ; this produce will find an outlet in Siberia, which is being connected up direct with Turkestan by a railway. Early varieties of fruit will also be marketable in Russia, as they ripen about a month earlier than the crop in the European temperate regions.

II. *Vine growing*. — It is estimated that 25 000 dessiatines (67 500 acres) are at present under vines, of which 13 000 dessiatines (35 100 acres) are in the Samarkand district. Small vineyards are the rule. The writer gives a detailed account of cultural methods practised by the natives, including irrigation, which consists of five or six waterings during the summer.

As the Mahommedan law prohibits the use of wine, the varieties usually cultivated, amounting to about 40, are all table fruit with thick skins, few or no pips, and firm pulp ; they grow in long loose bunches. About three quarters of the vineyards are planted with Kichmich, which is dried to produce currants. Masca is a very large kind with bunches averaging 3 lbs. in weight and sometimes reaching 10 lbs., while each grape may have a diameter of 1 ½ in. ; the fresh fruit is in good demand not only locally but also in Moscow and Petrograd. Khoussaïné is a common variety in the neighbourhood of large cities and is exported to the north

under the name of Ladies'-fingers; it keeps well and is a heavy cropper, producing 1 000 to 3 000 poods per dessiatine (13 000 to 40 000 lbs. per acre). Early varieties such as Ak-tchiliaku, which ripens at Tashkent about the middle of June, have also been cultivated of late years.

Russian colonists have tried certain European wine-making varieties, but though the vines appear to have become thoroughly acclimatised and yield good crops, the wine is of poor quality.

The exportation of fresh grapes to Russia is capable of great developments and is receiving encouragement from the Government in the shape of a supply of cold-storage trucks and an accelerated railway service; exports have increased steadily since the opening of the Tashkent railway.

The dried raisin industry, too, is worthy of encouragement, for the climatic conditions are eminently suitable for the drying process and the produce could be vastly improved by the introduction of more up-to-date methods. About 1 250 000 poods (45 million lbs.) of dried raisins and currants are sent annually from Turkestan to Russia and another two million poods, consumed by the latter country, are furnished by Persia and Greece when they might easily be produced in Turkestan.

Wine making, on the other hand, suffers on account of the great summer heat and excessive sweetness of the grapes and has made little progress; white wines are coarse and have a bitter after taste, especially when made with local table varieties; the writer is of opinion that ordinary table wines will never be greatly improved unless the processes of vinification are considerably modified, but there are great possibilities as regards the production of sweet wines with a high alcohol content. The manufacture of brandy has been attempted by a few firms, but without much success, as only a coarse high coloured spirit has been obtained.

Phylloxera is unknown in Turkestan, while fungoid pests are rare, being limited to oïdium and *Cercospora*. The most serious enemies are certain birds which destroy large quantities of grapes in some places; dogs too do considerable damage, as they are rarely fed by their native owners and grapes represent a welcome addition to their diet.

LIVE STOCK AND BREEDING.

830 – **Experiments on the Control of Warble Flies in Germany** (1). — SCHÖTTLER and GLÄSER, in *Mitteilungen des Ausschusses zur Bekämpfung der Dasselplage*, No. 6, pp. 1-31. Berlin, 1914. HYGIENE

In 1913 the Warble Control Committee undertook the treatment of the cattle in the district of Neuhaus on the Oste; out of a total of 3892 head, 2933, or 75.4 per cent., were freed from warbles; the number of larvae removed was 47 625, that is an average of 16.2 warbles per head. The work was done in the second half of April shortly before the cattle were turned out to graze; the average time for dealing with each animal was a quarter

(1) See also No. 534, *B* June 1914. (*Ed.*)

of an hour. The larvae were either squeezed out by hand or extracted by means of tweezers. Most of the cattle kept fairly quiet during the operation, and in only 21 cases did a slight nettlerash follow. The total cost amounted to 423.70 M. (£20 15 *s* 5 *d*), or 0.89 Pfg. (0.11 *d*) per larva, and for each of the 3892 head of cattle existing in the district a little over 1 *d*. This is about the price paid formerly in Oldenburg for removing warbles. The cost, however, varied from one locality to another and with the kind of cattle. Heifers and steers were the most affected with warbles, while cows had not so many, though they were certainly not free from them; bulls had the lowest percentage of warbles. Considering the depreciation of each hide due to warbles to be 3.89 M. (3 *s* 9 $^{3}/_{4}$ *d*), the loss of the farmers in the district under consideration was about £ 560. If the reduction in the amount of flesh laid on and the check in the growth of the young cattle be also taken into account, the loss would probably be twice as much.

In a second part of their paper the writers report upon last year's campaign against warble flies in the district of the Wesermarsch Herdbook Association in the Grand-duchy of Oldenburg, where for several years it has been compulsory to free cattle from warbles. In order to give an idea of the success of the control of warbles the Chamber of Agriculture, by means of the communal authorities, distributed among the owners of cattle upwards of 13 700 question-sheets; 3000 replies containing sufficient data were arranged statistically. The extraction of warbles in Oldenburg was carried out in most of the cases by the owners themselves and only exceptionally by professionals, who in general were more successful than the former. The number of cattle to which the replies referred was 42 593, that is 40.60 per cent. of the whole stock of cattle in the district; of these, 27 870 head or 64.43 per cent. bore warbles. The percentages were: cows 66.35, heifers 87.69, steers and bulls 85.81, and calves 8.58. In the herds examined there were 312 495 warbles, which would give about 770 000 for all the cattle of the district, or 7 or 8 per head of the whole and 11 or 12 per animal infected. The lowest number was found on the calves, which had barely one each, while the cows had 4 or 5 and the steers 12 or 13. The total number of larvae killed was 204 184; the greatest freedom from warbles was obtained where the operation was repeated in May. On the "Geest" (high-lying land) pastures the cattle suffered more from warbles than on the marsh pastures on account of the greater dryness of the former. The same had been observed also at Neuhaus on the Oste.

Lastly the writers report an experiment made by them to demonstrate that the warble larvae caused the cattle to lay on less flesh. Ten steers were kept under exactly the same conditions, five being freed from warbles and the others not. The result was that the former gained an average of 37.3 lbs. per head more than the others. Thus it appears that the loss in flesh caused by warbles is still greater than the loss caused by damage to the hides.

331 – **Effect of Long Storage of Meadow and Clover Hay on its Composition and Digestibility.** — HONCAMP, MÜLLNER and STAU, in *Die landwirtschaftlichen Versuchsstationen*, Vol. 84, Part 5-6, pp. 447-481. Berlin, June 16, 1914.

I. *Meadow hay.* — The hay used in this experiment had been stored for six weeks in a hay loft; it was then chaffed, uniformly mixed and wrapped in paper to prevent losses of any portion of it. After this it was kept for three years in a large airy room not heated in the winter. The samples were analysed: 1) at the beginning of the experiment; 2) after a year and three-quarters; 3) after three years. The results of the three analyses did not differ to any extent from each other.

In the digestibility trials, the hay was fed to two sheep at the rate of 1.54 lbs. per head per day at five different periods. The average coefficients of digestibility obtained are shown in Table I (averages of the two sheep).

TABLE I.

Period	Dry matter %	Organic matter %	Crude protein %	N-free extract %	Crude fat %	Crude fibre %
I. August 1909	58.9	60.8	68.0	59.6	48.2	59.8
II. May-June 1910 . . .	60.4	62.5	68.3	62.6	48.1	61.6
III. May 1911	59.6	61.3	69.6	60.5	46.0	59.7
IV. February 1912 . . .	58.0	59.8	67.4	58.1	51.5	59.5
V. Aug.-Sept. 1912 . .	59.8	61.5	68.8	60.5	51.1	61 –
Increase of digestibility in 5th period as compared with 1st.	0.9	0.7	0.8	0.9	2.9	1.2

The digestibility of meadow hay has thus remained very constant during the three years and has in nowise suffered from the long storage; the variations of digestibility observed fall within the limits of experimental error. The writers conclude that by proper storage with suitable ventilation meadow hay does not suffer any loss either in its nutritive contents or in its digestibility, and that the different results obtained by other observers are due to losses caused by mechanical action, such as the dropping of the leaves rich in nitrogen and consequent proportional increase of the more fibrous stalks, or by lack of proper precautions in sampling.

II. *Clover hay.* — The clover hay used consisted of 60 per cent. clover and 40 per cent. ryegrass; it was chaffed and well mixed, part being wrapped in paper and part placed in a dry loft. It was kept for two years, and during this time did not show any change in its content of nutritive matter. For the experiments on its digestibility it was fed to two sheep in six different periods. The average coefficients of digestibility for the two sheep are given in Table II.

TABLE II.

Period	Organic matter %	Crude protein %	N-free extract %	Crude fat (Ether extract) %	Crude fibre %
I. July-Aug. 1911	62.9	65.0	66.0	58.9	56.5
II. Dec.-Jan. 1911-12	61.9	60.8	67.2	55.3	54.0
III. Sept. 1912	62.7	62.4	67.4	56.0	55.5
IV. Sept.-Oct. 1912	60.2	60.2	65.3	53.4	52.4
V. Sept. 1913	61.8	60.7	66.9	61.4	54.0
VI. Sept.-Oct. 1913	60.0	60.7	63.9	56.4	53.7
Decrease of digestibility in the 6th period as compared with the first	— 2.9	— 4.3	— 2.1	— 2.5	— 2.8

During the periods 1, 2, 3 and 5 the hay fed was taken from the paper wrappers and during periods 4 and 6 from the loft.

The differences in the digestibility during the various periods are so small as to lie within the limits of experimental error. The writers therefore conclude that clover hay does not suffer any loss either in its nutritive contents or in its digestibility.

With both meadow hay and clover hay the valuation according to botanical analysis agreed with that based on the digestible protein and on the starch value ; on the contrary valuation according to crude protein and crude fibre content did not agree with valuation according to botanical analysis.

The classification of fodder is therefore to be based exclusively on its content in digestible protein and starch value.

832 – **The Value of Different Kinds of Straw as Fodder.** — HONCAMP, RIES and MÜLLNER, in *Die landwirtschaftlichen Versuchsstationen*, Vol. 84, Part 5-6, pp. 301-398. Berlin, June 16, 1914.

This is a critical study on the present views, mostly based upon old experiments of Henneberg, Wolf and others, on the food value of different kinds of straw. The investigations dealt with the straw of barley, oats, wheat, rye, spelt, peas, lupins, rape and colza. Each kind of straw was examined as to its content in organic matter (according to the usual methods) and inorganic matter and crude fibre (according to König, Weender, Cross and Bevan) ; it was then fed to two sheep in order to ascertain its digestibility.

As the weather is said to influence the chemical composition of straw and also to a certain extent its digestibility, the straw of the very dry year 1911 was compared with that of the wet year 1912, as far as possible. In most cases the different straws were taken from the same farms. The

wheat straw was mixed with hay and 0.66 lb. of it was given to each sheep per diem. The straw of Cruciferous and of Leguminous crops was fed at the rate of 1 lb. per day and mixed with beet-slices, soy-meal and hay.

The results are summarised by the writer as follows :

1. The general opinion that spring grain straw is poorer in crude fibre than the corresponding winter grain straw is in many cases erroneous.

2. The weather conditions have in general a relatively small influence on the percentage of organic and inorganic matter in the different straws, or at least this influence is not so marked as in fodders richer in protein.

3. König's crude fibre method gives mainly a pentosan free crude fibre, which is not the case with Weender's method. To this is probably due, in many cases, the lower yield of crude fibre by the former method. König's method for the determination of pure cellulose is not correct; at present Cross and Bevan's method is more trustworthy.

4. The straws of spring and winter grain can be considered of equal value as to their digestibility. The straw of Cruciferae (rape and colza) is inferior in value to cereal straw, while the straws of Cruciferae and of Leguminosae are about equal.

5. The value of a fodder is correctly expressed only by its starch value. The classification of fodders according to protein and crude fibre content leads in general to erroneous conclusions.

833 – **The Contribution of Bacteria to the Feces after Feeding Diets Free from Indigestible omponents.** — Osborne, T. B., and Mendel, L. B. (Connecticut Agricultural Experiment Station) in *The Journal of Biological Chemistry*, Vol XVIII, No. 2, pp. 177-182. Baltimore, Md., July 1914.

The feces of 17 rats fed on various diets entirely free from indigestible components were investigated with a view to determining what proportion of the excrement was made up of dead bacterial bodies. The special diets consisted of protein, starch, protein-free milk (1), and lard, so that it was possible to avoid the great difficulty always encountered in previous experiments of separating the bacterial cells from fragments of more resistant undigested food. The feces were dried and ground ; the powder thus obtained was then successively extracted with ether, alcohol (absolute and 80 per cent), 0.2 per cent. hydrochloric acid, and absolute alcohol containing 0.2 per cent. hydrochloric acid. The final residue varied from 22 to 41 per cent. of the dried feces and its nitrogen content calculated on an ash-free basis was fairly constant, amounting to from 10.7 to 12.2 per cent., which corresponds closely to numerous recorded analyses of bacterial cellular substance. Microscopical examination also suggested that the residue consisted of an almost uncontaminated mass of bacterial bodies.

HORSES, ASSES AND MULES

834 - **The Breeds of Horses in Norway.** — *Communication from* CHR. WRIEDT, *presented by the Delegate of Norway.*

Under the action of the special conditions of Eastern Norway a special breed of horses, known under the name of Gudbraundsdal (a valley in Central Norway), has been developed. These horses are raised by small farmers.

As for its origin, it is most probably the most northern branch of the western horse. Its appearance and anatomical structure resemble greatly those of the Danish Jutland and of the old Hessian horses. This agrees with the hypotheses as to the emigration of the human races. To the native breed of the Gudbrandsdal foreign blood was introduced during the 17th and 18th centuries and during the first half of the 19th. During the first two centuries it was especially Danish blood, chiefly due to stallions from the old stud of Friedriksborg. Later, in the first half of the 19th century, only a relatively small amount of foreign blood was introduced and that of very different origins. The importation of a Thoroughbred English stallion *Odin* is of special interest : its third generation included *Balder*, whose blood is at present diffused in all the Gudbrandsdal breed.

These horses are mostly bay or black ; about 4 per cent are chestnut and 1 per cent cream, while white is quite exceptional. Specially marked animals are relatively rare. The stature of the stallions taken as an average of 90 four-year-old horses born between 1900 and 1904 was 15 hands 1 inch. The mares are generally about 1 inch less.

The head is usually of average length, with a straight and broad forehead and well set ears. The neck is somewhat heavy for the size of the horse, and the head not very well set on. The chest, of average depth, has a good breadth ; the average girth of the above-mentioned 90 stallons was 74.02 inches. The withers are of a good shape. The back is inclined to be too long, but there are many specimens with a very handsome back. The ribs are well arched ; the rump is somewhat sloping and of average length and breadth and on the same level as the withers. The tail is set on high. The thighs are well proportioned as to length and are muscular. Altogether the muscular system is well formed. The legs are of average length. The hocks are large, well shaped and clean forming a proper angle. Occasionally turned in hocks occur. The cannon bones are of average length and clean, the pasterns short or medium and duly sloped, sometimes upright in stallions. The shoulder has a good position. The knee is well formed and strong ; flat and knock knees never occur. The cannon bones of the fore limb are also clean ; measured in the narrowest part, they averaged, in the 90 horses examined, 8.37 inches. The fore pasterns are of average length and duly sloped ; occasionally however defective positions are met with. The hoofs are of average size and of excellent quality; formerly they were often thin and flat owing to defective breeding, but now these defects have completely disappeared.

The action of these horses is regular, their trot long, but their gallop

not very elegant. It is a very suitable horse for the peasants, being hardy and thrifty as to food.

They are usually fed on hay, oats and rye bran ; in some places forest leaves are added but hay is always the principal food. Foals usually get about 11 lbs. a day during the first winter and 13 to 20 the next three winters. The daily ration of oats is from 2 to 3 ½ lbs. during the first winter ; in the succeeding winters very little oats are fed, 2 to 3 lbs. of rye bran being given instead.

Throughout the whole summer the young animals are turned out to graze and the brood mares are collected in droves of about 40, with one stallion, on the mountain pastures. These pastures belong to the State or to private owners. The latter let them to associations or possess a stallion of their own. In 1907 the national stallions gave 85 to 95 per cent. of fertile matings on the pastures and only 68 to 77 per cent. in the stables.

The State assistance consists of grants to associations for the purchase of stallions. These grants amount in some cases to £ 100 or £ 150. The State endeavours also to favour horse breeding by yearly shows, the most important of which is held at Lellehammer at the end of April or beginning of May; often as many as a hundred or a hundred and twenty stallions are collected here. The greater number are sold, fetching from £ 150 to £ 600. Most of them remain in Norway, but a good number go to Sweden and Russia and of late years some have been sent to Austria. Besides the Lillehammer show there are smaller national shows which are generally held in the autumn and in which mares are more in evidence. The mares which have had prizes or have been approved, obtain for five years the right to pasture free with the national stallions. The price of a draught horse varies between £ 35 and £ 44.

The Studbook is kept by the State. The first volume appeared in 1902, the fifth this year. Only the stallions that have been awarded prizes at the shows are entered. Exception may be made for a stallion getting good stock. Mares must be pure bred and must have already borne foals to a Gubrandsdal stallion. Some conditions concerning their outward conformation have also been added.

Among the measures for enccuraging horse breeding due to private initiative, the numerous trotting societies which organize matches during the winter must be noticed. Most of them are united in a large association " Det norske Traverselskab " (The Norwegian Trotting Association). At most races only pure bred Norwegian horses are allowed to compete.

The native breed of Western Norway is called the Fjord breed. Its origin is not completely known ; possibly it is a branch of the Celtic pony. The Fjord is a wiry horse, standing 14 to 15 hands 1 in. high. Its coat is almost always whitish, but of different shades ; from time to time also bays are met with. The head is small with a broad and straight forehead and small and very mobile ears. The neck is strong and the head well set on. The chest is deep and of average breadth. The withers are round, the back of average length, and the ribs well arched. The rump is slop-

ing and often not quite muscular enough. The tail is high set and free. The thighs are muscular and of satisfactory length; the hocks are always clean but their breadth is not always sufficient ; they are often much turned in and the angle they form is not always ample enough. The cannon bones are of average length, and clean ; the pasterns are short and set at a true angle. The shoulder is somewhat short and vertical ; the arm and forearm are of medium length, the latter being often poor in muscle. The knee is well formed ; the fore cannon bones are clean and well marked ; the fore pasterns are short and generally well formed, though sometimes owing to defective breeding knock-kneed animals are met with. The hoofs are small and of excellent quality. The step both walking and trotting is rather short, but the rapid action allows a great speed to be attained. These horses are very hardy and exceptionally enduring, and frequently travel 50 to 70 miles in a day.

SHEEP

835 – **Formation of a German Sheep-breeders' Union.** — *Zeitschrift für Schafzucht*, Part 7, pp. 145-150. Hanover, July 1914.

On the occasion of the German Agricultural Society's Show at Hanover this year a Union of German sheep-breeders was founded (Deutscher Schäfereiverband) with the object of uniting all the existing associations of sheep-breeders and individual breeders in an association for furthering sheep breeding in Germany.

GOATS

836 – **The Angora Goat.** — HELLER, L. L., in *U. S. Department of Agriculture, Farmer's Bulletin*, No. 573, pp. 1-16. Washington, April 27, 1914.

The value of the 1909 clip of mohair in the United States was $901 597, that is nearly four times as much as in 1899. The number of fleeces of mohair rose from 454 932 in 1899 to 1 682 912 in 1909. Of this latter number 1077 463 came from Texas, 155 980 from New Mexico and 141 588 from Oregon ; Arizona and California each contributed upwards of 100 000 and Missouri was the only other State with over 20 000. The average weight per fleece was 3.7 lbs. in Oregon and 1.85 lb. in Texas. In the latter State many Angora goats are shorn twice a year, for which reason the yield of mohair per head is undoubtedly above the census figure for the average weight per fleece in the State. Assuming that one third of the Texan Angoras are shorn twice it would appear that in the United States the total number of Angoras of shearing age was about one million.

During the last few years the breeding of these goats has increased in importance more than that of any other animal and it is now carried on in almost every one of the States. Conditions are especially favourable to this branch of animal husbandry in the North-West, in which brush is so abundant, and where the Angora goat contributes greatly to the control of forest fires by clearing brush lands. American Angoras have hitherto been exported mostly from California to South Africa, Canada, Alaska and recently also to Brazil and the Argentine Republic. The first Angoras introduced into the Union were mostly crossed with common goats in order to obtain a larger and hardier animal. The first and second crosses showed but little mohair and much kemp, and five or six crosses with pure

Angoras were necessary before a really superior animal was obtained. After the fifth cross the product could be considered as pure bred Angoras. The writer does not consider it advisable to cross with common goats in order to obtain Angora flocks. He considers it better to import good original animals and to keep them pure from other strains.

The Angora goats of the United States are generally pure white and horned. Their ears are either partially erect or drooping. Their bodies denote a good constitution ; they are symmetrically built, and with the exception of the inside of the upper part of the legs they are well coated with fleece. The demand is for fine quality, closely curled, very glossy fleeces and as nearly as possible free from kemp.

The price of mohair has of late years much increased in the Union owing to the many usages to which it is put (manufacture of plush, overcoats, wigs, etc.). The weight of fleece for American Angoras ranges between 2 and 12 lbs. The fleece of a one-year-old goat weighs 2 ½ lbs. Where the fleece is allowed to grow for 12 months the average length of staple is about 10 inches. The total weight of the fleeces produced in the United States in 1913 amounted to nearly 5000 000 lbs. The best of it comes from the North-Western States. The average cash production of a goat is, according to the North-West Angora Goat Association, $ 1.75 and with many as much as $ 2.25 per annum. Besides this considerable home production, the United States import, in round numbers, about 2 000 000 lbs. of mohair, which is on the average superior in quality to the American produce.

The loss of weight in washing of the home hair is about 12 to 15 per cent., rather greater than that of the imported article. The skins of Angora with the hair attached are sometimes tanned in the United States and are much used for rugs, carriage robes, etc. The flesh finds a ready market, especially in Kansas City. The average weight of the goats slaughtered there is about 68 lbs.

Shearing takes place from February to March and the second clip in September or October in the South-West, and from March to April in the rest of the country.

The most important Angora breeding associations are the " American Goat Breeders' Association ", the " National Mohair Growers' Association " and the " North-West Angora Goat Association ".

837 – **hicken Rearing.** (1) — *The Journal of the Board of Agriculture*, Vol. XX, No. 12, pp. 1049-1057. London, March 1914. POULTRY

The demonstration by Mr. F. G. Paynter of his system of producing table poultry, which was commenced in December 1912 at Haslington Hall, near Crewe, under the auspices of the Board of Agriculture and Fisheries in conjuction with the Cheshire County Council, came to an end in December last. An area of 4 acres in the middle of a newly formed small holdings colony was devoted to the demonstration, and from that point of view was particularly suitable for the purpose.

(1) See also No. 160, *B.* Feb. 1913. (*Ed.*).

During the whole time the demonstration lasted it was thrown open to the public. The Cheshire County Council appointed a temporary demonstrator whose chief duty it was to show people round and explain the system to them; the result of these and of other means to attract those for whose benefit the demonstration was designed, was that a large number of people visited Haslington Hall while the work was in progress.

Incubation was commenced in the beginning of December 1912 and terminated by the middle of the following July. Three incubators holding 340 eggs, and one holding 390 eggs were used. All the eggs were bought from various sources. The result of the incubation was as follows:

Number of eggs bought	9 897
» » broken	294
» » infertile	1 690
» » not hatched	3 885
» of chicks obtained	4 028
Percentage hatched on total number of eggs incubated	41
» of chickens hatched after allowing for broken and infertile eggs	51
Average cost of eggs per chicken hatched	4½*d*

The proportion of chickens hatched to eggs purchased was never more than 54 per cent. This relatively small proportion was partly due to shaking in transit and it is probable that better results would have been obtained if reliable eggs could have been purchased locally.

From the incubators the chickens were removed to the brooders, and when they were seven weeks old they were removed to larger wire runs (100 × 10 yards) and housed in so-called "Sussex arks," where they stayed until about 16 weeks old, when they were ready for sale. The plan adopted by Mr. Paynter for disposing of them was to contract beforehand for the sale of the whole of his output to a poulterer near London, at fixed prices varying from 3*s* 9*d* in April to 2*s* 6*d* in September.

The number, values and weights of the chickens sold were as follows:

Number of birds sold	3 471
Weight	13 968 lbs.
Average weight of chickens when sold	4.024 lbs.
Value of birds sold	£496 8*s* 1*d*
Average price per pound	8½*d*

The following is a summary of the food consumed and of its cost:

		£	*s*	*d*
3 437 lb.	Chick feed	24	10	1
7 071 »	Biscuit meal	40	5	8
711 »	Oatmeal	5	3	1
389 »	Rice	3	2	3
1 899 »	Bran	6	18	9
2 862 »	Meat and fish meal	24	9	3
4 475 »	Barley meal	19	18	4
21 210 »	Sharps	77	0	7
18 985 »	Wheat with 10 per cent. of maize	68	3	5
		£ 269	17	5
Grit		5	10	0
	Total food bill	£ 275	7	5

The profit and loss account shows a net profit of £55 1*s* 2*d*. This is relatively small, but it must be borne in mind that the work was seriously interfered with by the reception of so large a number of visitors, and that the outlay was valued somewhat high. In practice a small holder would save on several items, such as part of the work, and his profits would be higher.

During the current year Mr. Paynter is conducting a similar demonstration in Cambridgeshire.

838 – **Experiments on Egg Laying in Different Breeds of Poultry.** — (Eighty-fourth Report of the Royal Veterinary and Agricultural College Laboratory for Agricultural Experiments at Copenhagen). *Communicated to the International Institute of Agriculture by the Correspondent for Denmark.*

The object of these experiments was : 1) to determine the difference in the yield of eggs of various breeds of poultry ; 2) to throw light on several conditions of fertility of the eggs and on the colour of the shells.

1. Experiments were carried on for three years on the egg laying of the following breeds : White Leghorn, Brown Leghorn, Barred Plymouth Rock, White Wyandotte, Black Minorca and Houdan. The Leghorns took first place for both number and total weight of the eggs. While the average number of eggs laid by the Leghorns during the three years was about 100, the Plymouth Rocks laid about 70, the White Wyandottes about 60, the Black Minorcas about 90 and the Houdans about 80. The figures for the last three breeds, however, are only approximative as in several of the pens disease was rife.

In comparative trials of Brown Leghorns, Nassaus and Orpingtons, the latter gave the highest yields, followed by the Leghorns, the Nassaus coming last. Considering only one-year-old hens the Nassaus and especially the Orpingtons laid more eggs than the Leghorns, but if the two to three-year-old hens be included in the amount the result is somewhat more favourable to the Leghorns. The good result with Orpingtons is to be attributed not only to relatively better laying, but especially to a more uniform distribution over the individual months in the year.

2. As to the most profitable age for egg laying it has not been possible to determine any sure rule. Most hens lay the greatest number of eggs during the first or second year, but there were some that produced more in the third year. In general it may be considered that the greatest number of eggs is obtained during the first year.

3. As for summer and winter laying there is no large difference between Plymouth Rocks and Leghorns, the former laying a slightly greater percentage of their eggs during the winter months than the latter. It has also been observed that the older hens lay a smaller percentage of their eggs during the winter months than the younger ones.

4. The weight of individual eggs was greater for Minorcas and Leghorns than for White Wyandottes and Houdans. It seems as if the weight of the eggs increased with the age of the hen.

5. Repeated weighing has shown that the weight of the birds increases with age, but only up to the end of the second year, when they are

fully grown. Within each year the weight of the body seems to follow certain laws, according to which it grows from autumn to spring and sinks again during spring and summer. This is especially noticeable in good layers, the body weight of which decreases to a greater extent than that of the bad layers during the spring months when egg laying is more active.

6. From the observations made, it appears that broodiness, which is more frequent among Plymouth Rocks than among Leghorns, is most pronounced in the best layers.

7. The above experiments have further shown that 16 days after mating the hens still lay fertile eggs. When mating is repeated after a period of more than 16 days, the first fertile egg is generally laid three days, and sometimes four days later.

It has not been possible to influence the colour of the egg shell by pairing a cock of a breed which has yellow or brown eggs with a hen of another breed that lays white eggs, or viceversa. The breed of the hen is alone responsible for the colour of the egg shell.

The number of eggs laid, as given in paragraph 1, will be thought somewhat low and there are doubtless many flocks of poultry in Denmark that lay more eggs. One of the reasons of the relatively low number of eggs obtained during these experiments is that for the sake of other tests, the poor layers, which a private breeder would soon get rid of, had also to be kept. Thus, for instance while one Plymouth Rock laid in the three years 200, 177 and 182 eggs, another one laid during the same time only 2,5 and 4 eggs respectively.

839 – **Contribution to the Study of Sericulture in Indo-China.** — BUI-QUANG-CHIÈU, in *Bulletin économique de l'Indo-Chine*, Year 16, Nos. 101 and 102, pp. 165-178 and 376-401. Hanoï-Haïphong, March, April, May, June 1913.

Silkworm breeding was introduced into Annam from China about the tenth century. It was encouraged by the Annamese emperors, especially Gia-Long and Minh-Mang, and soon became a flourishing industry in the peninsula, continuing in this condition up to 1851, after which date its progress ceased. The French administration, notwithstanding many efforts, has not yet succeeded in giving sericulture in Indo-China the development which the good natural conditions of the country would allow; on the contrary the industry has even declined. This state of things is due to deep-seated economic and social causes:

1. The intense literary culture, which induces the educated Annamese to take up administrative careers (as mandarins) and to neglect agriculture and industry.

2. The improvements in the European cotton industry, which provides Indo-China with cheap and good cotton goods that have in many cases taken the place of the old silk tissues.

3. The natives were formerly taxed, by the mandarin administration, arbitrarily and according to their apparent wealth; consequently they did not dare to use the fine Chinese silks which would have marked them out to the rapacity of the mandarins. Under the French administration they have abandoned the Indo-Chinese silks in favour of the Chinese

fabrics and of late years they have made much use of Lyons and Japanese silks, notwithstanding their higher prices.

4. The neglect of the cultivation of mulberries for that of rice, the latter being easier to sell than cocoons ; besides which there is no doubt that the diseases to which silkworms are liable have discouraged many native breeders.

At the time of the French conquest, according to Dr. TURC, great centres of production existed in the huyen of Kien-duong (now Cai-fây, Cai-bé and Rach-gâm) in the province of Dinh-tuong (Mytho) ; the districts of Sadee and Bentré, which sent their produce to the great market of Vinh-long ; in the east of Cochin-China the districts of Baria, Long-thanh and Thu-dau-môt ; at present next to nothing remains of the great plantations. In 1870 French spinning mills were started at Cholon, but they had to be abandoned on account of the fall in prices on the Lyons market. In 1883 the Government nominated a mission for the reorganization of sericulture and founded a silkworm breeding establishment at Cholon, in which an attempt was made to improve the native worms by crossing with foreign breeds. The results were bad, and the same was the case with all attempts at crossing with Chinese or Japanese worms. M. VIEIL believes that these failures are due to the fact that the native worms, being more slender, can eliminate water vapour better than the French, Chinese, or Japanese worms, which are fatter and consequently present a smaller evaporating skin surface in comparison to their weight ; he does not think that there has been, as has often been asserted, any degeneration of the Indo-Chinese worms. He believes also that breeders have launched thoughtlessly into the system of crossing, which, if it had been preceded by study and systematic experiments on the best breeds more akin to the native breeds, might have yielded far better results.

In 1905 a silk specialist was entrusted by the Governor-General with a mission which resulted in the formation of a French company ; this entered into an agreement with Indo-China for the selection and free distribution of silkworm eggs to the natives by means of subscription. The old spinning mills of Nam-dinh were resumed and the breeding farm of Phu-lang-thuong, which was managed by M. VIEIL, was attached to it. The latter came to the conclusion, from the experiments he made, that it was better to keep to the improvement of the Annamese breeds and to teach the natives how to rear the worms. At the same time reeling basins of European pattern were simplified for the natives. These basins, the price of which is not above 12 shillings, were given free of charge to the Annamese; a Lyonnese employee of the Agricultural Service, a silk specialist, was instructed to teach them the way of using them.

All these efforts are beginning to bear fruit and already the quality of the silk exported to the mother country is improving. Indo-China has not followed the rapid progress of Japan; even Corea and Siam have developed their sericulture. Indo-China, which has a population well adapted to this kind of industry and which might make use of the scientific results

acquired by the mother country, will also see a great increase in its silk production.

Geographical distribution of sericulture in Indo-China.

The whole of Indo-China raises silk, but the delta districts take the lead.

Tonking. — The provinces in which silkworms are reared on a large scale are the following, arranged according to their importance: Nam-dinh, Thai-binh, Bac-ninh, Phu-lien, Phu-lang-thuong, Phu-ly, Hung-yen, Hanoï and Son-tay. Mulberries are grown in the alluvial lands, on the banks of rivers (Red river, Song-thai-binh, Song-thuong, etc.). Reeling and weaving are practised especially at Nam-dinh and Thai-binh. There are at Phu-lien flourishing plantations and important native weaving factories (Do-son, Kien-an).

Annam. — Sericulture is practised in all the provinces, but in the south (Khánh-hoá, Phú-yén) and in the north (Thánh-hoa, Quang-binh) it has rather declined; it has markedly progressed in the centre in Binh-dinh and Quang-nam. At Phu-phong, in the province of Binh-dinh, there is a great industrial spinning and weaving centre. Silk raising has declined in the province of Thua-thien, the only centres being the huyen of Phu-vang and the district of Thien-mô, which are not very important.

Cochin-China. — The silk industry is more widely spread but in a more backward state than in Tonking. There are no European factories and the attempt made twenty years ago by commander COLBERT DE TURGIS at Tan-chau to establish a station for killing the pupae in the cocoons failed. There are, however, about 3700 acres of mulberry plantations and all the silk industry is in the hands of small native growers and is at the same level as it was two thousand years ago. There are also some important centres of mulberry growing and silkworm rearing in the province of Chau-dôe, especially in the mountainous district about Thai-son, Tu-tê, and Triton, where the inhabitants are chiefly Cambodians. The island of Cù-lao-ba and the Malay canton of Châu-giang form an important spinning and weaving centre. In the province of Long-xuyên, the mulberry belt extends from Cu-lao-giêng to the Ongchuong canal, including the village of Long-diên and others, as well as some islands round Cu-lao-giêng. The village of Cho-tu-chên-sai is the most important centre of this district (and perhaps of the whole of Cochin-China), exporting its silks (generally dyed black) especially into the provinces of Cân-tho, Rach-giá and Bac-lieu. The province of Sadec, formerly renowned for its worked silks called "hang-không-tren," has to day only La-vung as centre, and this is of no great importance. The course of the Mékong has then to be followed as far as Bentré (Batri and Mocay) before the mulberry is again met with. A kind of taffeta called "lua", which formerly had a certain reputation, is woven there. In the provinces of Bac-lieu, Soc-trang and Tra-vinh all the silk industry is in the hands of Cambodians; the Cambodian centres of Tra-kha, Tra-cu (Tra-vinh), Vinh-châu, Vinh-phuoc (Bac-lieu), Lai-tâm, Var-

thap, Phuoc-lai and Yên-tâp (Soc-trang) cultivate mulberries, breed worms and weave the silk.

Cambodia.— All the banks of the Mékong between Tân-châu and Pnom-penh are planted with mulberries in the parts that are inundated every year. On the borders of Cochin-China is the silk centre of Banam, in the province of Prey-veng, which has raised worms from the eggs of the Station of Takeo (Pnom-penh).

The Upper Mékong seems to have a certain future before it from the sericultural point of view ; silk raising is much scattered ; the resources of Laos are imperfectly known, and unfortunately the attempts made in Tonking and Cochin-China have not been extended to this locality.

The breeds of silkworms in Indo-China.

They are polyvoltine, generally with yellow cocoons, exceptionally dirty white. It requires 18 to 20 lbs. of fresh coccons to produce 1 lb. of raw silk reeled after the European fashion. The complete evolution of the worms lasts from 42 to 46 days: 10 for hatching the eggs, 20 to 30 according to the weather for the growth of the worms and from 10 to 11 for spinning and pupation.

Annamese breeders distinguish the following four breeds : Bâu-bi, Bau-diêu, Ken-se and Tâm-soc ; their characters however are badly defined. The writer gives some of them. The Tonking breeds are generally of larger size.

Silkworm rearing.

The writer studies the native systems in order to draw the attention of European breeders who would improve their defective details.

The breeders themselves attend to the egg-laying ; the unit adopted is the " cup " (the quantity of eggs laid by 4 or 5 fertilized female moths put together under a cup). No selection is practised. Native breeders generally undertake the raising of a number of worms too great for their available space. Their yields are not remarkable, 22 to 28 lbs. of cocoons for 100 layings, and often less.

Incubation does not require any special care. Hibernation is not practised. The eggs have only to be protected against red ants. Annamese breeders remove the newly hatched worms only in the afternoon or the day after the first eggs are hatched, which has the effect of obliging those that are hatched first to fast until the late ones come out. The young worms are swept off with a feather, many being injured in the process.

Moulting lasts 24 hours ; the longest of the stages, the last, is of eight days. The food of the worms is frequently very imperfectly chopped and may contain fragments of wood which wound many worms. The worms are set to spin their cocoons on hurdles which yield up to 11 lbs. of cocoons each.

The breeder does not usually spin the silk, but sells his cocoons to a spinner at current prices minus a rebate of 1*d* per 11 lbs. in favour of the

spinner. When the worms have thriven well and produced cocoons suitable for reproduction they fetch as much as twice the price paid for cocoons for spinning.

The defects of native breeders are the following. They hatch out a quantity of eggs much superior to their means (this applies specially to the Cochin-Chinese) ; being short of hands they hurry roughly through the various operations, causing injury to the worms ; this injury is then attributed to occult powers, which the breeders seek to appease by superstitious practices instead of improving their methods of breeding. The most elementary rules of hygiene are unknown ; the diseased worms are thrown about anywhere and become new sources of infection.

Diseases and enemies of silkworms in Indo-China. — The most widespread diseases are : " pébrine, " " grasserie ", " flacherie " and " muscardine " ; a fly called " con-lang " also causes a good deal of damage.

Pébrine, called in Tonking " tam-gai ", causes much less havoc in Indo-China than in France. It is beginning to decrease owing to the free distribution of selected eggs ; the sale of unselected eggs should be forbidden and more lectures for the natives should be given.

Flacherie, called " tam-lung " in Tonking and " tam-di-duor " in Cochin-China, appears especially in the last stages.

Some worms cannot digest their food and die without exhaling the characteristic odour of flacherie ; under the microscope they show bacilli in moniliform strings.

Another disease, called "atam-kuong " in Tonking, causes the worm to stretch out, and the third to the sixth ring to blacken ; the last rings become transparent ; the worm then dies and exhales a fetid odour.

Grasserie appears under various aspects, according to which it bears various names ; it is especially frequent in moist and stormy weather. It causes much havoc and often destroys whole batches of worms.

Muscardine is rather rare in Indo-China and is not much dreaded by native breeders.

The " red disease " is not very serious ; it attacks the moths, which die after having laid a limited number of eggs.

The fly " con-lang " deposits its eggs on the worms and secretes at the same time a corrosive liquid which attacks the skin and makes an opening in it, through which the egg penetrates into the worm where the larva feeds on the tissues of its host, reducing them to pulp ; one worm can carry as many as 6 or 7 larvae. When the latter are fully developed they issue from the body of the worm by a large opening and enter into the crevices of the floor, where they pupate. The pupa is at first light brown, then black and it develops in about 12 days. In order to guard against this insect, breeders protect the worms during the first stages by a mosquito curtain. In Tonking the windows are closed by a fine bamboo network. This fly is in its turn parasitized by *Encyrtus sericophilus* (Hymenoptera), the study of which has been the object of a communication to the Académie des Sciences of Paris.

Another fly, called " rui dâ ", which resembles a wasp, attacks the worms when placed on the hurdles to spin their cocoons ; its sting is instantaneously fatal, but the damage it does is insignificant.

The silk industry.

Though the industry is established throughout the country it is still in a very backward condition. Spinning in the European fashion is not practised by the natives ; there are in Indo-China only three filatures, two belonging to Frenchmen at Nam-dinh (Tonking) and at Phuphong (Annam); the third at Thai-binh (Tonking) belongs to a native company. All three possess improved plant.

The Annamese systems of spinning produce a raw silk unacceptable on European markets.

The unit of cocoons in the filature is the " cân " of 11 lbs.; the unit of weight for the cocoon trade in Tonking is a bundle of 600 " sapeks " (" quan-tiên "), weighing 3.25 lbs., but considered in the French trade as 3.3 lbs. The unit for raw silk in skeins is 10 taels, or 9.25 lbs.

The thread of the cocoon that is formed in damp weather often breaks on spinning ; it yields a fluffy silk of inferior quality and is used to adulterate spun silk for export.

The floss is sold to the Chinese, who export it to Cholon, whence it appears a certain quantity is sent to France to the silk by-product factories. It is estimated that in Indo-China the floss pays the labour and the firing in the spinning mills.

The raw silk obtained in Cochin-China is useless in Europe; the " to-lua " or first quality is utilized by the local looms, while the " to-be " quality is exported by the Malays to Bangkok.

Annam silk is exported to Hongkong and Singapore. Tonking silk, which has improved thanks to the combined efforts of the Administration and of the Nam-dinh mills, finds its way in increasing quantities to France, but four-fifths of it still goes to Hongkong.

The native production is very low and is not sufficient for present demands ; consequently it does not seek other outlets. Neverthless the efforts made by the neighbourng countries, especially Siam, the Philippines and Corea, to extend their production, render considerable efforts in the same direction necessary on the part of Indo-China. But there are still great obstacles to be overcome : 1) the lack of a technical direction sufficiently endowed by the administration ; 2) the want of European factories in Cochin-China and in Cambodia ; 3) the ignorance of the natives in general and especially of the spinners, and their lack of initiative ; 4) the want of capital, interest on which is almost always 50 per cent. and upwards, often reaching 100 per cent.

The first steps towards progress must be made by the administrative authorities. The following would be useful measures :

1. Promoting in Cochin-China and in Cambodia the formation of native societies for reeling silk, under the technical direction of French officials. Such societies have given excellent results in Tonking.

2. Providing the natives with improved spinning apparatus, as has already been done in Tonking, and granting prizes either to the spinners or to the exporters according to experience.

3. Teaching the Annamese to reel off a fixed number of threads with knolled ends, replacing bamboo reels by aluminium ones, increasing the twist and adjusting better the motion of the combs. A great deal of tact and a full knowledge of the industry are necessary in the officials who are to induce the natives to adopt these measures, which would considerably increase the value of Indo-Chinese silks even on Asiatic markets and procure profitable sales for raw silks.

4. The awarding of prizes in money and honours by the Government.

Native weaving. — Silk is woven everywhere in Indo-China, but the processes are not equally developed in all centres; Tonking and Annam are more advanced than Lower Cochin-China.

In Tonking weaving is especially prosperous in the provinces of Nam-dinh, Thai-binh and Kiên-an. Dô-son is renowned for its silks, a kind of taffeta called "lua"; in the province of Hâ-dóng the village of La-ca is distinguished for its gauze called "the La-ca". With the exception of the gauzes, taffetas, serges and satins which compete with the same Chinese woven goods, the natives turn to China for their finest garments. Of all Indo-Chinese countries, Cochin-China is the one which consumes the greatest quantity of Chinese silks.

In Annam, fine satins, gauzes and crapes are woven at Binh-dinh. The importation into France of Binh-dinh crapes continues to increase.

In Cochin-China weaving is limited to plain silks and some taffetas with very small patterns. The most important looms of Cochin-China and Cambodia are those of the orphanage of Cu-lao-giêng, managed by the Sisters of the Apostolic Mission : here taffetas are made with patterns of Cambodian or Siamese style, 28 and 32 inches wide, as well as crapes (foulards and shawls) with French hand embroidery. Tissues of the same kind are manufactured by the Malay cantons of Xom-châ-và (or Xom-châu-giang) over against Châu-doc. The same Malays excel in the manufacture of "sampots" called "chàng hung" (a special kind of taffeta).

Indo-Chinese mulberries : their diseases and pests.

The mulberry cultivated in Indo-China is the white mulberry. There are many varieties of it, which have not yet been studied from the botanical or the nutritive point of view. The native varieties may be reduced to four : dâu-tau", with leaves cordate, thin, entire or lightly serrate ; "dâu-phung", with trifid leaves ; "dâu-se", small cordate leaves ; "dâu-thù-du" (papaw mulberry), with leaves deeply divided, somewhat like those of the papaw.

Enemies. — In the mountainous region of Châu-doc, where the mulberries are grown as standards, occurs a longicorn beetle, the larva of which

bores holes in the trunk ; this insect has no special name among the Annamese ; the perfect insect gnaws rings in the bark of the branches.

The writer found in 1908 in the province of Ben-co some mulberries suffering from the attacks of an aphis lodged in the underground parts of the tree between the bark and the wood : the bark dries and falls off the parts attacked.

Termites cause serious damage to the mulberries planted on the dunes, called " giông ".

The mulberries on the banks of the Mékong at Tân-châu are attacked every year in the dry season by a fungoid disease which curls up the leaves and dries them, rendering them useless. The trunks of the trees attacked show swellings and become brittle. The natives do not do anything to combat the disease, which disappears as soon as the rains come.

840 – **Fraudulent Introduction of Dead Lobsters in the Parcels sent to Market by Certain Breeders.** — JUGEAT in *L'Hygiène de la viande et du lait*, Year 8, No. 7, pp. 341-343. Paris, July 10, 1914. FISH BREEDING.

The wholesale death of lobsters caused in the breeding basins by the variation in the salt content of the water due to accidental infiltration of fresh water, causes considerable losses to the breeders, a certain number of whom do not hesitate to mix these dead lobsters with the live ones in the parcels they send to market, especially to Paris, where the writer on one occasion seized no less than 295 lbs. of them. The flesh of these animals is of a very inferior quality; it is lean, dry, friable and tasteless; it turns to pulp on being cooked and putrefies rapidly. It is therefore important to recognize such lobsters at once. Their characters are as follows :

1. *External characters.* — The muscles are completely relaxed, the membranes of the articulations are thick, dull and whitish (instead of being thin, shiny and transparent) and turn black in a few hours.

2. *Internal characters.* — The tissues are soft and swollen with water; if a membrane be cut, water flows from the aperture, which never occurs when the animal is taken alive from the breeding basin.

FARM ENGINEERING.

841 – **Trial of Machine Ploughing in Rice Fields.** — TARCHETTI, A., in *Il Giornale di Risicoltura*, Year IV, Nos. 5, 7 and 8, pp. 65-80, 103-107 and 122-128. Vercelli, March 15, April 15 and 30, 1914. AGRICULTURAL MACHINERY AND IMPLEMENTS

The Italian Experiment Station for Rice Growing at Vercelli organized a trial of machine ploughing in ricefields which took place on March 30, 1914, at Sig. Eusebio Saviolo's estate at Sali Vercellese, near Vercelli. Upwards of 64 acres of land were placed at the disposal of the Committee ; the fields were very uniform and large, so that the average length of the furrows was about 1000 feet, and the plot assigned to each machine about 7 ½ acres.

The following eight machines were admitted to the competition :

A. Motor-hauled ploughs — BARONCELLI, of Ravenna, Italy ; FERRETTI GOGGIA, of Tortona, Italy.

B. Self-contained motor ploughs — PAVESI TOLOTTI, of Milan, Italy; STOCK of Berlin, Prussia.

C. Cable-hauled ploughs — CASALI, of Suzzara, Italy; SANTACHIARA of Reggio Emilia, Italy; VIOLATI-TESCARA, of Ariano Polesine, Italy.

D. Rotary digger — V. MEYENBURG, of Bâle, Switzerland.

1. *Baroncelli's motor.* — 24 H P. (effective), 800 revolutions per minute, total weight 3960 lbs. — Has been somewhat modified to meet the special requirements of rice fields; the diameters of the wheels have been increased, as well as the breadth of their tyres.

2. *Ferretti-Goggi motor.* — 24 to 30 effective H P., 500 revolutions per minute, total weight 9 900 lbs. — Its wheels are on the Lefebvre or Holt Caterpillar system; that is they run on an endless chain of steel plates.

3. *Pavesi and Tolotti's "moto-aratrice"* or self-contained plough. — 16 to 20 effective H P., 700 to 800 revolutions per minute, total weight 4180 lbs. — In this machine the steering wheel has been enlarged and all the tyres have been widened.

4. *Stocke's motor plough.* — 42 to 50 HP, 700 revolutions, total weight 11 000 lbs. — This machine has also been somewhat modified in view of the special work before it.

The three cable-hauled machines (5, 6 and 7) are all on Howard's single-engine system, with a separate windlass bearing two drums and a cable running round the field, though they differ in the construction of the windlasses and in other particulars.

5. *Casali's apparatus* was presented with a 13 effective HP, heavy oil motor, built by the National Gas Engine Co. (Ashton); the two-wheeled windlass truck, with 1600 to 2000 feet of wire cable, weighs 3 550 lbs.

6. *Santachiara's* windlass was presented with a Garret 12 effective HP steam engine; it is mounted on a four-wheeled truck and weighs with 1600 feet of wire cable, 3960 lbs.

7. *Violati-Tescara's* outfit was entered with two different motors: one is a heavy oil Mietz and Weiss 25 effective HP motor, and the other an electric three-phase motor of the same horse-power.

8. *Meyenburg's rotary digger.* — 25 effective HP, 1000 revolutions per minute; the drum bearing the diggers makes 180 revolutions per minute. Its total weight is 4400 lbs. and its breadth of work 6 ½ feet.

Of the above outfits, Nos. 3, 4 and 8 require only one man to work them, while Nos. 1 and 2 require two men and Nos. 6 and 7 require four.

All the machines entered finished off the work allotted to them, except the electric motor of No. 7, which did not arrive in time for the trial of March 30.

The points given by each of the 19 judges were 70, distributed as follows:

20	for quality of the work done
20	» cost
10	» ease and safety of handling and transporting
10	» regularity of work of motor and suitableness to other purposes
10	» construction and solidity.
70	

The following were the awards :

Group of cable-hauled outfits:

CASALI	1 222 points
VIOLATI-TESCARA	1 215 »
SANTACHIARA	1 102 »

Group of direct-traction outfits:

BARONCELLI	1 170 points
STOCK	1 108 »
PAVESI-TOLOTTI	1 051 »
FERRETTI-GOGGI	960 »

842 – **Experience with Motor Plou hs in the Cultivation of Moor Soil.** — *Protokoll der 72 Sitzung der Central-Moor-Commission vom* 15-17 *Dezember* 1913, pp. 164-202 + 21 figs. Berlin.

In the 72nd sitting of the Central Moor Commission, four members, Dr. Ramm, Herr Volckmann of Kienberg, Herr Schmig of Etzin and Prof. Falke of Leipzig, reported upon their practical experience with motor ploughs. The earliest experiments were those begun in 1907 at Wiesmoor ; electric machines were used, as the steam ploughs then existing seemed too heavy. The division of the land to be worked into fields is shown in the accompanying figure. The arrangement of the electric line at right angles to the roads requires long cables, but on the other hand it saves expense on the permanent lines and on the roads. When each machine is provided with 2300 feet of cable, cross-roads are required only every 4 600 feet. With steam ploughing the arrangement is the same except that the cross roads with power lines are not necessary.

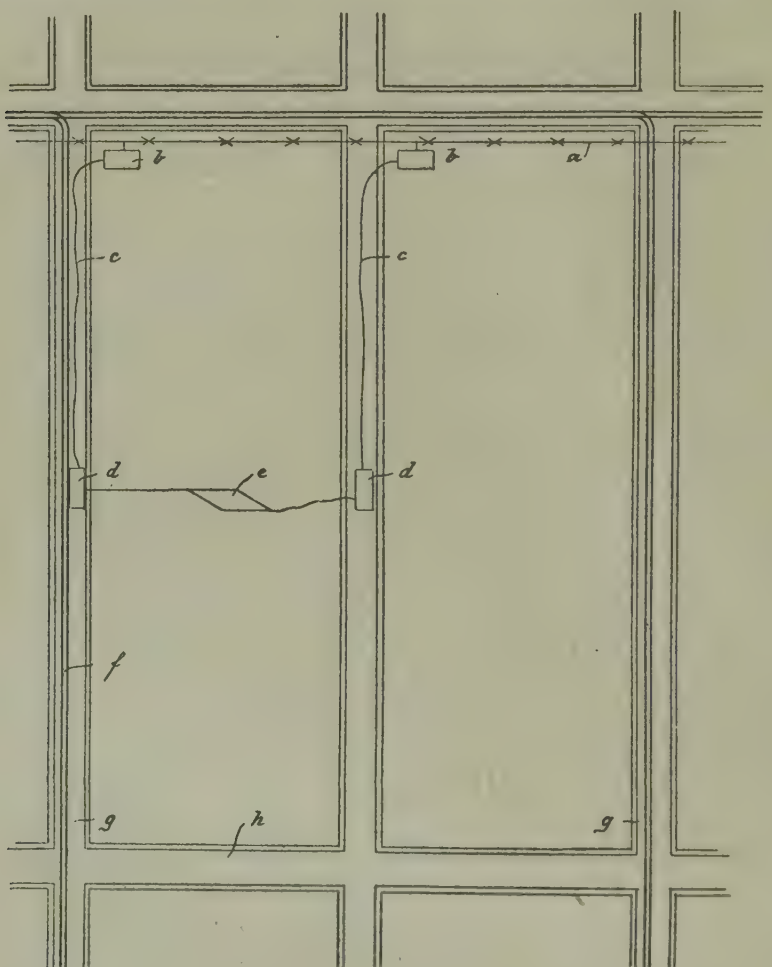
After several trials, satisfactory results have been obtained. Ploughing by electricity costs from 5 *s* 11 *d* to 6 *s* 8 *d* per acre ; a steam engine propelling itself along the moor roads and burning peat costs 5 *s* 7 ½ *d* to 6 *s* 2 *d* per acre. The lower figures represent the cost with favourable weather and with a long duration of work.

Thanks to the experience gained the windlass (anchor) trucks were constructed in such a way that they did not require a road to be made for them. In order to prevent their being dragged sideways by the powerful strains put upon them they are fitted with large hook-like attachments which press against the side of the ditch on the edge of the field and slide along it like a sledge when the truck moves forward.

As regards the ploughshare, experiments are now being made in order to ascertain whether a share which turns the furrow-slice completely over (which has been found suitable in fens) is advisable for these moors.

Experiments with cable-hauled disk-harrows have been successful and those with rollers also. For roller work, with the exception of that on the rough ploughed land, motor rollers are now used and have proved successful. They can be made heavier at will and are so arranged that they can haul a manure spreader at the same time.

Arrangement of moor land for electric ploughing at Wiesmoor.



EXPLANATION.

a. Electric line.
b. Transformer truck.
c. Cable.
d. Electric windlass.
e. Plough.
f. Portable field railway.
g. Sanded road.
h. Road not sanded.

Each plot measures 550 × 1540 yds.

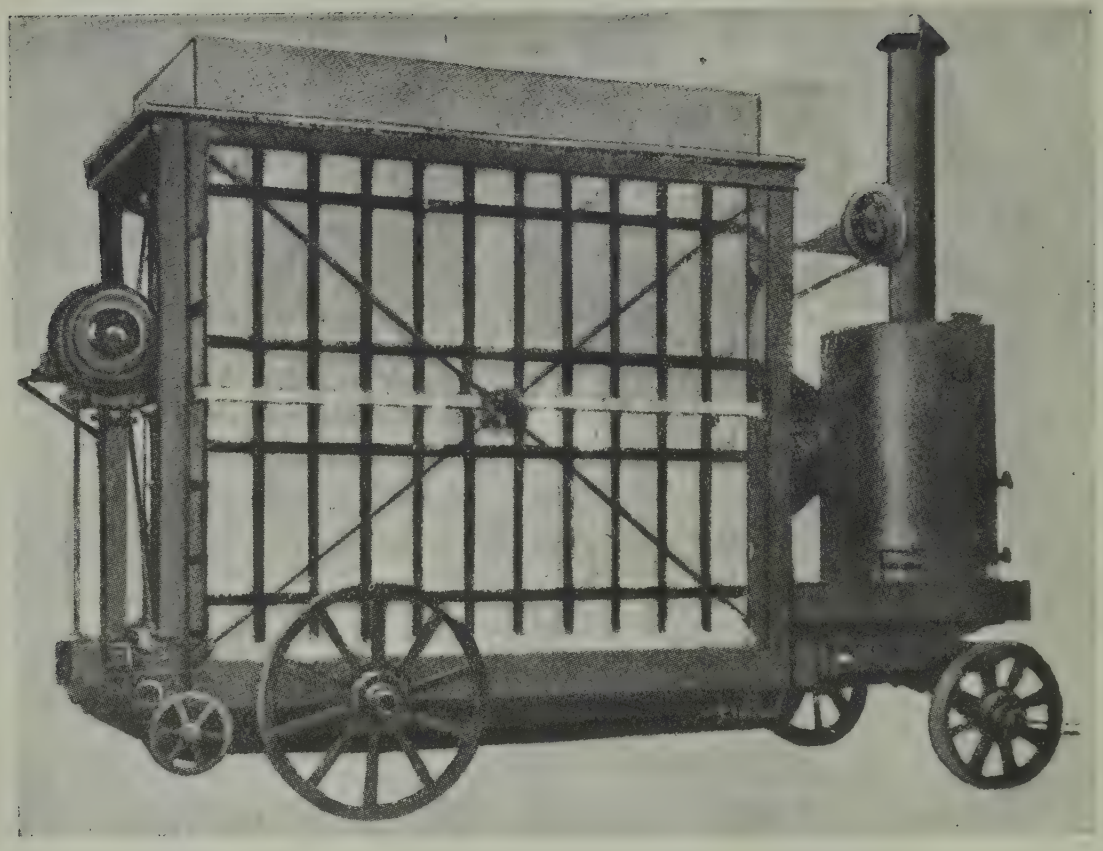


Fig. 1. — Side wiew of paddy esiccator.

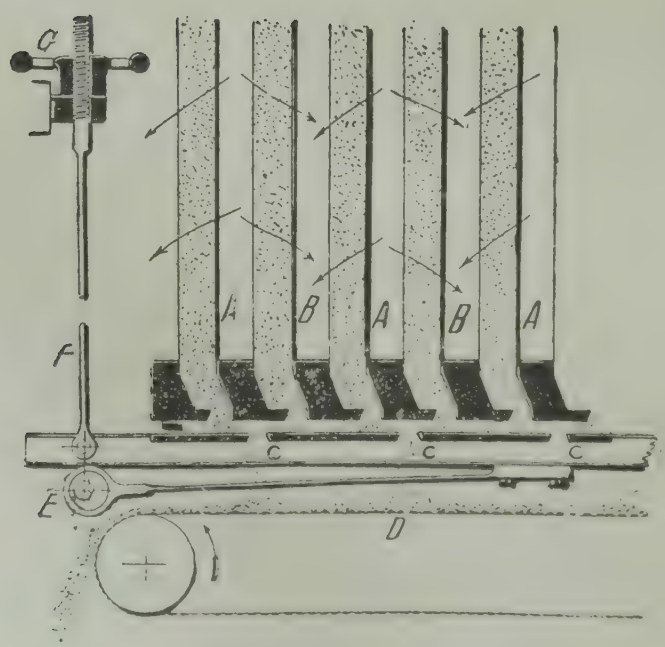

Fig. 2. — Partial longitudinal vertical section of paddy esiccator.

At Kienberg a two-engine Ergomobil plough and a rotary digger have given good results.

At Etzin a two-engine benzine motor outfit has proved very suitable for deep soft moor soil. The 24 HP motors ploughed 0.62 acre per working hour. On dry hard soil, however, the motors are not powerful enough ; they should be at least 30 HP.

At Hartenholm the motor plough has been successful on waste land that had been once broken up, but it is not yet known how it would behave on the rough virgin moor.

On the whole the reports show that the efforts for the construction of motor ploughs suitable for moors have yielded good results.

843 – **A New Esiccator for Paddy.** — TARCHETT I., A., in *Il Giornale di Risicoltura*, Year IV, No. 6, pp. 88-90. Vercelli, March 30, 1914.

A new type of portable paddy esiccator has been designed and built by Geminardi, Guidetti & Co., mechanical engineers, of Vercelli, Italy. A side view of the machine, which is simple and strong, is shown in fig. 1, and part of its longitudinal section in fig. 2.

The paddy is fed from the top into a series of vertical parallel chambers about 2 ½ inches wide and separated from each other by air spaces, A, B, of the same width. The hot air from the generator first enters into the spaces A; as these are closed at the top it is forced to pass through the rice into the spaces B, whence it escapes into the atmosphere. The temperature of the air is regulated by suitable slides in the hot air generator and in the fan.

The dried paddy issues through a slot in the bottom of the vertical chambers and falls onto the horizontal plane, CCC, which moves forwards and backwards by means of an excentric and connecting rod, and thence onto a canvas carrier which delivers it at one extremity of the machine.

The amount of rice passed through the esiccator is regulated by changing the speed of the excentric and by raising or lowering the plane C by means of the screws in G.

The vertical chambers in which the rice is dried are formed by light iron frames on which wire netting is stretched and which slide easily into grooves in the framework of the esiccator.

The machine can hold about 112 cwt. of paddy.

844 – **Artificial Hay-Drying.** — *The Country Gentleman*, Vol. LXXIX, No. 22, p. 1033. Philadelphia, May 30, 1914.

In many countries a great deal of hay is more or less spoiled or even completely lost every year by the heavy dews and rains of the haying season.

Several years ago T. P. Russell, a Southern Missouri farmer, wrote to the United States Department of Agriculture to ask whether the artificial curing of hay was not an economic possibility. The office of Farm Management began to investigate the question at his farm from 1907 to 1913 and now the problem has been solved.

Hay can be cured at a profit, be it green, half cured or soaked with rain-or dew. Freshly cut grass covered with dew or rain and containing 70 to 80 per cent. of moisture can be cured in 20 to 40 minutes into hay containing 10 per cent. of moisture and this hay can be baled immediately on leaving the kiln and will keep indefinitely.

The above-mentioned office has erected an experimental plant for the curing of hay; it is practically a barn heated by a steam boiler. At one end of the barn is a feeder chute into which the green or wet hay is fed as it comes from the fields. As it enters the chute it is caught on slowly moving belts which carry it round and round the heated interior of the barn, finally bringing it out at the other end cured and ready for baling or for storing loose.

The existing plant is worked at a steam gauge pressure of 80 or 90 lbs., which gives a maximum temperature of 260° F. (126 °C.) at the bottom of the drier, and 223° F. (106 °C.) at the top.

The hay it turns out is superior in colour to field-cured hay and has a very sweet aroma, and in repeated tests the animals before which both kinds of hay were placed ate the former first and often refused the latter.

Analysis shows that the drier-cured hay differs little from the uncured grass and is superior to field-cured hay. The protein content, on a water-free basis, is 19.15 for uncured grass, 18.70 for drier-cured hay and 13.71 for field-cured hay. This difference is partly due to larger leaf content.

Mr. Mc Clure, the official of the Farm Management Office, gives the following estimate for a hay-drying plant capable of turning out 1 ½ tons or more cured hay per hour:

Excavation	$ 104.00
Kiln superstructure, walls, roof, settings for conveyors, etc.	$ 2 160.92
Doors, hinges, guide plates	$ 233.75
Engine shed	$ 300.00
Painting and glazing	$ 281.20
Conveyors, drive, fans, turbine, elevator, regulator, castings boiler and other machinery	$ 10 422.08
Contingencies	$ 2 500.00
Total	$ 16 001.95

Of course no farmer of ordinary means can afford to invest such a sum, but large owners and cooperative associations could easily do so.

As for the cost of artificially curing hay, at the experimental plant in S. Missouri it was found that a ton of cured hay required 1.3 tons of coal. According to other experiments, however, it is asserted that in a 1500-ton drier the fuel requirements would be reduced to 0.6 ton of coal to one of cured hay. The total cost is given in table I.

Considering the advantage of assuring the regular output of crops regardless of weather, and the increased nutritive value of the hay produced by artificial means, it is safe to say that though artificial curing will not take the place of sun or field drying where and when good haying weather prevails, it will enable the grower so to cure his entire crop that it will all grade as " choice " and thus command the highest prices.

TABLE I. — *Cost of artificial hay drying.*

	When a ton of coal costs		
	2.50	3.50	4.50
Fuel cost based on 0.6 ton of coal per ton of cured hay . . . . . $	1.50	2.10	2.70
Total labour, interest, maintenance, etc. . . . . $	2.97	2.97	2.97
Total cost of curing from standing grass to baled hay in barn . . . . . $	4.47	5.07	5.67
Less cost of curing one ton in field . . . . . $	2.60	2.60	2.60
$	1.87	2.47	3.07

Besides the above investigations, the Office of Farm Management has examined the possibilities of a plant operated by direct heat. The drier consists of a sheet-iron box, 6 by 3 by 3 feet, equipped with a sliding pipe containing damper and thermometer connecting this firebox to the firebox of an ordinary steam boiler. It was fitted with woven wire trays for holding hay and a fan.

With this equipment the drier could be operated up to 700° F. (370° C.), and with an air circulation through the drier up to 4 500 feet a minute. Table II gives the results of experiments with this direct heat drier.

TABLE II.

Velocity of fan discharge	Temperature		Time required to cure	Protein
	Front (1)	Rear (1)		
ft.	deg. F.	deg. F.	minutes	per cent.
3 600	600	250	8	18.81
4 200	640	260	5	17.62
900	450	220	15	17.50
650	400	200	15	19.50
800	400	250	15	18.69
800	350	225	20	17.61
4 200	600	415	15	24.69
2 800	320	200	10	19.75
1 400	320	215	20	20.38
Cured in sun at ordinary temperature (2)				21.31

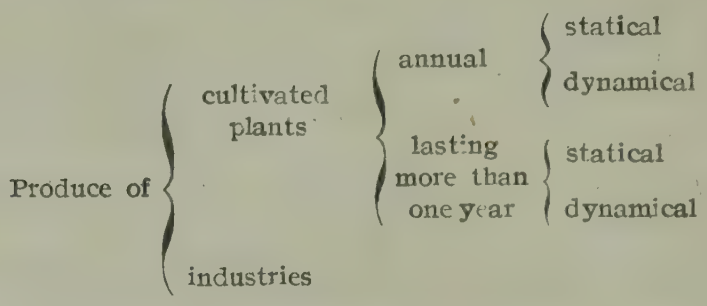
(1) "Front" where the hot air first comes into contact with the hay ; "Rear" where the air has passed through the hay and is ready to be discharged from the drier by the fan.

(2) This sample was carefully cured without the loss of any leaves and therefore does not truly represent ordinary field-cured hay.

RURAL ECONOMICS.

845 – **Statistical Research on Farm Produce.** — MARENGHI, ERNESTO. Extract from the "*Giornale degli Economisti e Rivista di Statistica*", Part I, pp. 1-31 + 2 tables. — *Atheneum*. Rome, 1914.

As an introduction to his research, the writer draws up the following scheme of farm produce:



I. — THE PRODUCE OF CULTIVATED PLANTS.

A: The group of statical annual produce. — To this belongs the yield of herbaceous crops, as well as that of woody plants submitted to yearly cultivation, that is subdivided into as many groups of the same age as there are years in the whole cycle of production.

This produce is *statical* on condition that the systems of cropping do not vary. The relative succession of these products may acquire increasing *dynamical* character only if the systems of cropping improve or deteriorate, or if new enemies or modifications of physical environment appear; but apart from these factors, the annual range of these products represented by a Cartesian diagram gives rise to a broken line, the general trend of which is parallel to the axis of the abscissae. The phenomenon of production of these crops belongs therefore to the group of those which are expressed quantitatively with sufficient approximation by the arithmetical means of a sufficient number of cases. In practice it is suggested to extend the same observation to a period of 10 to 12 years, which is justified also by theory. The writer, however, observes that in periods of very rapid intensification of agricultural production it is well to restrict oneself to the comparison of a still more limited number of terms, because to every successive stage of progress for a given crop a different *normal production* corresponds. The idea of normal production is nothing absolute in itself, as it can only refer to sharply defined conditions of cropping, case by case.

B: Group of *yearly dynamical produce.* — To this belongs the produce of ordinary woody plants not subjected to yearly management. This produce varies from time to time, not only through accidental causes like the statical, but also as a function of the age of the plantations, giving rise to very characteristic dynamical chronological series which serve for the construction of the law of production concerned. The *normal curve of production* of woody plants varies from case to case as a function of many factors: species of trees, system of management etc. One of the

fundamental aims of economic statistics is that of investigating these curves by suitably applied methodical observation.

With this object the writer proposes to replace *observations in time* which require long periods of time, by *observations in space*, by recording the actual yields of woody plants in similar regions, separately for the plants of each age.

When this observation has been continued for a certain number of years, for instance 10 or 12, there will be sufficient material to determine the normal curve of production, assuming as the normal produce of the n^{th} year of age the average of the produce ascertained on trees of that age during the various years of observation. The series of the normal yields thus obtained is the numerical expression of the normal curve which is sought.

The writer notes that by the same process, in the short space of one year the data sufficient to draw a *gross curve of coexistent yield* may be collected, and that this may lead to the normal curve when the ratio between the actual unit yield of the year under observation and the average of the region under investigation is known. Thus, representing the equation of the gross curve by

$$y = f(x)$$

the normal one will be:

$$y = K f(x),$$

in which K is the ratio defined above. The writer obtains similar results (on the hypothesis that the methods of management do not vary sensibly) with the data of a *gross series* of *successive yields*, the perfecting of which may be obtained by arithmetical, algebraical or graphical means. The first is the simplest of all: it consists in substituting for every term of the series the arithmetical means of the three, five, seven, etc., terms of which it is the middle one (Wittstein's method). The *algebraical* process consists essentially in replacing the gross curve by a simpler one which it is assumed corresponds to the real law of the phenomena. The problem is solved by causing a curve of a certain order to pass through certain points under determined conditions according to the method of interpolations. The *geometrical* or *graphical* method consists in representing the gross series by a Cartesian diagram and in interpolating in it a curve which approaches the same series and then determining according to scale the values of the ordinates corresponding to the theoretical curve.

The writer then discusses the fragmentary series and the process of interpolation based on the hypothesis, which corresponds with sufficient approximation to reality, that the yield of woody plants varies approximately according to geometric progression provided the intervals considered be not too long and the accidental oscillations be neglected.

This process of interpolation finds its analytical expression in the following formula, which allows the missing data of the series to be interpolated:

$$y = K \alpha \rho^x.$$

in which :

y = average yield of the plant at the age of $\alpha + x$

$K\alpha$ = average yield of the plant at the age of α.

ρ = constant ratio of variation

x = independent variable quantity which gives the age of the plant in any year of the interval considered, supposed to be of n years.

It follows that setting $K\sim$ for yield at the end of the same, the equation

$$K\,\alpha\,\rho^{n-1} = K\sim$$

is obtained, from which the following results :

$$\rho = \sqrt[n-1]{\frac{K\sim}{K\,\alpha}}$$

This process of interpolation thus consists in the analytical representation of the production of woody plants bearing annual produce, not by means of a single curve (in which case the approximation would be too wide), but with several and successive branches of curves connected with each other. These may be considered as the expression of as many empirical laws of the phenomenon that is investigated, each of them being, with sufficient approximation, with certain limits of age of the same plants.

The exactness and the value of the process of interpolation may be experimentally checked when suitable statistical data are available.

The writer notes in this connection the low trustworthiness of the statistical data existing as to the curves of production of woody plants bearing yearly produce, and the necessity of systematic observations of the same in order to collect valuable material for the solution of the most varied economic problems.

C : The group of polyannual produce. — To this belongs the principal production of woods not under regular rotation. These woods are either high forest, in which case the cycle of the formation of the product coincides with that of the plant, or they are coppice, and then it is a submultiple of the latter. The distinction is of a certain importance for these statistical researches, since high forest gives rise to a *chronological series of statistical produce*, whilst coppices — at least in some cases — gives rise to *dynamic series*.

The data that are necessary and sufficient to individualise the fundamental production of woods are two : the *physical quantity* (discriminated if necessary in selected groups or otherwise) and the *extent of the corresponding cycles of elaboration*, which are not fixed as they are for the annual products, but are susceptible of being varied within certain limits with the object of realizing a maximum profit, other conditions being equal. Thus the curve of the increment of wood in forest plants is characterized by the progressive decrease of the rate of increment; during this progressive diminution the limit of profitableness is reached when the rate of wood increment expressed in money coincides with the rate of interest.

D: The indices of variability of crops and the ways of determining them. A crop, other conditions being equal, presents less risk the steadier its productivity, which is expressed by suitable figures called *indices of variability*. One of the indices most frequently used for statistical series is obtained by dividing the square of the mean deviation of the mean of the fields during the various years of observation from the arithmetical mean of the whole period by this latter mean.

The writer notes that these indices of variability are not liable to generalization but are strictly connected to the special conditions of environment and proves by means of suitable examples that the range of the yield of the same crop varies within very wide limits from one locality to another as a function of many circumstances.

II. THE PRODUCTS OF AGRICULTURAL INDUSTRIES WHICH RESULT IN A MORE OR LESS ELABORATE TRANSFORMATION OF CROPS.

The ratio (at least approximately) between them is *constant* in some cases and *variable* in others. It is constant, for instance, in the transformation of grapes, olives etc., but variable in that of forage crops. The statistical investigations to be carried out in the first case are not many, it being enough to determine the coefficient of *yield per unit*. If this ratio is variable the *law of variation* has to be sought according to the systems of methodological statistics.

The writer restricts himself to a consideration of the production of milk and of meat.

The production of milk varies — for every individual kind of cow — according to many factors: breed, age, diet, stage of lactation, etc. In order to get the principal characters of the process, a sufficient number of animals have to be subjected to experiment and they have to be grouped according to age, diet, or other factor, in agreement with the problem to be solved. Supposing the factor considered be age, the average individual yield of the animals under observation will have to be determined for each class of age. The series of average yields obtained will give the curve of the facts as functions of the age; this can be further simplified by transforming the individual terms in index numbers, that is by making the first term equal to 100 or 1000 and reducing the others in proportion.

The writer reports some data collected on a group of Simmental cows and notes that the general trend of the curve of the annual individual mean shows a certain analogy to what is observed in the production of woody plants bearing fruit yearly.

The writer examines similarly the influence of the time that has elapsed from the beginning of the lactation on the yield of milk, and from the individual chronological series obtained from a Swiss cow belonging to the Perugia Agricultural Institute he finds the corresponding normal curve by means of a suitable process of equalizing. The production of milk in the months following calving diminishes very nearly in geometrical

proportion and consequently the normal curves may be represented analytically by functions of the type of:

$$y = p_1 \rho^{x-1}$$

in which
y = milk yield of any month x.
p_1 = milk yield of the first month after the birth of the calf.
ρ = a constant ratio to be determineed either by the method of the least squares or, simpler still and with sufficient approximation, by taking the average of the actual ratios which are obtained by dividing every term by the one which precedes it.

In a special table the writer compares the actual series of a group of Swiss cows with the theoretical series and notes that the agreement between the two is more than satisfactory. Even on the hypothesis that the actual series should present some gaps, the ratio ρ of variations could be equally determined (though less exactly) and the analytical formula could be found and it would among other things allow the whole series to be reconstructed and the total corresponding yearly production to be determined.

Submitting to a similar process some data relating to the production of flesh, the writer notes that the series of the increments of weight per unit in young and in adult animals in course of being fattened gives rise to a descending curve which turns its convexity to the axis of abscissae and which may be represented — as in the case of milk yield — by an equation of the type of:

$$y = p \rho^x$$

The development of animals by weight follows the economic law of increasing production. A gradually diminishing increment by weight corresponds to an increasing consumption of fodder. Admitting as a fairly probable hypothesis that the rations of animals are homogeneous for every group and directly proportional to their weight, the writer infers that the above equation represents also the action of the said law as regards the production of flesh.

846 – **The Position of Non-Breeding Dairy Farms in Modern Agriculture.** — BRINKMANN, THEODOR, in *Fühlings Landwirtschaftliche Zeitung*, Year 63, Part 13, pp. 433-449. Stuttgart, July 1, 1914.

The subject of dairy farms which do not breed their cows, especially in their importance from the point of view of social economy, is much discussed at present. The writer studies the problem exclusively from the point of view of rural economy and proposes to answer the two following questions:

1. Is it justifiable from the economic point of view to keep dairy cows without breeding them, and if so under what general conditions is this to be preferred to dairy farming with breeding?

2. What are the effects of the present changes in the conditions of the industry and of agricultural production upon the profitableness of the

two rival systems? Do they affect both systems equally or do they favour one more than the other?

I. — Both systems are intended to utilize to the utmost the fodder produced on the farm itself, and this especially by transforming it into milk. The non-breeding dairy farm can, with the same quantity of fodder, produce much larger quantities of milk than the breeding dairy farm, because the former keeps only milk-producing animals; further it possesses another advantage from the point of view of the utilization of milk in that while in the breeding farm a part of the milk produced is consumed by the calves, the other type can utilize at will all the milk that it produces and may besides regulate its production to suit the demands of the best possible utilization. These advantages ensure the non-breeding dairy farm gross returns in money which are fairly high in comparison to the quantity of fodder to be utilized. This, however, cannot be obtained without a relatively high cost of production, caused especially by the loss, which in general is considerable, entailed by the purchase and sale of cows, by the necessarily intensive feeding and great consumption of concentrated foods, by the relatively high price of labour and by the considerable risk attendant upon the continual purchase of strange cows.

From these considerations it is evident that the conditions which justify the existence of non-breeding dairy farms are present when it is possible to utilize the large quantities of milk produced in the farm in such a way that the receipts balance the high cost of production. If the price of the milk increases gradually, a point must be reached at which the advantages given by the high gross yield are superior to the disadvantages caused by the high cost of production. This is clearly shown by Table I (1), in which the yield in milk and the gross returns in cash for the different prices of milk have been calculated, then the cost of keeping the cattle, that of the concentrated foods and lastly the difference between gross returns and outlay, that is the net returns obtained by utilizing the fodder at the different prices of milk, referring all the figures to 100 kilos (220 lbs.) of starch value of the fodder produced in the farm itself. These calculations have been made for three different groups of farms: 1) dairy farms which do not breed their cows; 2) dairy farms which breed a part of their young stock; 3) dairy farms which breed all their stock.

The division of labour which exists under these two systems of dairy farming is thus perfectly justified as an economic necessity, as a consequence of the variations, from one farm to another, of the net returns obtained by the utilization of milk. After all the problem of the non-breeding dairy farm is only a question of the price of milk. Nevertheless the conclusion cannot be drawn that a limit of fixed profitableness, true under all conditions, can be established between the two systems; on the contrary, the deciding limit in the price of milk must be determined separately in each case, as it depends upon the special conditions of each farm:

(1) This table is taken from FUNK: Die landwirtschaftlichen Betriebsverhältnisse der bäuerlichen Milchwirtschaften im Havelland. — *Arbeiten der D. L. G.*, Part 169.

TABLE I. — 100 *kg.* (220 *lbs.*) *of starch value of*

	Number of farms	I. Supply					
		Gallons	Gross receipts in cash when the price of milk per gallon is:				
			d 6.44	*d* 7.48	*d* 8.56	*d* 9.60	*d* 10.7
			s d	*s d*	*s d*	*s d*	*s*
In dairy farms which do not breed	23	50.25	26 9 3/4	31 3 1/4	35 9	40 2 3/4	44 8
In mixed dairy farms. . . .	21	45.50	24 4	28 4 3/4	32 5 1/2	36 6	40 6
In breeding dairy farms. . .	13	34.75	19 2	22 4 3/4	25 6 3/4	28 9	31 11

its size, the quality and quantity of the fodder to be utilized, the requirements as to the production of farmyard manure, the professional capacity of the farmer and the amount of his capital. In general it may be said that the conditions to warrant the division between the two systems exist only where the milk is sold as such.

II. — It is evident that in the course of time the limits of the areas occupied by each system shift in consequence of the changes which occur in the conditions of profitableness. The expenses due to certain factors of production, chiefly those which weigh heavily on farms that do not breed, have increased considerably of late years. This is especially the case with concentrated foods and the losses caused by restocking the stables, and with the price of labour.

On comparing the average prices of the two periods 1901-03 and 1909-12, an increase of 14 per cent. is found in the price of earthnut cake, 12 per cent. in cotton seed, 17 per cent. in coconut cake, 18 per cent. in wheat bran and 23 per cent. in brewer's grains. The increase in the price of labour and the decrease in the quality of the work done are notorious. The increase of the cost of concentrated foods and of other expenses weighs also on the budget of breeders, but not so heavily as on the non-breeding dairies, which spend almost twice as much as the former on concentrated foods (see Table). Furthermore there has been, since 1900, a rapid rise in the prices of milch-cows, amounting to £ 5 to £ 6 per head in the Rhine Province. Though the increase in the price of milch-cows has been partly balanced by the increase in the prices of fat cattle, this rise in the price of cattle weakens considerably the position of non-breeding dairies, for in the competition between the two systems the increase in prices injures the one and benefits the other, since the high prices paid by the non-breeding dairies are an advantage to the breeders.

It is undeniable that of late years there has been a considerable increase in the sale price of milk, but according to the writer the consequent increase of the gross returns has not been sufficient to counterbalance the

odder produced on the farm (hay, straw, mangolds, etc.)

II. Require the following expenses						III. Yield a net profit when the price of milk per gallon is:									
for labour, interest, amortizement of working capital, depreciation of stock			for purchase of concentrated foods			Total			d 6.44		d 7.48		d 8.56		d 9.60		d 10.72	
s	d	per gal. d	s	d	per gal. d	s	d	per gal. d	s	d	s	d	s	d	s	d	s	d
	$3\frac{1}{4}$	1.96	13	$7\frac{1}{2}$	3.28	21	$10\frac{3}{4}$	5.24	4	11	9	$4\frac{1}{2}$	13	$8\frac{1}{4}$	18	4	22	$9\frac{1}{2}$
	$3\frac{1}{2}$	1.92	10	$6\frac{1}{2}$	2.80	17	10	4.72	6	6	10	$6\frac{3}{4}$	14	$7\frac{1}{2}$	18	8	22	$8\frac{3}{4}$
	$4\frac{3}{4}$	2.16	5	$3\frac{1}{4}$	1.76	11	8	3.92	7	6	10	$8\frac{3}{4}$	13	$9\frac{3}{4}$	17	1	20	$3\frac{1}{2}$

increased cost of production. And if such were really the case the considerably increased chances of profit in breeding caused of late by the conditions of the market would always signify a sensible loss for non-breeding dairy farms. The fact is that during the last ten years the profits of cattle breeding farms have considerably increased, both absolutely and also relatively to those of non-breeding dairy farms; it is this latter fact which settles the matter, because the question of the profitableness of a branch or a system of farming does not depend upon this branch or system paying its expenses absolutely, but rather upon its bringing in more profit than any other branch which might replace it.

The weakening of the position of non-breeding dairy farms will be still better understood when it is considered that the technique and the improvement in the means of communication and other factors tend always more to abolish the monopoly in the supply of fresh milk which formerly belonged to the districts of production nearest to the markets. Many and various circumstances concur in rendering easier the supply of milk to the centres of consumption, such as the facilitations offered by the railways for the carriage of milk, the better preservation of fresh milk due to systematic treatment, the ease with which milk can be obtained from distant districts thanks to a series of organizations of producers, traders and sometimes of consumers; all these factors and others also act in the same sense, favouring the offer of milk and opposing the increase of its sale price, increasing the utilization price in new districts of production and decentralizing the production of fresh milk. The creation of new districts of supply tends to equalize the local prices of milk and the intensity of production in the districts of supply. Those that are situated at greater distances may adopt a more intensive system; all of them, however, approach an average line in their degree of intensity. Thus, the farms which are intermediate between the non-breeding ones and those which breed all their stock are especially favoured by recent developments and will increase in importance.

847 – **The Organization of Team Work according to the Results of Bookkeeping and to Net Returns.** — OSTERMAYER, ADOLF, in *Mitteilungen der landwirtschaftlichen Lehrkanzeln der k. k. Hochschule für Bodenkultur in Wien*, Vol. II, Part 3, pp. 411-431. Vienna, 1914.

The expense for the work done by draught animals is a large item in the total working expenses of a farm. Calculated on the results of bookkeeping they have been found to be as follows, when expressed as percentages of the total cost of production.

For cereals	in the plains . . .	11.0 %
	in the mountains .	17.2 »
For beets	in the plains . . .	24.9 »
	in the mountains .	28.2 »
For potatoes . . .	in the plains . . .	19.9 »
	in the mountains .	18.3 »
For hay	in the plains . . .	13.5 »
	in the mountains .	11.4 »

The range of the amount of these expenses exerts a great influence upon the net returns of the whole farm, as the writer proves with the aid of the books of 61 Moravian peasant farms. The average net return of these 61 farms is 19*s* 11 ½*d* per acre and corresponds to a rate of interest of 3.5 per cent. on the average capital of £28 4*s* 0½*d* per acre. This result has been obtained at the average cost of 2*s* 11*d* per day's work per animal and an average number of 4.66 days per acre, which brings the expenses of team work to 13*s* 8*d* per acre. With the help of these figures the writer calculates the net returns which correspond to the range in the cost of the day's work of the animals from 2*s* 1*d* to 3*s* 11½*d*.

	s	*d*		£	*s*	*d*	
When the work day costs	2	1	the net returns are	1	3	8 ½	per acre
» » »	2	6 ½	» » »	1	1	8	»
» » »	2	9 ½	» » »	1	0	5	»
» » »	3	2 ½	» » »		18	6	»
» » »	3	5	» » »		17	7	»
» » »	3	10	» » »		15	9	»
» » »	3	11 ½	» » »		15	2	»

Among the components of the cost of the work of draught animals, the cost of feed and wages exert a decisive influence, as may be seen from Table I, in which the total cost of the day's work of an animal has been divided into its component parts for three groups of farms, each of them presenting different amounts for the keep of their draught animals.

TABLE I. — *Composition of day's work of teams.*

Group	Average cost of a day's work	Daily outlay					Partial items in percentage of total outlay				Actual number of work days out of 100 available days
		Fodder	Labour	Amortizement and interest	Sundries	Total	Fodder	Labour	Amortizement and interest	Sundries	
	s d	*s d*	*s d*	*s d*	*s d*	*s d*	%	%	%	%	
I	2 3½	– 9	– 6	– ¼	– 1½	1 4¾	53.6	34.6	2.4	9.4	60.9
II	2 8	– 10½	– 2	– 1	– 1	1 2½	70.7	14.1	6.9	8.3	45.8
III	3 8	– 11½	– 5½	– 1	– 1	1 7	58.9	28.6	5.8	6.7	43.1
Average . .	2 11	– 10½	– 4½	– 1	– 1½	1 5½	60.8	26.1	5.1	8.0	46.5

Table I shows also that the cost of an animal's day's work does not always follow the cost of keep, because it depends also to a great extent upon the degree of effective utilization of the draught animals. Consequently this utilization has a great influence on the net returns, as may be seen in Table II, which shows the average net returns of several groups of farms arranged according to the degree of effective utilization of their teams.

TABLE II. — *Average net returns of groups of farms arranged according to the degree of effective utilization of their draught animals.*

Group	Small farms		Medium farms		Large farms	
	Degree of effective utilization	Net returns per acre	Degree of effective utilization	Net returns per acre	Degree of effective utilization	Net returns per acre
		£ *s d*		£ *s d*		£ *s d*
I	98.3	1 15 4	72.5	2 10 7	62.2	1 14 0
II	76.3	18 7	54.7	1 13 10	48.5	1 13 6
III	51.9	9 10	36.8	1 4 1	41.5	1 8 0

The same results are obtained by grouping the farms according to their net returns and calculating for the groups thus formed the average effective utilization of the draught animals, as in Table III.

TABLE III. — *Average utilization of draught animals by groups of farms arranged according to their net returns.*

Group	Small farms		Medium farms		Large farms	
	Net returns per acre	Degree of effective utilization	Net returns per acre	Degree of effective utilization	Net returns per acre	Degree of effective utilization
	£ s d	%	£ s d	%	£ s d	%
I	2 5 11	95.8	3 17 3	58.7	3 8 3	51.0
II	0 18 8	82.2	1 12 6	54.0	1 0 11	55.0
III	—0 7 1	70.9	—0 4 4	53.1	0 2 0	47.1

With one exception the net returns diminish with the degree of effective utilization, so that the most intense and regular utilization of the available draught animals is a fundamental factor for obtaining satisfactory net returns.

Nevertheless in organising the work of draught animals there is another problem also to be solved, namely that of suiting the animals to the needs of the farm, not only according to their number but also according to the different kinds of draught animals. As such, horses, oxen and cows may be considered, and they differ from each other by their individual characters, pace, intelligence, facility of being driven, etc., and by the cost of their keep. The writer calculates the influence of the size of the farm, of its situation, of the intensity of farming, of the intensity of hoed crops and the outer and inner means of communication, on the conditions of the work of the draught animals in the 61 Moravian peasant farms, and illustrates by means of diagrams the employement and the degree of utilization of the different kinds of draught animals in the farms, divided into two groups according to the amount of the net returns. The results of these calculations are set forth in Table IV.

In small farms the great use of the cow as a draught animal is very advantageous ; a too liberal use of horses and oxen causes a decrease in the net returns; on the other hand in large farms the work of horses is very advisable and it should be completed by that of oxen only to a limited extent, because large farms require team work more continuously than small farms and horses are more suitable than cattle, and especially cows, to continued work.

In well organized mountain farms the work of horses is much employed, to a lesser degree that of oxen, while cows are only used as a temporary reserve during the busiest time in the summer. The increase of the number of oxen and the simultaneous reduction in the number of horses causes a decrease of net returns. Similarly in the plains the best utilizatilon of the draught animals is obtained only by the supplementary use of the labour of oxen, though the number of horses is by far superior to that of the oxen. The organization of the team work in intensive farms with high net returns resembles very closely that of well managed plain farms,

TABLE IV. — *Work-days of horses, oxen and cows under various conditions.*

			Small farms, less than 24.7 acres	Large farms, over 74.1 acres	Plain	Mountain	Working expenses per acre: Intensive, over £5 1s 2½d	Working expenses per acre: Extensive, under £5 1s 2½d	Hoed crops: Intensive, over 12 %	Hoed crops: Extensive, under 12 %	Distance from market: under 3.11 miles	Distance from market: over 4.66 miles	Rounded property and fields near farm	Scattered property and fields far from farm

		used (1)	1 859	2	0	782	886	0	1 364	909	750	492	922	640

(1) As the cows' keep is not to be debited to the labour account except when the cows actually work, the available cow days have been put equal in number to those effectively utilized.

because the good climatic conditions and the fertile plain land lead to an intensification of farming. It is a mistake to make much use of cows as draught animals in intensive farms and it reduces the net returns. Nearly the same results are obtained by grouping the farms according to the intensity of the hoed crops.

It follows that the horse may be considered as the draught animal *par excellence* for intensive farms. On the other hand well managed farms under extensive cultivation show a remarkably small use of the horse and a notable preference for the work of cattle, both oxen and cows, and it is especially in farms with not much land under hoed crops that the work of cows is prevalent. Errors of organization in this case are the prevailing use of horses, which are insufficiently utilized, and the neglect of cows, which are the most suitable draught animals for extensive farming.

Farms near the markets can utilize cattle to a greater extent than those situated further off, notwithstanding the constant tendency towards the intensification of culture, and without diminishing their net returns; they are even forced to do so in order to utilize regularly their draught animals. Indeed the necessity of a good deal of carriage is a factor of an equal distribution of animal labour, inasmuch as this transport work may generally be performed at the times in which work is slack on the farm. This explains the great amount of horse labour in farms at a distance from markets and yet yielding considerable incomes.

It is the same with the distance between the fields and between these and the farm. A very small distance or none at all favours the intensification of culture and leads to the prevalent work of horses, completed by that of oxen and cows, with a view to equalizing the distribution of the work. The use of horses becomes still more prevalent in those farms in which the fields are wide apart and distant from the farm itself. This group of farms is the only one which still gives high returns while using only horses as draught animals; this is explained by the time saved by the quick pace of the horses in covering the above distances. In these conditions the use of cows would be an error.

From what has been said it appears manifestly that in organizing the work of the animals of a farm the capability and the characters of the different draught animals employed are the basis on which they are to be chosen. It is only by combining and completing reciprocally the work of the various animals in harmony with local conditions that it can best be utilized with the object of keeping the cost of production low and of obtaining high net returns.

The writer demonstrates the truth of the above by means of diagrams containing for the previously mentioned 61 farms, divided into two groups according to the amounts of net returns, the curves of the horse, ox and cow days, per week and per 100 acres of area of cultivated land. These curves are compared with each other and with the line representing the annual average of the work days, expressed in horse-days per week, in the farms yielding high net returns.

848 – **Investigations into the Profitableness of Fen Cultivation.** —FRECKMANN, W., and SABOTTA, in *Landwirtschaftliche Jahrbücher*, Vol. XLVI, Part 2, pp. 275-326. Berlin, 1914.

The writers endeavour to solve the problem of the profitableness of fen cultivation on the basis of the experience collected during ten years of work at the Neu Hammerstein Moor Experiment Station, with the help of the data contained in the literature on the subject. In the first place they try to determine the capital that is necessary for such undertakings and then they discuss the ratio between the purchase price of the bare fen and the capital required for improvements. They estimate the capital for buildings for all kinds of farming at the average figure of 25 per cent. of the total value of the land.

In the calculation of the profitableness of the regularly installed fen farm, there is no question of ascertaining the amount of expense for each unit of the original acreage, but of determining the extent of utilisable areas after the improvements have been carried out, as well as the cost of purchase and improvement of the unit of productive surface of fen in order to know the interest that it bears. Draining by means of open ditches means a considerable loss of area. The writers calculate the amount of this loss, and the capital represented by the Neu-Hammerstein fen farm, as follows :

Unsanded meadows.

	£	s	d
A) *Drainage by open ditches :*			
1. Preparatory work per acre	1	19	8
2. Drainage by open ditches	1	6	9
3. Work on the slopes and sowing		6	4
4. For the main drainage canal		3	2
5. For roads		1	11
Total per acre of original area	£3	17	10
For one acre of cultivable surface the cost of cultivating is as follows :			
1. Preparatory work, draining, main drain, and roads per acre of cultivable land, with a loss of 2.25 per cent. or $\frac{£3.17.0}{0.9775}$	3	19	9
2. Ploughing (8 inches) including hoeing	1	11	9
3. Disk-harrowing		19	0
4. Manuring :			
a) 6.37 cwt. kainit, 4.78 cwt. basic slag, including haulage	1	1	1
b) Mixing, carting and spreading.		2	4
5. Sowing :			
a) Rolling		1	2
b) 9 ½ lb. clover and grass seeds	1	7	11
c) Sowing			9
d) Rolling with light roller		1	2
Total	£9	4	11
Purchase value £11 18*s* per acre of bare fen : cost of cultivable area $\frac{£11\ 18s}{0.9775}$	12	3	6
Cost of buildings per acre	7	18	9
Total cost per acre of cultivable area	£29	7	4

B) *Drainage by fascines:*			
1. Preliminary work	1	19	8
2. Drainage by fascines	2	7	8
3. Main drainage canal		3	2
4. Roads		1	11
Total per acre	£4	12	5
5. Ploughing and hoeing	1	11	9
6. Disk-harrowing		19	0
7. Manures, carting and spreading	1	3	6
8. Sowing	1	11	1
Total	£9	17	9
Purchase value	11	18	0
Buildings	7	18	9
Total	£29	14	6

In this way the writers calculate the cost of purchase and improvements per unit of area of the meadows and arable land and come to the following results (Table I).

In preparing sanded fen cultivation it is generally much more advantageous to bring the sand from outside rather than to excavate it from the subsoil of the fen, because a layer of 5 inches taken from the subsoil would cause an average loss of area of 20 per cent.; the consequent increase of the cost of installation per acre of cultivable surface would equal the cost of getting the sand from a distance of 2 660 yards, so that up to this distance this means must be preferred. There is the further reason that the subsoil sand is often exceedingly fine and harmful.

An argument in favour of underground drainage is that it avoids loss of surface. Unless special technical reasons, such as the depth and special nature of the fen, or the constitution of the subsoil, or the impossibility of obtaining pipes or fascines at reasonable prices and of conveying them to the fen (often lacking in roads), oblige the open drain to be resorted to, this form of drainage should be avoided.

Besides the financial reasons it must also be borne in mind that open drains in winter do not carry off a sufficient quantity of water, and further that the vegetation on the edges and slopes of the ditches affords protection to animals and plants injurious to crops.

In establishing the cost of producing the several crops the writers include in the general farm expenses: the interest on the instruments of production (live and dead stock and stores), all expenses for management and supervision, for bookkeeping taxes, dues, repairs of buildings and roads, wear and tear of buildings and plant, etc. For the individual crops the following percentage of the gross yield is considered as general expenses: for meadows 12 per cent., for pastures 10 per cent., and for field crops 15 per cent.

In the calculation of the crop returns the writers use figures that are somewhat below the real average yields at Neu Hammerstein, as in Table II.

TABLE I. — *Cost of land and improvements on fen soil (per acre).*

Description of system of cultivation	1 Value of improvement	2 Purchase price of land	3 Value of buildings	4 Capital (2 + 3)	5 Total value (1 + 2 + 3)	6 Share of cost of improvement in % of total value	7 Ratio of purchase price of land to value of improvement

The results show that a fen farm when suitably drained and managed is profitable from the point of view of both private and public economy.

On the distribution of the area devoted to the different crops the general economic and market conditions have a great influence. Field crops always require a sufficient amount of labour for the suitable tilling of the fen soil.

The cultivation of unsanded fens is to be practised only when the excessive distance from the mineral soil does not allow the dressing to be applied at a reasonable cost.

Underground drainage by means of pipes or fascines is under all circumstances to be preferred to open ditches for permanent pastures and field crops and this all the more the higher the purchase price of the bare soil.

For sanded fen soils, wheat, rye, oats, barley, potatoes, beets, grasses, beans, rape and colza are to be considered as sure crops. Other pulse, as well as serradella and mixtures of pulse and cereals (with the exception of lupins) are not to be quite neglected, but they are less advantageous. Sugar beets are to be grown according to the results of local trial in each individual case. Clover can only be considered in connection with grass leys.

For unsanded fen land the most suitable crops are rye, mixtures of wheat and pulse, beans, potatoes, and Swedes; next come rape and colza; oats and barley must be considered as doubtful. Wheat and beets are in general to be avoided, and they can at most be considered on fens that have been warped.

The injury to fen crops by frost and pests must also be carefully examined with a view to finding the most suitable means of protection. There is, however, a certain compensation between the drawbacks of farming on fens, such as severe winter or spring frosts, various pests and the abundance of weeds, and the fact that fens are better ensured against the consequences of continued drought than the best deep higher soils.

In the droughty year 1911 the valuable loess soils gave miserable yields of hoed crops, clover and spring cereals, while the crops in the fens were not much inferior to the average. At Neu Hammerstein they yielded as follows:

	Lbs. per acre	
Winter rye	3 200 grain	6 000 straw
Horse beans	2 750 »	7 300 »
Oats	3 900 »	5 600 »
Potatoes	40 900	
Mangolds	50 700	
Carrots	83 750	
Meadows	8 000	
Pastures	430 increase of live weight.	

849 – **The Cost of Establishing an Orchard.** — EVANS, L. A. — *The Cultivation of the Apple in Tasmania.* Hobart, 1914.

The following are the data on the cost of establishing two apple orchards, one 25 acres in extent and the other 100.

Twenty-five acre orchard.

	£
Twenty-five acres at £20 per acre (ready for the plough)	500
Fencing, packing-shed and cottage	350
Five thousand trees at 70*s* per 100	175
Planting 25 acres	15
Five years' cultivation, pruning, etc., at £4.10*s* per acre	560
Interest on outlay for five years at 5 per cent. compound interest.	370
Unforeseen expenses	30
Total . . .	£2000

The returns from the fifth to the seventh year may fairly be calculated to pay the orchard expenses. From the tenth year onward the annual return from the orchard should be at least 6 000 bushels. These, at the moderate estimate of 2*s* 6*d* per bushel on the trees, give £750; deduct £225 for working (calculating at £9 per acre), leaving £525, from which the annual interest on £2000 has also to be deducted. Thus there would be a clear income of £425. It must not be forgotten that a *bona fide* settler gives his own work and would thus save £80 a year; in addition if he has £2000 capital he would get the interest on the amount invested, or an average of £74 per year, giving him £154 to live upon until the orchard came into bearing; further that the price of 2*s* 6*d* per bushel on the tree is a moderate price and that by careful attention to packing and good judgment in marketing higher prices can be realized.

The following estimate deals with a 100-acre orchard:

Estimate of cost of 100 acres of land cleared and planted with apples.

	£
First cost of 100 acres of land, at £5 per acre	500
Grubbing, etc., and clearing land to make it fit for ploughing, at £6 per acre	600
Cost of ploughing and subsoiling	100
Two-year-old apple trees at £3 per 100, planting 100 per acre . .	300
Cost of planting	100
Purchase of four farm horses	100
Implements and tools	300
Fencing with wire netting	80
Draining	100
Cost of buildings for manager, workmen, stables, etc.	780
Manuring young trees, artificials	450
Horse feed and cost of keeping horses for one year £100, labour and management £824 per year for five years	4620
Total cost of 100 acres of orchard at the end of five years containing 7-year-old trees	£8000

AGRICULTURAL INDUSTRIES.

INDUSTRIES DEPENDING ON PLANT PRODUCTS

850 – **Refrigeration and Aeration of New Wines as as a Means of Hastening their Maturity.** — KLOSS, J., and SCHNEIDER, F., in *Allgemeine Weinzeitung*, Year 31, No. 28, pp. 313-315. Vienna, July 9, 1914.

The writers carried out at the zymo-chemical laboratory of the College of vine and fruit growing at Klosterneuburg (Austria) several experiments on new white and red wines in order to study the effect of refrigeration followed by intense aeration on the maturing process. The wines, in bottles and in casks, were kept during 24 to 48 hours at temperatures of 28.4 to 26.6° F. (at which temperatures they did not freeze), after which they were aerated (by passing air through them for 24 hours or racking them off and allowing them to fall in a shower through air) and then stored in a cool cellar for a fortnight. They were then filtered and examined. The wine used as control was not refrigerated, but otherwise it was treated in the same way.

The results were as follows : In red wines no effect of refrigeration could be determined. In white wines, on the contrary, the colour was darker than in the control wine and the taste and fragrance had decidedly more of the character of old and ripe wines. Chemical analysis showed a marked decrease in the content of nitrogenous matter; such a decrease is produced only by keeping wine a long time in cellarage and racking it repeatedly. The processes of oxidation, which cause certain constituents of wine (especially those containing nitrogen) to become insoluble and consequently to precipitate, take place much more rapidly in refrigerated wines.

Another benefit derived from refrigeration and aerating was seen in that the wines so treated and then filtered kept perfectly clear, whereas the control wines very soon became turbid, which change is connected with the nitrogenous matter still contained in the wine.

INDUSTRIES DEPENDING ON ANIMAL PRODUCTS

851 – **Development and Present Situation of Milk Recording and Book-keeping Associations in Denmark.** — *Prepared from a communication from* A. C. DUBORG, *Adviser, Rudköbing, Denmark.*

According to a communication from the Danish Statistical Bureau, there were in 1909, 519 Record Associations in receipt of subventions from the State. Of this number 128 had been founded between 1895 and 1899, 207 between 1900 and 1904 and 184 between 1905 and 1909.

In 1909, 12 572 farmers possessing 224 837 cows were members of record associations, while 167 235 farmers with 1 047 316 did not belong to any association, and 2 566 farmers with 9 821 cows had not sent in any answer to the enquiry.

The following figures for the year 1909 show the connection between the size of the farms, the number of animals and milk recording :

Size of farm	Percentage of farms in which milk records are carried out	Percentage of cows under record out of total of country
up to 1.36 acres	0.3	0.5
from 1.36 to 12.26 »	1.1	1.4
» 12.26 » 36.80 »	3.3	4.7
» 38 80 » 73.60 »	11.2	14.8
» 73.60 » 147.20 »	18.9	24.5
» 147.20 » 588.82 »	21.1	34.4
Above 588.82 »	38.8	46.3
On the whole . .	7.2	18.0

It is thus evident that it is mostly the larger farms that submit their cattle to milk recording.

Many of the larger farms carry out milk recording by themselves and these are not included in the above figures.

The number of milk recording associations has been almost stationary since 1909; this is due to the fact that the greater part of farmers interested in cattle breeding, in so far as conditions allow, belong already to these associations.

In northern and western Jutland there are only a few record associations, as there fattening is prevalent. On the islands and in south-eastern Jutland about a quarter of the number of cows are under record, in Fünen a third.

By the union of the associations into federations a certain uniformity of method is attained. Milk recording has already exerted some influence on breeding. At cattle shows only bulls which can show controlled performance records of their dams, grandams, etc., are exhibited. In Fünen fairly high performances of the dams have been required as the lowest limits for admission to the shows.

The law of June 8, 1912, provides a yearly state subvention of £5 600 for these associations, each of which gets £11 on condition of conforming to certain regulations.

A record association has usually from 15 to 25 members with about 400 cows. The control work is carried out about every 20 days. The yearly cost per cow amounts to from 1*s* $5\,^3/_4 d$ to 1*s* $10\,^1/_2 d$ per cow and without the State grant to 2*s* 2*d*; in these sums the board and lodging given by the members to the control assistant are not reckoned.

Of late years the tendency is towards entrusting the control assistants not only with the accounts immediately connected with the milk records but also with the whole book-keeping of the farm. Thus the record associations gradually become book-keeping associations. The beginnings of these associations were fairly simple but not uniform. In the year 1908 such a book-keeping association was founded at Langeland and it has been followed by others. The work of milk recording goes on in them as usual, only as the book-keeping associations are smaller, the records

can be made oftener, which is all to the advantage of the greater trustworthiness of the results. Tha farm accounts at the same time supply a certain check on the performance records. The number of members is, as a rule, from 15 to 18; they farm from 1 200 to 2 000 acres and own 200 to 300 head of cattle.

The cost of the book-keeping is reckoned on the basis of the acreage of the farm, while the cost of milk-recording is based on the number of head of cattle, as in the other record associations. A farm of 61 acres pays for its book-keeping from 22 to 33*s* a year. The farmers enter in specially prepared books and a cash book the several transactions according to the system of simple entry. When the record association assistant visits the farm, for the first time in every month, he posts the farmer's entries in the regular account books kept on the double entry system. This has the advantage that any error can be rectified at once *viva voce* and on the spot. According to the wish of each member the books are kept with a greater or lesser number of accounts. In general the farmers desire to know the returns of the various crops and the profitableness of the different branches of their farms.

852 – **Preserving Milk Samples for Examination.** — TILLMANNS, F., SPITTGERBER, A., and RIFFART, H., in *Zeitschrift für Untersuchung der Nahrungs- und Genussmittel sowie der Gebrauchs-Gegenstände*, Vol. 27, Part 12, pp. 893-901. Münster i. W., June 15, 1914.

According to the writer's experiments the requirements of an ideal means of preservation are: 1) It must preserve the degree of acidity of the milk for at least 72 hours. 2) It must not bring about any change in the behaviour of the milk to alcohol. 3) It must cause no change in the physical and chemical composition of the milk. 4) It must not have any action on the nitrates which may be contained in the milk and especially *a*) it must preserve the nitric acid from decomposition, *b*) it must have no action on diphenylamine, neither weakening nor reinforcing its effect.

In view of these requirements the experiments made by the writers in their research for the most suitable substance, led to the discarding of a number of substances commonly used. They tried chloroform, thymol, oil of mustard, phenol, creosote, sodium fluoride, mercuric chloride, and potassium bichromate. The latter substance reacts strongly on diphenylamine and should have been discarded, but it was tested owing to its current use.

The examination of the above-named substances led to the following results:

Thymol, phenol, creosote and sodium fluoride cause the milk to coagulate after 24 to 48 hours. Bichromate of potash, owing to the intense yellow colour it gives to milk, does not allow an accurate determination of the degree of acidity to be carried out. Chloroform causes an increase of refraction and of fat content. Creosote causes a decrease of specific gravity. Thymol and creosote enfeeble the diphenylamine reaction to a considerable extent. This is also the case in a small degree with oil of mustard and phenol. Bichromate of potash causes milk to give a strong

positive reaction with diphenylamine, even without the addition of a nitrate. Of all the means of preserving milk only chloride of mercury answers to the above-mentioned requirements. When used in a 0.04 to 0.03 per cent soution it preserves milk quite fresh for 120 hours without any noticeable increase of acidity.

Further it has no action whatever upon the milk constants and allows the quantitative determination of nitrates to be carried out even after 120 hours. The use of chloride of mercury for official milk control is, however, owing to its poisonous nature, only admissible with certain precautions. Thus to allow it to be easily recognized the writers add Congo red to the sublimate. This colouring matter, used at the rate of 0.2 cc. of a 2 per cent. solution in water in 250 cc. of milk, has no effect at all upon the results of the analysis of the latter.

PLANT DISEASES

GENERAL INFORMATION.

LEGISLATIVE AND ADMINISTRATIVE MEASURES.

853 – **Decree of the President of the French Republic, June 9, 1914, Authorizing the Introduction into France of Plants other than Vines through the Dijon Customs House.** — *Journal officiel de la République française*, Year 44, No. 166, p. 5389. Paris, June 20, 1914.

Art. 1. — Trees, shrubs and all plants other than vines coming from foreign nurseries, gardens, hot-houses and orangeries may be introduced into France through the Dijon Customs House under the conditions set forth in articles 2 and 3 of the decree of August 28, 1882.

Nevertheless, the certificate of the competent authorities of the country of origin will not be required when the plants come from an establishment entered in the lists published according to article 9, paragraph 6, of the International Phylloxera Convention.

Art. 2. — The Ministers of Agriculture and of Finance are charged, in their respective spheres, with the carrying out of the present decree.

854 – **Order of the French Minister for the Colonies, June 19, 1914, forbidding the Importation of Hevea Plants into Indo-China.** — *Journal officiel de la République française*, Year 46, No. 170, p. 5488. Paris, June 24, 1914.

Art. 1. — The importation into Indo-China of hevea plants is forbidden ; the introduction into the Colony of hevea seeds is allowed and is not subject to any disinfection.

Art. 2. — The Governor-general of Indo-China is charged with the execution of the present order.

855 – **Order of the French Minister for the Colonies, June 19, 1914, Establishing Regulations Concerning Disease in Coconut Plantations in Cochin-China and in the Annam and Cambodia Protectorates.** — *Journal officiel de la République française*, Year 46, No. 171, pp. 5534-5535. Paris, June 25, 1914.

Art. 1. — A regulation concerning disease in coconut plantations has been established on the following bases in the Colony of Cochin-China and in the Annam and Cambodia Protectorates.

Art. 2. — Any person, owner, manager, farmer or holder in any way of coconut plantations which have been attacked by the Coleoptera known as elephant beetle or black beetle (*Oryctes rhinoceros* L. ; in Annamese the perfect insect is called " con kien vuong " and its larva " con sung ") or those known as coconut weevil (*Rhynchophorus ferrugineus* Oliv. ; in Annamese the perfect insect is called " con bu xe ", its larva " con duong ") or by any other insect or in general by any disease of whatever nature, must immediately declare it to the nearest native or French authorities, who will without delay forward such declaration to the Chief Administrator of the Province, who, after having ordered a technical examination of the plantation, will order one of the following measures.

Art. 3. — If the trees are only slightly attacked by the elephant beetle, that is to say if only 5 or 6 holes bored by the insect have been found, the owner or other person in charge must have the holes stopped with a composition containing pitch, coal-tar or similar compounds, and must destroy throughout the property all the sources of infection as defined in art. 5 ; he must also carry out such other measures as may be ordered by the authorities, in particular those which will be set forth in the special instructions published by the Administration.

Art. 4. — If the trees are either dead, badly attacked by the elephant beetle, or simply attacked by the weevil, they must be uprooted and either entirely destroyed by fire or completely immersed in water so that the eggs, larvae, pupae or perfect insects be destroyed and that the débris may not became a breeding place or a refuge for new parasites.

Art. 5. — Any person possessing lands at a distance of less than 2 km. (1 ¼ mile) from a coconut plantation (that is an area planted with about 40 coconut palms per acre) is bound to destroy on the land belonging to him, the palms or other plants attacked by the elephant beetle or the weevil, to remove or destroy the dead plants, trunks or debris of coconut trees, and the heaps of manure or any other decomposing organic matter in which the presence of larvae of beetles has been detected or which may become sources of infection.

Art. 6. — The Chief Administrators of the provinces and their assistants, the Agents of the Agricultural and Commercial and Forest Services, or any officials appointed by the Government, are to have free access to the coconut plantations, whatever their extent, in order to ensure the observance of the present Order. They can draw up reports which will be conclusive in default of proof to the contrary.

Art. 7. — Any person refusing or neglecting to comply with the instructions contained in the above articles 1, 2 and 3 is subject to the penalties set forth in articles 479 and 482 of the Penal Code.

Art. 8. — The same judgment inflicting the above penalties may, in the cases contemplated by articles 4 and 6, order the destruction of the trees or sources of infection by the village and at the expense of the offender. If it is an European or a person considered as such, this destruction will be carried out in the same way but under the supervision of a police officer.

Art. 9. — The Governor-general of Indo-China is charged with the execution of the present Order.

856 – Italian Royal Decree of May 3, 1914 (No. 425), Instituting an Independent Phytopathological Observatory at Turin. — *Gazzetta Ufficiale del Regno d'Italia*, Year 1914, No. 136, pp. 3056-3057 Rome, June 10, 1914.

Art. 1. — An independent Phytopathological Observatory is founded at Turin on the initiative of the Agricultural Association (Comizio Agrario) of Turin ; the expenses are defrayed by the Commune, the Savings Bank, the Chamber of Commerce, the Charitable Foundation of St. Paul, the Grand Masters of the Orders of Saints Maurice and Lazarus and of the Crown of Italy, and the Agricultural Association, with assistance from the State.

Art. 2. — The objects of the observatory are : *a*) to follow carefully any condition of disease in cultivated plants and to study its causes and remedies ; *b*) to spread among farmers, by means of meetings, talks and practical lessons to be given in various localities, a precise knowledge of the diseases of plants and of the best means of controlling them ; *c*) to start, with the cooperation of farmers, experiment fields for the protection of plants against the most widely spread diseases ; *d*) to watch over the public gardens and avenues of the city of Turin from the point of view of plant diseases and at the request of the Municipality, and if necessary to assist in the application of suitable means of control ; *e*) to examine doubtful mushrooms and other fungi at the request of the Bureau of Hygiene ; *f*) to give verbal or written consultations to the farmers of the district ; *g*) to attend to the institution of a special Museum of Plant Pathology ; *h*) to examine the seeds of cultivated plants as to purity and germination ; *i*) to undertake the services of vigilance, warning, prevention and cure of the diseases of plants in Piedmont.

Art. 3. — The observatory is managed by a Board of Administration composed of representatives nominated one each by the Ministry of Agriculture, the Turin Savings Bank, the Turin Agricultural Association, the Municipality of Turin, the Chamber of Commerce and Industry of Turin, the Charitable Foundation of St. Paul, the Grand Master of the Order of St. Maurice, and those bodies or private persons who contribute annual subscriptions of not less than £ 20. The members of the Board hold their seats for three years and may be re-elected. The Board elects from among its members a president, also for three years and eligible for re-election. The director of the observatory is a member of the Board and acts as secretary.

Art. 4. — The Director is at the head of the scientific activity of the Institute ; he must present every year to the Board of Administration a report upon the work done in the course of the year, the programme of the experiments to be carried out in the following year, the estimate of the expenses and the balance sheet of the preceding year, audited by an accountant who is elected every three years by the Board and who may assist at the Board meetings as advisory member. Every year a copy of

each of these documents will be sent to the Ministry of Agriculture, Industry and Commerce.

Art. 5. — Besides the Director, the staff of the Observatory includes an Assistant Director and a Curator-Secretary. The Assistant Director has the supervision of the Laboratory and, when necessary, replaces the Director. The Curator-Secretary is entrusted with the books, correspondence, library and collections, and if he has a degree he may substitute the Assistant-Director. If the budget allows, a second Assistant may be engaged according to the decision of the Board of Administration. The President, after consulting the Director, may nominate one or two special volunteer or honorary unpaid Assistants, who will have the right to frequent the Observatory and to make use of the scientific material according to rules laid down by the Director.

Art. 6. — The Director is nominated according to the results of a competition organized by the Board of Administration and his nomination must be approved by the Ministry of Agriculture. The rest of the staff is nominated by the Board of Administration on the proposal of the Director.

Art. 7. — The funds of the Observatory are provided as follows: the State contributes £80 under chap. 66 of the Budget of the Ministry of Agriculture, Industry and Commerce for the year 1913-14, and in the corresponding chapters for the succeeding years; the Municipality of Turin £ 20; the Turin Savings Bank £ 80; the Chamber of Commerce of Turin £ 20; the Grand Master of the Order of Saint Maurice £ 20; the Charitable Foundation of St. Paul £20; the Agricultural Association of Turin £ 10. The Commune, besides its pecuniary assistance, provides housing, water, gas, stationery and plant other than scientific (furniture, etc.). The Ministry of Agriculture will also, in virtue of the Law of June 26, 1913 (No. 888), which deals with measures for the prevention and cure of the diseases of plants (1), furnish special funds for the services of vigilance, reporting, prevention and treatment of diseases of plants in Piedmont.

Art. 8. — The advice given to farmers is free of charge. The Board of Administration may however establish a tariff for the reports and other work demanded by the public.

Art. 9. — Other local institutions may give their adhesion to the present Statute, lending their aid to the Observatory and securing representation on the Board by agreement with the founders and with the approval of the Ministry of Agriculture, Industry and Commerce.

Art. 10. — Special regulations proposed by the Board and approved by the Ministry of Agriculture will regulate the working of the Observatory.

Temporary provision.

Art. 11. — The present staff (Director and Assistant Director) of the District Observatory (2) will continue its work in the Independent Phytopathological Observatory.

(1) See No. 995, *B.* Aug. 1913.
(2) See No. 278, *B.* Jan. 1911 and pp. 1000-1005, *B.* July 1913. (*Ed.*)

BACTERIAL AND FUNGOID DISEASES.

GENERALITIES

857 – **The Conditions determining the Outbreak of Vine Mildew in Hungary** (1). — *Communicated by Dr.* Gy. Von Istvanffi, *Professor at the University and Director of the Royal Hungarian Central Ampelological Institute, Budapest.*

The Royal Hungarian Central Ampelological Institute of Budapest has now published (in Magyar) the fifth volume of its works ; this contains the studies made by Dr. F. Sávoly under the direction of Dr. Gy. von Istvanffi. An abstract has also been published in French, as Vol. V of the *Annals* of the Institute ; this was prepared on the occasion of the International Congress of Viticulture held at Lyons from July 20 to 22, 1914.

The most important results of Dr. Sávoly's work may be summarized as follows :

I. — The climatic conditions required by mildew cannot be determined except by carrying on researches for several years on an extensive and varied territory and by methodically working up the data thus obtained.

II. — Only study of the weather before the first appearance of mildew can lead to satisfactory results. It is sufficient to consider the temperature and the quantity and frequence of the rain. As unit of territory, the district (" járás") has been taken. The dates of the first appearance of the disease were noted on a map and the parts in which it appeared simultaneously were joined up by lines. The curves so obtained are called " isophanes " and the areas enclosed between them " isophanic belts ". Starting from the first appearance of mildew and proceeding to the relatively late appearances, we distinguish a series of isophanic belts, each member of which corresponds to a period 1.55 times as long as the preceding one.

III. — Comparing the data obtained from 1910 to 1912 the following observations can be made : 1) The earliest appearance of mildew in Hungary was on May 21. 2) In general most of the dates of appearance were between June 5 and 15, that is to say during the flowering -period of the vines. 3) The date of the infection which causes this general outbreak of the disease must be sought in the last ten days of May.

IV. — The comparison of the mildew maps of the last four years gives the following results : 1) The first appearance of mildew occurs in the same locality every year, and its spread almost always follows the same main routes. 2) This characteristic constancy does not depend so much upon the weather as upon orographic causes and those connected with the nature of the soil. 3) In its spread mildew does not make jumps, but proceeds gradually from one locality to another ; starting from the point at which it first appeared, numerous transition points are found towards the spots in which it appeared later. 4) The speed at which mildew spreads is not the

(1) See also No. 68, *B.* Jan. 1913; No. 1208, *B.* Oct. 1913 ; and No. 529, *B.* June 1914. (*Ed.*)

same in all directions, but the speed in the several directions seems to be constant every year.

V. — The features more or less common to these four years are very visible on the map representing the appearance of mildew in its general outlines. It is seen also: 1) That in general mildew starts from a triangular area the vertices of which lie near Kaposvár, Villany and Kecskemét. 2) That the disease advances for a certain time approximately in the directions marked by the angles of this triangle. 3) Independently of this first area, and one or two isophanes later, secondary centres of infection are observed, especially in the Kis-Alföld (Small Hungarnia Plain), then near Versec and on the sands of Hajdu and Szabolcs counties. The last-named is the most important, as it is the point of departure of an independent invasion.

VI. — Mildew generally makes its appearance in the following order: first in the country to the north of the Mecsek mountain, between Kecskemét and Lake Balaton, and in the valley of the Danube towards Mohács; a little later on the plain in the angle between the Danube and the Drava and the northern part of the sandy land in Pest county; next follow the country about Versec and Fehértemplom and the sandy region of Hajdu and Szabolcs counties, which are separated from the central part of the Great Plain by a belt in which the disease appears late. After these two sandy regions comes the Kis-Alföld.

VII. — Mildew appears relatively late on the alluvial soils of the left bank of the Tisza, and along the Bodrog and the Maros and especially in the parts watered by the three branches of the Körös and the Berettyó, as well as on both banks of the Tisza (in Szolnok and Heves counties) from Szolnok as far as Tokaj; the same is the case in Torontál and Temes counties, in the valleys of the Temes and of the Bega, and in the southern parts of Bács county; the orographic and climatic conditions of these localities differ very little from those of the districts in which mildew appears early. This delay is rather due to the lack of great extents of sandy soil and the presence of large areas on which water stands.

VIII. — The disease appears latest, about 60 or 80 days after the first appearance in Hungary, in the western, southern, north-eastern and south-eastern parts of vine-growing Hungary situated at heights above 200 m. (660 ft.) and lastly in the eastern parts (Transylvania).

IX. — It appears from the study of the climatic data that the temperature of the month of April has a determining influence on the appearance of mildew. Provided there is enough moisture in winter and spring, which is almost always the case, mildew appears the earlier the more regular the rise of temperature in April. If in the month of April or at least in its second half night frosts have ceased (even though the warmth during the day may not be considerable), the appearance of mildew may be expected about the middle of May. But if there are repeated relapses in the rise of temperature in April the appearance of mildew will be retarded. This retardation will be all the greater the more frequent the relapses have been

and the longer they have lasted. In this case the appearance of mildew may be retarded to the end of May.

X. — The account of the weather before the first appearance of mildew has been kept as follows. A determination was made for each locality and then for the whole of the country situated within the same isophanes of the amount and frequency of the rainfall and the mean daily temperatures from April 1. By multiplying these three data by the number of days after April 1, a figure has been obtained in which the climatic factors appear in proportion to their biological value.

These biological values of the weather seem to show that in general mildew makes its appearance in a district when the biological value of the weather reaches the figure that it had in the first isophane of the year. The great deviations that the biological values of the different years present may be eliminated by introducing into the calculations a factor connected with the value of the position of the rain. (1) The biological value thus obtained for 1910 to 1913 is 281 $\pm$ 14.

The writers call this figure " Bios ". It expresses the value given by the weather calculated according to the above formula, when the meteorological conditions for the first appearance of mildew have been realized. Expressed in a mathematical formula: $-B = c.\,g\,h.\,k.\,T$, in which B = Bios, c = the mean rainfall from the first of April to the day of the first appearance of mildew, g = the average of its frequency, h = the mean daily temperatures, k = the influence of the date at which the rain fell, T = the number of days of the period.

The regular decrease noticed in the table of the " Bios " values may serve as a kind of forecast. It is assumed that after the first isophane there will be no greater irregularities in the weather than in the period between the 1st of April and the first isophane. The deductions are made according to the rule of three, using the " Bios " of the first isophane and the " Bios " of the isophane in question. A series of numbers in inverse ratio to the series of decreasing " Bios " values is thus obtained.

Carrying out this calculation for the years 1910 to 1913 the following numbers of days are obtained:

Isophane		II	III	IV	V	VI	VII
1910		**51**	**55**	**63**	**69**	**83**	**90**
		51	56	63	74	91	117
1911		**47**	**57**	**65**	**73**	**80**	**97**
		47	52	59	70	87	113
1912		**56**	**60**	**63**	**65**	**71**	**86**
		61	66	73	84	101	127
1913		**55**	**66**	**65**	**79**	**80**	**81**
		53	58	65	76	93	119

The figures in heavy type show the date on which mildew was calculated to appear, those in ordinary type the actual date of appearance.

(1) This refers to the fact that rains of equal amount are more effective when they fall nearer to the date of appearance.

It will be seen that the two sets of figures show very considerable agreement.

The prognostic value of these series is undoubted, but their application is limited by the delay of three days necessary in calculating from the first isophane.

But the formula $B = c.g.h.k.T.$ renders one independent of the first isophane; it has only to be borne in mind, according to the process described in the original work and for a great number of localities situated as regularly as possible, when the "Bios" attain towards the middle of May the value of 281 $\pm$ 14. It is in such localities that the appearance of mildew may be expected shortly; in this forecast use may advantageously be made of the temperature curve of the month of April and of the knowledge of ecological factors. One of the chief conditions of success of this method is a network of meteorological stations in perfect working order and with telegraphic connection.

XI. — According to these researches the districts in which mildew makes its first appearance in Hungary are determined by orographic and climatic conditions and especially by the nature of the soil and the conditions of superficial hydrography. The weather only influences the date of appearance. The disease does not appear first in the warmest districts and where most rain falls, but in the southern part of the Great Hungarian Plain where there are extensive sandy areas and a number of tracts liable to flooding. On the other hand the disease appears late, even in the southern districts, on cold soils, notwithstanding the abundance of superficial water and favourable weather. After an April with regular temperature and without white frosts the first appearance of mildew may be expected about the middle of May, and in general when the value of the "Bios" calculated from the 1st of April reaches the figure of 281.

858 – **Results of Investigations made in Austria in 1913 into the Leaf-curl of Potatoes** (1). — KÖCK, G., KORNAUTH, K., and BROZ, O., in *Zeitschrift für das landwirtschaftliche Versuchswesen in Oesterreich*, Year XVII, Part 5, pp. 270-300. Vienna, 1914.

During 1913 the writers continued in several parts of Austria the research work which had been commenced on a large scale several years ago. Among other investigations they carried out a whole series of infection experiments with different species of *Fusarium* on several varieties of potatoes by simply surrounding the root crown of the plants with infected soil.

The most important conclusions that have been drawn from these and from the preceding investigations are the following:

1). Leaf-curl is a fungoid disease caused by forms of *Fusarium* or *Verticillium*; the former are predominant towards the south (for instance in Austria-Hungary), the others towards the north (northern Germany).

2). The primary infection (that is that of a plant that till then had

(1) See also No. 580, *B.* June 1914; No. 683, *B.* July 1914. (*Ed.*).

been heatlthy and had sprung from a healthy plant) is caused by soil containing the above disease-producing agents.

3). The tubers obtained from a plant attacked by leaf-curl are not all necessarily diseased ; some shoots may be quite immune and will naturally produce sound tubers ; tubers formed on the shoots infected by the fungus are in some cases more or less infected by the mycelium of the parasite, or when the mycelium remains restricted to the vascular bundles of the haulm and the stolon, such tubers appear singularly weakened by the injurious action of the mycelium on the movements of the sap.

4). When tubers infected by the mycelium are planted, one of the two following circumstances is observed : either the mycelium grows (and this is rather rare) in the young shoots in course of formation — and the result is what the writers call " secondary infection ", with a new appear ance of curled leaves, — or (as is the case with tubers not containing mycelium but weakened) sickly and weak plants are produced but without leaf-curl ; the writers give this the name of " Folgekrankheit " (after-effect of the disease).

5). Leaf-curl and its after-effects may be spread by tubers produced by shoots which had suffered from primary infection (deriving from the soil).

6). Different varieties of potatoes possess a very different resistance to the disease ; it seems as if none were completely immune.

7). For the control of the disease the following measures are recommended : *a*) to abstain from growing potatoes for at least five years in those fields in which leaf-curl has appeared ; *b*) to select seed potatoes with the greatest care, to grow only varieties which have proved suitable to the locality and to choose a favourable soil ; *c*) to strengthen the plants by appropriate manuring ; *d*) to pick out carefully and remove from the growing crop any infected plants.

BACTERIAL AND FUNGOID DISEASES OF VARIOUS CROPS

859 – **A Disease Affecting the Sisal Hemp Plant : *Colletotrichum Agaves* Cav.** (1). — BANCROFT, C. K., in *The Journal of the Board of Agriculture of British Guiana*, Vol. VII, No. 4, pp. 181-182. Demerara, April 1914.

The leaves of sisal hemp (*Agave rigida* var. *Sisalana*) grown in British Guiana have during the past five years been affected by a disease which renders them useless for the preparation of the fibre, and which is due, according to laboratory observations, to *Colletotrichum Agaves* Cav.

As far as is at present known the parasite has appeared only on plants grown away from the coast, but the plant has not been cultivated near the coast to any great extent.

The fungus has been grown on artificial media. Inoculations on the cut surfaces of leaves (incisions, wounds, etc.) have confirmed the observations of Shaw on the reproduction of the disease and on the pathogenic agent. Attempts to reproduce the disease by placing the fungus on uninjured surfaces of the leaves have failed, thus again confirming the con-

(1) See No. 883, *B.* July 1913. (*Ed.*).

clusion that the organism is a wound parasite, *i.e.* can only affect the leaf originally at a broken surface.

860 – **The "New Disease" or "Dry Disease" of the Sugarcane: *Marasmius Sacchari*.** — BANCROFT, C. K., in *The Journal of the Board of Agriculture of British Guiana*, Vol. VII, No. 4, pp. 183-187. Demerara, April 1914.

The writer describes under the name of "new disease" or "dry disease" the disease caused on the sugarcane by the fungus already known under the name of *Marasmius Sacchari*. The disease was first observed in British Guiana at Berbice in 1907; it has subsequently been reported to occur on many estates in different parts of the Colony. On some of these it has extended greatly, while on others it does not appear to have progressed rapidly and in some few cases it has disappeared after a short time.

The writer reports upon the methods employed in combating the disease. The varieties which are generally badly affected in this Colony are Bourbon, D 625, B 208 and Green Transparent. The two former suffer more than any other varieties. D 109 is also frequently affected; D145 and D 118 are more resistant, while D 216 and D 159 are not reported to be affected.

The planting of the more resistant varieties in badly affected fields for a period of several years for the purpose of checking the spread of the disease is a matter which should receive careful consideration, as well as replacing infected stools with plants of more resistant varieties. The object of these methods would be to reduce the fungus in the soil to a minimum before replanting with the more susceptible varieties.

861 – **Two New Species of Fungi in Tobacco Seeds Beds: *Gloeopeziza turricula* and *Hyalopus geophilus*.** — SACCARDO, P. A., and PEYRONEL, B., in *Bollettino tecnico della coltivazione dei tabacchi, pubblicato per cura del R. Istituto sperimentale in Scafati (Salerno)*, Year XIII, No. 1, pp. 3-6, 1 plate. Scafati, 1911.

The writers received from the Royal Experiment Institute for the Cultivation of Tobacco at Scafati two samples of mould from tobacco seedbeds, attacked by two species of fungi which they consider new to science and which they describe under the names of *Gloeopeziza turricula* and *Hyalopus geophilus*.

The former is a discomycete characterized chiefly by its ascophores, which are cylindrical or shaped like elongated truncated cones resembling little towers (whence the specific name); it is visible as brick-red dots on the mould, and, according to the information collected by the writers, it appears generally in January and February on the seedbeds formed of mould, which have previously been warmed and are protected by coverings. It develops in patches, frequently large, and forms a kind of red crust that hinders the development of the germinating tobacco seeds and often kills them. The species is allied to *G. Rehmii* Zuk. and *G. Zukalii* Rehm, from which it is easily distinguished by certain morphological characters. In another sample of mould received later the writers recognized *G. turricula* in a very young stage of development; this material allowed of preliminary observations on the sexual organs (carpogonia

and antheridia) contained in the young ascophores, which are then completely red.

Hyalopus geophilus (Mucedineae) is very minute and completely hyaline, so that it is difficult to distinguish it without the help of the microscope; this fungus develops on the same places as *G. turricula*, over which it spreads.

These two species do not live on moulds that have been carefully heated to about 100° C. (212° F.) for a couple of hours. Such partial sterilization is therefore recommended for the prevention of these fungi, as well as of parasitic diseases, weeds, etc.

862 – ***Cladochytrium Mauryi* and *C. Ollivieri*, New Phycomycetes on the Leaves of *Colchicum autumnale* and of *Orchis incarnata* and *O. laxiflora* in France.** — HARIOT, P., in *Comptes rendus hebdomadaires des séances de l'Académie des Sciences*, 1914, 1st Half-year, Vol. 158, No. 23, pp. 1705-1707. Paris, 1914.

The writer describes (with Latin diagnosis) two new species of *Cladochytrium*. One, *C. Mauryi*, was found in May 1914 on leaves of *Colchicum autumnale* at Châlons-sur-Marne; it seems to differ from all the other species that have been described as parasites of Liliaceae and Irideae. The other, *C. Ollivieri*, was found in May and June of the same year on leaves of *Orchis incarnata* and *O. laxiflora* at Esbly (Seine-et-Marne).

C. Ollivieri is very near *C. Mauryi*, but can be distinguished by the spots it forms being darker, longer and smoother; its spores also seem larger.

Orchis laxiflora appears to be only exceptionally attacked, and the spots upon it seem smaller and more scattered and never run together to occupy the whole area of the leaf. At Esbly plants of *Colchicum* growing in abundance among the orchises are never attacked; at Châlons-sur-Marne on the contrary the orchises are never attacked.

The leaves of *Orchis* on which *C. Ollivieri* is growing are frequently infected by the aecidium stage of *Puccinia Orchidearum-Phalaridis* Klebahn.

Perhaps the two species of *Cladochytrium* are only biological species and resemble in this the rusts of the group of *Puccinia graminis* and *P. Rubigo-vera*, and the species of *Peridermium*.

INSECT PESTS.

GENERALITIES

863 – **Occurrence of the Colorado Beetle (*Leptinotarsa decemlineata*) in Germany** (1). — *Illustrierte landwirtschaftliche Zeitung*, Year 34, No. 57, pp. 538-539, 1 fig. Berlin, 1914.

The presence of the Colorado potato beetle (*Leptinotarsa decemlineata*), which had not been seen in Germany since 1887, has been reported from Hohenwedel near Stade (Hanover); the Government immediately ordered the most drastic measures against this dangerous beetle.

(1) See also Nos. 2295 and 2360, *B.* July 1911. (*Ed.*).

864 – ***Micrococcus nigrofaciens*** **as Cause of an Infectious Disease of the Larvae of *Lachnosterna* spp. in the United States and in Portorico.** — NORTHRUP ZAE. in *Centralblatt für Bakteriologie, Parasitenkunde u. Infektionskrankheiten*, Part II, Vol. 41, No. 11-17, pp. 321-339, figs. 1-5, plates I-IV. Jena, 1914.

During the summer of 1912 specially severe injury to various crops due to the white grubs of May or June beetles (*Lachnosterna* spp., *Scarabaeidae*) were reported from Michigan.

The appearance of these beetle larvae was accompanied by the manifestation of a bacterial disease characterized by the blackening of the parts of their bodies affected. The cause of the infection is a species of *Micrococcus*, for the above reason named *M. nigrofaciens*. It was found under the microscope in almost pure culture on agar plates inoculated from the diseased part of a live larva. It is frequently associated with a gas-producing bacillus (*Bacillus septicus insectorum* of Krassilstschik ?), from which it is separated with difficulty.

The *Micrococcus* lives in the soil and is present in many soils of Michigan, Illinois, Maryland, Northern Carolina, Portorico and very probably in other countries also. It grows well on the usual nutritive media, but much better on the special media prepared with the larvae (gelatine, agar, broth) and on the larvae themselves. It colours well with the usual water and alcohol colours, and shows clearly the process of division ; it is Gram-positive but not acid-fast.

The disease has been successfully reproduced in a healthy larva of *Lachnosterna* by placing it on artificially infected soil and incising its integument.

The characteristic alteration was also caused in some healthy larvae of another beetle, *Allorhina nitida*, by placing them on soil soaked with water and sterilized, to which some broth containing the *Micrococcus* in suspension was added. It seems as if in the individual larvae of the same genus the power of resistance to the *Micrococ us* varies greatly. The youngest seem to be the most susceptible ; the larvae of *Lachnosterna* seem less resistant than those of *Allorhina*.

The micro-organism in question proved pathogenic to adults of *Periplaneta americana* ; the disease followed its course as in the larvae of *Lachnosterna* ; nevertheless the infection was apparently limited to the legs.

It has not been possible to determine whether the *Micrococcus* is pathogenic for earthworms, nor have repeated attempts to isolate it from the naturally infected soil succeeded.

Excessively moist soil favours the progress of the disease and this may be considered one of the chief factors in rendering the infection mortal.

In the soil there exist other organisms which may produce an infection in the larvae. The above-mentioned gas-producing bacillus found in the culture plates appears in determined conditions to contribute to render the disease mortal and it may be the first micro-organism to invade the insect.

The *Micrococcus* does not lose its virulence after having been cultivated artificially for upwards of a year.

It has not yet been possible to try this micro-organism as a remedy in the control of the larvae of *Lachnosterna* ; this will, however, be done as soon as possible. The larvae of some *Lachnosterna*, commonly called " caculo " or " gusano blanco " at Portorico, are there very injurious to sugarcane : in order to experiment the *Micrococcus* against them, cultures have been sent to Rio Piedras and Mayaguez ; no definite results have been obtained.

From the conclusive results obtained by inoculating and saturating the soil, the inference may be drawn that the *Micrococcus* may in the future be usefully employed in the control of the larvae of *Lachnosterna*, especially in conjunction with other parasitic diseases to which the larvae are subject. Since this micro-organism has also the power of infecting the larvae of another genus (*Allorhina nitida*) and also adult insects (*Periplaneta americana*), it seems to suggest the possibility of extending its use, applying it especially in the control of other injurious larvae in the soil.

INSECTS INJURIOUS TO VARIOUS CROPS

865 – **The Grass Moth *(Remigia repanda)*, a Pest of Sugarcane, Rice and Paragrass in British Guiana** (1). — BODKIN, G. E., in *The Journal of the Board of Agriculture of British Guiana*, Vol. VII, No. 4, pp. 171-177. Demerara. April 1914.

Remigia repanda is a member of the family *Noctuidae;* owing to its habit of living on numerous grasses, and particularly paragrass (*Panicum muticum*) it has been given the popular name of Grass Moth. In British Guiana it has been a well-known pest for many years, though this is the first account of its life-history published in the Colony.

On sugarcane, rice — with the rice caterpillar (*Laphygma frugiperda*) — paragrass and other grasses throughout the coastlands this moth may be found all the year round, and at certain periods, particularly on the occurrence of rain after prolonged drought, the larvae appear in vast hordes completely destroying whole areas of the above crops. It also occurs in several of the interior districts.

In Trinidad it has recently occurred as a serious pest and it is also known as a pest in Jamaica. The following are the localities whence *R. repanda* has been recorded : Canada, Labrador, United States (Texas, Florida), Mexico, Honduras, Costa Rica, Panama, Colombia, Venezuela, Guiana, Brazil, Argentina, Antilles (Cuba, where it has beea recorded on *Hypericum*, San Domingo, Jamaica and Martinique).

Under normal conditions this insect is not responsible for any serious damage and may easily be controlled.

The various instars of the life-history of this insect in the Colony coincide with those which have been described by Dr. Dyar of the United States ; his description is appended by the writer. The ova have never been observed on the food-plants in this colony. The complete life-cycle occupies under normal circumstances from 26 to 31 days.

No actual parasites have so far been secured from this insect in Bri-

(1) See also No. 803, *B.* Aug. 1914. (*Ed.*).

tish Guiana. The Coccinellid beetle *Megilla maculata* De Geer frequently preys on the young larvae, and the so-called Demerara Robin (*Leistes guianensis*) will also feed on them.

On sugar estates the usual method employed when a slight attack of this pest occurs is to pick them off the canes by hand and drop them into buckets containing kerosene and water. When efficiently carried out this is an effective measure, but the application of dry powdered arsenate of lead would give just as satisfactory results and would prove cheaper.

When it attacks rice in the nursery beds, flooding may be resorted to, as described for the control of the rice caterpillar.

As regards paragrass, the value of the crop hardly guarantees the application of control measures ; a field when badly attacked may be left till the caterpillars enter the chrysalis stage and then burnt off to prevent further infestation.

866 – **A New Sugarcane Aphis *(Aphis bituberculata)* in Louisiana.** — WILSON, H. F., in *Entomological News*. Vol. XXV, No. 7, pp. 298-299, plate XIII. Philadelphia, 1914.

The writer received in 1912 some specimens of an aphis which had been found on *Saccharum officinarum* in Louisiana (Audubon Park, New Orleans). Not having been able to indentify it with any other aphis found on sugarcane, he describes it as new to science under the name of *Aphis bituberculata*.

867 – **Eelworms Injuring Hops in Bavaria.** — WAGNER in *Praktische Blätter für Pflanzenschutz*, Year XII, Part 6, pp. 66-68, 1 fig. Stuttgart, 1914.

In August 1913 the writer observed at Pörnbach in a well cultivated seven-year-old hop garden a few dozen plants near each other which presented a very stunted growth. The hops were quite withered and worthless.

It has been ascertained that the mischief was due to the presence of eelworms — very probably *Tylenchus devastatrix* Kühn — on the rootlets. Eelworms had not previously been observed at Pörnbach, even on other crops.

868 – ***Godara comalis*, a Cabbage Moth, Attacking Turnips in Queensland.** — JARVIS, E., in *The Queensland Agricultural Journal*, New Series, Vol. I, Part 6, pp. 427-429, plate 62. Brisbane, 1914.

One of the least known cablage moths, *Godara comalis*, has recently manifested a decided liking for turnips, the caterpillars feeding freely on the leaves so as to leave only the skeleton.

This species is sometimes found in association with *Hellula undalis*, a notorius pest known as the cabbage webworm, which not only causes serious damage to this vegetable, but is destructive at times to turnips and other cultivated Crucifers.

With reference to control, prompt measures at the commencement of the season are of the utmost importance, since destruction of the first brood of moths will materially decrease the injurious action of succeeding generations. Arsenical sprays are of little use against larvae well established

among the heart leaves of big cabbages, but should be effective applied to young plants or to the foliage of turnips.

The writer does not believe that this pest has hitherto been recorded as attacking cabbage seed-beds, but if it should do so Bordeaux mixture sprayed upon seedlings whilst in the bed and when planted out should act as a deterrent.

It is advisable to destroy carefully all weeds, especially of Cruciferous plants, and any badly injured cabbages, and never to allow stumps with worthless leaves to remain in the field after the crop has been removed. Such refuse should be put in a heap and burnt without delay. Cultivating between cabbages at a time when the larvae are in the pupal stage would doubtless destroy many of them, and also improve the general condition of both crop and soil.

869 - **The Rose Beetle *(Adoretus vestitus)* and the Injury it Causes in the Samoan Islands.** — FRIEDERICHS, E., in *Zeitschrift für wissenschaftliche Insektenbiologie*, Vol. X, Part 2, pp. 41-47, figs. 1-6. Berlin-Schöneberg, 1914.

The writer gives a minute description of the larva, pupa and imago of *Adoretus vestitus* Boh., which is very abundant in the island of Upolu, where it is called " Rosenkäfer " by the German colonists, as the perfect insect attacks by preference rose leaves, which it riddles completely. The rose plants are often quite despoiled of their leaves and killed. The insect feeds also on larger leaves such as those of cacao, and in a characteristic manner, leaving only the outer edges and the ribs untouched. The writer recently observed many young cacao plants in a plantation destroyed by *Adoretus*. Even large trees were seriously injured by these insects. Other frequent host plants are *Coffea liberica*, *Hibiscus tiliaceus* (" fau " of the Samoans ; almost every plant has its leaves completely devoured), *Terminalia litoralis* (" talie " of the natives) and others.

The injury caused by these beetles, with the exception of that to roses (which have no economic importance in Samoa), has not hitherto been very severe ; the insect and the mischief that it does are, however, on the increase and perhaps before long it may become dangerous.

The eggs of *Adoretus* are unknown to the writer. The larvae when fully developed are about eight-tenths of an inch in length ; they are of a yellowish white and are found at all times and of all sizes on the roots of Gramineae and under rotting vegetable matter, especially in decomposing farmyard manure, from which it may be inferred that the insect multiplies all the year round. Before pupating, the larvae rest for a long time ; then they prepare, by means of a special secretion, a kind of cocoon of earth which protects them from their enemies. The larvae do not injure the roots of plants. Probably the insect has been introduced into the Samoan Islands (where it was first noticed about six years ago) in the larval stage by means of vegetable matter surrounded by earth. The adult insect is from 0.4 to 0.5 in. long ; its colour varies from yellowish to a brownish red. It lies hidden during the day and is therefore very rarely found ; it feeds and mates at night. If disturbed it allows itself to fall from the leaves. It appears in great numbers throughout the year.

It has been observed that it is always the small cacao trees not sheltered in any way which are killed by the insect, while those in the shade of other trees or surrounded by bananas, for instance, often remain uninjured. Roses have been protected by mosquito curtains being thrown over them at night and cacao nurseries might be equally protected by old fishing nets. Shaking the plants and collecting the adult insects has given only partial results, as new individuals keep on appearing. Spraying with various substances has prevented the beetle from devouring the leaves, but these have been damaged by the remedies used. Insectivorous birds or mammals ought to be introduced into Samoa to feed upon the larvae in the soil. Hitherto the attempts to infect *Adoretus* with the green muscardine fungus (*Metarrhizium Anisopliae*), which has been recently used in Samoa with very promising results against the larvae of *Oryctes rhinoceros*, the worst enemy of cacao, have failed. The writer will continue his researches in this direction.

RUGGERI ALFREDO, *gerente responsabile.*

The Present Status of the Cattle Industry in Canada

by

H. S. ARKELL,

Assistant Live Stock Commissioner.

According to the last Dominion Census held in 1911, there were in Canada at that time 6 533 436 cattle. The following table indicates how these are distributed by provinces as well as the comparative increase which has taken place during the last 40 years.

An examination of the above statistics, while making clear that there has been a regular and reasonable increase during the past fifty years in the cattle population of the country, reveals a somewhat anomalous situation as regards the proportionate development of the Eastern and Western areas of the Dominion. In Eastern Canada, production has barely held its own and particularly in the provinces of New Brunswick and Nova Scotia there has been a distinct falling off during the past two decades. On the other hand, Western Canada, including the prairie provinces and British Columbia, has made definite and satisfactory advancement.

The conditions causing this situation are not far to seek. The lure of free land has turned the tide of settlement westward, the movement of emigration being not only from across the Atlantic but as well from the rural districts of the Maritime provinces, Quebec and Ontario. The redistribution of population, following the opening for settlemnt of the extensive and fertile areas in the provinces west of the Great Lakes has had a very important bearing upon the development of the live stock industry.

A further feature, pertaining to the relative growth of urban and rural populations, should also be alluded to in this same connection. There has been, during the past ten years, in every province of Eastern Canada, with the exception of Quebec, a decrease in the rural population, while,

for the same period, there has been a significant increase in the urban population. In Western Canada, however, there has been an increase of population in both rural and urban districts. The following table will be of considerable interest in making clear this comparison.

Rural and Urban population of Canada in 1911 *and* 1901 *by Provinces and the Increase in the decade.*

The table given above throws considerable light upon the relation existing between supply and demand with respect to the marketing of meat products in the Dominion. Reason is presented for the fact that during the past decade exports have fallen off and imports have increased, while within the past three or four years prices have advanced at an unprecedented rate. It now becomes clear that while the consuming centres have been extending in area and increasing in population, the producing areas have become depleted in population and potentially, for the present at least, not largely increased in extent. In explanation of this latter statement it should be remembered that, hitherto, grain growing and not stock raising has been the most prominent feature incident to the agricultural development of Western Canada and that the increase in the rural population of that part of the country has thus far resulted in an increased output of wheat, oats, barley and flax rather than in an appreciable extension of stock-breeding operations. Moreover, the influx of settlers has gradually entailed a systematic reduction of the prairie pasture and ranching areas, with a correspoding curtailment in the rearing of cattle under range conditions. Much of the land, therefore, which was formerly

devoted to cattle raising has, during recent years, been placed under cultivation and, in consequence, is not now producing its one-time quota of marketable animals. Mixed farming is, however, now rapidly gaining ground in Western Canada, particularly in the more northerly portions of the three prairie provinces, and this accounts for the fact that, despite the reduction in the range areas, the West has been able of late to appreciably increase its cattle stock. It would seem that a considerable extension of this movement may be confidently expected within the next few years, there having been already established there the foundations of a great cattle industry.

As casting additional light upon the present relative demand and supply of beef and beef products, reference should now be made to the changes which have taken place in our export and import trade during the past few years. The following table furnishes a great deal of useful information in this connection.

Canadian exports and imports of cattle and beef.

Year	Export cattle trade		Import cattle trade	
	Cattle Number	Beef Lbs.	Cattle Number	Beef Lbs.
1883	66 396	628 728	20 978	2 764 736
1893	107 224	356 106	1 851	5 599 113
1903	176 780	2 378 175	37 528	1 381 254
1909	162 945	1 571 585	2 601	1 306 607
1910	157 386	1 318 397	1 012	1 446 302
1911	124 923	974 411	3 044	1 170 649
1912	61 517	948 771	2 976	1 976 949
1913 (calendar yr.)	216 295	—	9 127	—

By way of comment upon the above figures it should be explained that the export trade of live cattle to the United Kingdom has practically ceased, notwithstanding the fact that this trade, for a considerable period, absorbed the best and heaviest cattle produced in either Eastern or Western Canada. The great lairages in London and Liverpool, built exclusively to handle American live cattle, now remain permanently empty. The markets of the United Kingdom have been forced to the conclusion that they can no longer draw their supplies from this continent.

As the table does not make it sufficiently clear, reference should be made, perhaps, to the peculiar situation which developed during 1913 in connection with the exportation of cattle to the United States. Practically all of the cattle exported, as credited to that year, went across the American border. Such an anomalous development, however, has been significant of only one thing; that, with the removal of the American tariff

higher prices could be realized in the United States than in this country. The liquidation of Canadian stock continued until an equilibrium was reached, the movement further accentuating the already marked scarcity of marketable cattle on this side of the border. Never in our statistical history have prices attained so high a figure, either for cattle on the hoof or for meat in the butcher shops, as has been the case this year.

As regards prices, market returns and the movement of meat within the country, the average market returns for the past years in the case of choice butcher cattle sold in Toronto have been as follows: — In 1911, $ 5.76 - $ 6.10 per cwt; in 1912, $ 6.92 - $ 7.17 per cwt; and in 1913, $ 6.94 - $ 7.23 per cwt. These figures tell their own story and the facts which they suggest are fully featured in the scarcity of cattle in the country. Marketings on the whole have increased during the past few years. Particularly is this true in the case of calves, there being 112 053 head marketed at Toronto, Montreal and Winnipeg in 1909, as compared with 162 539 in 1913. It can scarcely be said, however, that the marketings of 1913 represent normal conditions, particularly in view of the large exportation to the United States.

Whereas formerly thousands upon thousands of cattle were received at the Toronto and Montreal markets for feeding and export purposes, those so received in 1913 did not total more than 2 239 head. The output of Alberta and Saskatchewan, which at one time went forward to Winnipeg, is now either consumed locally or, particularly in the case of Alberta, shipped into British Columbia. During the month of February 1913 three-quarters of a million pounds of beef were shipped from Ontario and one-quarter of a million pounds from Alberta to Canada's most westerly province. Even the prairie provinces are taking some supplies from Eastern Canada, partly through the importation of meat, but chiefly in the way of carloads of breeding cattle. In the latter movement British Columbia has also largely participated. As regards Eastern Canada, the Maritime provinces, particularly Nova Scotia, are now drawing freely from Ontario and Quebec. Very recently their receipts ran up to nearly a million pounds per month. The larger cities have each taken their quota, but fully a quarter of the amount went direct to Sydney, North Sydney and Sydney Mines in Cape Breton, where there are large manufactories of iron and steel.

A review of the facts already presented point to the one conclusion, that the country, owing to an inadequate supply, has been forced to a curtailment of meat consumption. That there is a remarkable shortage of cattle and that there has been a decrease in the per capita consumption of meat is borne out by an analysis of the figures. Notwithstanding her large area and great agricultural resources, Canada, in so far as live stock products are concerned, has now ceased, except upon occasion, to be an exporting country and has already been compelled to import considerable quantities of foreign meat. The present situation, it must be admitted, is largely consequent upon the nature of our economic development, but the causes producing it are steadily calling into being their own remedies. Everywhere throughout the country there is already on foot a comprehen-

sive movement toward the conservation of breeding stock and an extension of breeding operations. With breeding cattle in demand, with fewer calves going to the shambles and with a steadily growing domestic market, it may confidently be predicted that we are about to enter upon a period of general progress and expansion.

Up to this point, we have chiefly comprehended in the discussion the business of beef making. Special reference should now be made to the position occupied by the business of dairying in the development of cattle husbandry in Canada. There are, particularly in the provinces east of the Great Lakes, certain well defined areas where dairying and dairy cattle have for generations been directly associated with the agricultural operations of the people. In Nova Scotia and New Brunswick the Guernsey and Jersey breeds have predominated ; in Quebec, the French Canadian and Ayrshire, while in the dairy sections of Ontario, the Ayrshire and Holstein have attained the preference. In certain districts of the provinces mentioned, dairying has been, for many years, almost exclusively followed and it should now be pointed out that recently, particularly in the province of Ontario and in Western Canada, dairying as an industry has made very rapid progress, its devlopment paralleling, in part at least, the increase in our urban population. Formerly the making of cheese and butter constituted the most important part of the business. Now, on the other hand, more remunerative avenues have opened up in connection with the shipment of milk to our more important towns and cities, and with the supplying of cream to the ice cream trade and for export to the United States.

It is generally admitted that the dairy cow yields a larger economic return than does the beef steer and that milk as a wholesome, nutritious food product is cheaper than meat. While, therefore, there are large areas of the Dominion suitable only for beef raising, still, the attention of the farming public both East and West is being directed to the profit-earning ability of the cow that will produce milk.

It would almost appear that the successful future of the beef industry in this country is dependent upon the ability of the breeders of pure-bred beef stock to combine in the cattle they produce the capacity for reasonable milk production, with an inherited tendency to thick fleshing and to early maturity.

It would be of interest in an article of this kind to outline in some detail the progress and development of breeding operations in improving the type and quality of our cattle through the use of imported and home-bred pedigreed stock. The position of the Dominion, however, is now so well attested and so firmly established by the laurels won by Canadian-bred animals at International Exhibitions, where both beef and dairy breeds have been represented, as to make it scarcely worth while to dwell upon this feature of the industry. Certain of the older sections of the Dominion have long been recognized as amongst the most important and most dependable of live stock breeding grounds upon the North American Continent. Several factors have contributed to the attainment of this position, notable

amongst which in brief summary, may be mentioned: — the importation through a long period of years of carefully selected stock from the best herds of Great Britain; the climate and the character of the food which have developed hardiness, quality and finish; the competitive rivalry amongst breeders as encouraged by the great national and international exhibitions; the organization of district breeders' clubs, and the institution of the Canadian Record of Performance. Comment upon these factors is unnecessary except that it may be explained that the Canadian Record of Performance was initiated by the Federal Department of Agriculture in the interests of the breeders of dairy cattle and consists in the testing at reasonable intervals of the milk and butter-fat yield of cows whose owners apply therefor under the conditions laid down by the Department. The information which is rendered available by these records provides a standard for the selection, particularly of pure-bred sires, and its use is steadily leading to an improvement in breeding practice.

One other factor is yet to be alluded to: It is, the nationalization of the Canadian Records of pedigreed stock, which has not only made possible a systematization of our national live stock records, but has, as well, furthered and advanced in a very direct manner the business of the pure-bred stockman and the cattle industry of the country.

Until the year 1900 all the Live Stock Records in Canada were conducted by the Provincial Departments of Agriculture or by breed associations more or less provincial in character and scope. Although the most important record associations had their origin in the Province of Ontario, books of record were also established in Quebec, the North West Territories and in each of the Maritime provinces. This multiplicity of records, without uniform standards of registration, proved a source of confusion and expense to breeders and farmers and a hinderance to interprovincial and export trade. The first step taken to improve the existing situation was the passage in 1900 of an Act respecting the Incorporation of Live Stock Record Associations. Leading Record Associations promptly availed themselves of this Act and secured incorporation under Dominion charters within the next few months.

The establishing of a national system of records was the subject of discussion at many breeders' meetings up to the year 1904, when a General Convention of Live Stock Breeders from all parts of Canada was called at the instance of the Minister of Agriculture. At this Convention, committees were appointed to work out the details of a scheme providing for the nationalization of Canadian Live Stock Records, and in April of the following year another convention of delegates from each of the Live Stock Record Associations was held in Ottawa and a National Record Board established. The National Record Board is composed of representatives elected by the Boards of Directors of the various breed associations on the basis of two persons for every 100 members or under, and one additional representative for each 500 members.

It is to these men, forming the National Record Board, that the breed associations delegate the work of carrying on the National Record Office

to their mutual advantage, but with due regard to the Constitution and rules of entry of each association as laid down in the Dominion charter under which it is incorporated.

The Record Board meets annually and discusses and decides the larger questions connected with record matters. In order that the detail of registration may be efficiently looked after, an Executive Committee is elected by the Board, one man representing each class of stock as follows: — Heavy Horses, Light Horses, Beef Cattle, Dairy Cattle, Sheep and Swine. These representatives, presided over by the Chairman of the National Record Board, with a Secretary-Treasurer, constitute what is called the Record Committee. This Committee meets at sufficiently frequent intervals to look after the work entrusted to them by the Record Board in the matter of registration, which includes management of the National Records Office. This office is placed in charge of an Accountant, who is also Secretary-Treasurer of the Board and has full supervision of the several registrars and clerks. It will be seen that the work of registration is entirely under the control of the breeders themselves through their Breed Associations, Record Board, Record Committee, Accountant and Registrars. The Department of Agriculture, however, furnishes office accomodation and equipment, including stationery and other supplies, and assumes a further responsibility in connection with the work of the Records Office, to the extent of guaranteeing the authenticity of the certificates issued. That is to say, the registration certificates, after being prepared in accordance with the office records and carefully checked by the registrars, are handed over, along with the application forms received from the breeder, to an officer of the Department, who examines the certificates and compares them with the breeders' applications. If found correct, the certificates are approved by this officer, on behalf of the Minister, under his own hand and the seal of the Department.

Regarding the disposition of fees received, they are all deposited in a bank to the credit of the association for which they are sent. These monies are payable only to the order of each representative association through its officers. It is, therefore apparent that the Record Committee, after depositing these funds through the Accountant, has no further control of them.

To finance the affairs of the office, a monthly levy is made by the Record Committee on all self-sustaining associations. The amount charged for each association is based on the charges for the previous year. If the levies prove too large or too small, adjustment is made at the end of the fiscal year. The expenses of the Associations on which levy is not made are provided from a grant given by the Department of Agriculture to the Record Committee. In doing this the Department is carrying out an agreement to assist new records. The monies accruing to an association not expended as above noted, are, subject to the order of the association, to be used in meeting the expenses of officers and directors for the purposes of publicity, or in such other ways as are provided in Section 15 of the Live Stock Pedigree Act.

It may be added that the recording of live stock under the present system is found to work very satisfactorily. The methods now followed have eliminated not only the control of records by close corporations but the possibility of the occurrence of those complications inseparable from the existence of multiplicity of records in the same country. The recording of live stock is characterized by accuracy, promptness and economy of administration, while Canadian Records are now recognized as official not only throughout the Dominion but in other countries as well.

With the single exception of the Canadian Holstein Friesian Association, which has a Dominion charter but has not yet seen fit to co-operate with the other Associations, all Record Associations in the Dominion are operated under the National Records System.

By way of general information with respect to the strength and standing of the various pure-bred Cattle Breeders' Associations in the Dominion, the following statement, setting forth the registrations for the year 1913 and the total membership to date, is submitted :

Name of Association	Registrations 1913	Membership 1913
Dominion Shorthorn Breeders' Association	9 046	2 051
Canadian Ayrshire Breeders' »	3 258	1 084
Canadian Hereford Breeders' »	1 362	301
Canadian Jersey Cattle Club	1 155	267
North American Galloway Association	23	22
Canadian Aberdeen Angus »	831	179
Canadian Guernsey Breeders' »	79	31
French Canadian Cattle Breeders' Association	334	172
Canadian Red Polled Association	90	28
Holstein-Friesian Association of Canada	6 815	1 646

The Crisis in Italian Sericulture and the Measures for Averting It

by

ORESTE BORDIGA,

Professor of Rural Economy at the Royal Agricultural College, Portici.

The production of cocoons and the silk industry are among the greatest sources of revenue of the Kingdom of Italy. The former ranges between six and eight millions sterling per annum and the latter supplies an export trade which at present amounts to about 20 millions, but which some years ago reached 28 millions. Both have very ancient traditions, for the rearing of silkworms was introduced into Calabria by the Byzantine Greeks in the

tenth or eleventh century; the Norman kings extended it to Sicily and fostered the silk industry to such an extent that between the twelfth and the thirteenth centuries Catanzaro, Reggio and Messina had famous factories producing velvets, brocades and other silken goods. Later, both silkworm rearing and the silk industry spread northwards and flourished there also. Indeed the chief characters of the greatest Italian historical novel — the "Promessi Sposi" of Alessandro Manzoni — are two humble silk-weavers of the year 1630. In the eighteenth and nineteenth centuries silkworm rearing and the industry connected with it continued their progress throughout the Valley of the Po (while they declined in the south of the country), and underwent a considerable increase owing to the excellence of the product, unequalled by that of any other country. The reeling, spinning and weaving of silk and the silk by-products industry, notwithstanding serious obstacles and several financial disasters, established themselves firmly, especially in Liguria, Piedmont and Lombardy; Como and Milan came to be as important centres of the silk trade as Lyons, Zurich or Crefeld. The service known in Italian as "condizionatura" or in French "passage à la condition" of silk, that is the deposit of the bales of silk in certain warehouses, whence samples are taken with a view to investigating the quality of the silk and determining the use to which the raw product is to be put, has attained and maintains in Milan much greater proportions than in the other silk centres of Europe.

These results are all the more worthy of consideration as they have been attained in spite of ever increasing difficulties, especially the fall in prices, the increase of the cost of production, and the customs' duties levied by the countries importing Italian silk fabrics. The fall in prices from 1*s* 6*d* or 1*s* 9*d* to less than 1*s* per lb. was caused by the competition of Asiatic silks, which, though much inferior to Italian silks, beat them through their lower price. Further, while the produce exported more than trebled in a quarter of a century, as the table below shows, since 1890 the wages of agricultural and industrial labour have increased by fully 50 per cent. Against the effects of this increase of cost, both the silkworm rearers and the factories opposed continued improvements in the yield and technique of their output. Lastly the silk substitutes appeared on the market: artificial silk, mercerized cotton, *viscose* and the like. Though these only take the place of silk for special purposes they contribute to reduce the demand and consumption.

The ever increasing arrivals of Chinese and Japanese silks on the European and American markets have altered the relative position of Italy in the world's market as shown by the figures in Table I. From them also it is easy to judge to what an extraordinary degree the consumption of silk has increased, notwithstanding the increased production of substitutes (1).

(1) These data have been collected by the "Union des Marchands de Soie" of Lyons, and published in the *Bollettino di legislazione commerciale e doganale*, Part II, 1890, p. 614, 1903, p. 388; 1913, p. 1034.

TABLE I. — *Average yearly production of silk (in metric tons).*

Country	1885-1889	1899-1903	1907-1911	1912
Italy	3 113	4 272	4 190	4 105
France	669	599	542	505
Spain	66	81	82	78
Austria-Hungary	245	300	352	294
Total Europe	4 093	5 252	5 175	4 982
Levant and Central Asia	667	2 083	2 903	2 233
Exports from Shanghai	2 549	4 598	3 222	6 400
» Canton	1 149	2 153	2 258	2 260
» Yokohama	1 928	4 309	8 124	10 867
» Calcutta	553	290	261	133
Total of the whole world	10 939	18 685	23 943	26 915

The ratios between the figures for the period 1885-1889 and those given above for 1907-11 show how the individual States have modified their output :

Italy	from 1 to 1.35
France	» » » 0.80
Spain	» » » 1.24
Austria-Hungary	» » » 1.43
Levant and Central Asia	» » » 4.36
Exports from :	
Shanghai	» » » 2.04
Canton	» » » 1.96
Yokohama	» » » 4.21
Calcutta	» » » 0.47

While the European and American world increased its demand for silk by 13 000 metric tons, Europe contributed only about 1000 tons, the remaining 12 000 being supplied by China and Japan and forming the basis of the great business and trade activity of the last decade in the Far East. Italy's contribution, which between 1885 and 1889 amounted to 28.4 per cent. of the total silk, fell to 17.3 per cent. in 1907-11. According to our statistics the production of fresh cocoons, which was from 38 000 to 40 000 metric tons between 1880 and 1889, reached 57 300 tons in 1900 to 1904 and in the succeeding years fell to the following figures :

Production of cocons in Italy from 1905 *to* 1913 (*in metric tons*).

Year	Tons	Year	Tons
1905	51 940	1910	47 964
1906	53 838	1911	41 951
1907	57 058	1912	47 470
1908	53 193	1913	38 490
1909	50 760		

The prices of the raw material and of silk were in keeping with this trend of affairs. Up to 1875 they were high, as much as 1*s* 6*d*, 1*s* 9*d* and 2*s* 2*d* per pound of cocoons, and sometimes even 36*s* per lb. of silk; after 1880 they varied as follows:

Periods and years	Prices at Milan, per lb. in gold			
	Fresh cocoons		Raw silk (sublime $^{10}/_{12}$ brand)	
	s	*d*	*s*	*d*
1880–1884	1	5	19	7.4
1885–1889	1	2.8	17	9
1890–1894	1	2.4	17	9.4
1895–1899	0	9.8	16	0.6
1900–1904	1	0.8	16	6.3
1905–1909	1	2.9	17	6.8
1910	0	11.6	15	3.6
1911	1	0.3	15	3.6
1912	0	10.5	14	9.1
1913	1	1.6	17	1.2

After 1900 the highest prices of cocoons were in 1907, namely 1*s* 5 $^1/_2$ *d* with the raw silk at 18*s* 2 $^1/_4$ *d*; but in 1908 and 1909 the former fell to 1*s* 1*d* and 1*s* 3*d* and the latter to 15*s* 8*d* and 16*s* 6 $^3/_4$ *d*.

At the same time, this fall in prices, due to competition from China and Japan, allowed the world's consumption to quadruple itself in thirty years, as the use of silk extended to all classes; this gave a fresh impetus to the industry. But the same causes produced difficulties for the Italian industry and rearing, especially in conjunction with the increased cost of labour. The rearers and manufacturers fought against these difficulties and held out for over ten years, so that up to 1907-08 the increase in the production of cocoons kept pace with the increase in the silk trade shown by the following figures (in millions of francs):

Periods and years	Imports	Exports
1891–1895	114.6	321.8
1896–1900	147.3	410.9
1901–1905	218.5	555.6
1906	250.5	683.7
1907	314.0	710.2
1908	242.5	553.4
1909	236.3	615.6
1910	269.5	583.1
1911	259.7	505.7
1912	212.8	549.5
1913	200.3	497.1

The data on the commercial activity also show an *optimum* in the period 1905-1907, in which the imports averaged about £10 000 000 per annum and the exports about £26 600 000. But from then up to 1913 there is a fall of about £8 800 000 in the total trade, which is a very eloquent index of the difficulties against which silkworm rearing and the silk industry have to contend. They have had to struggle for several years against low prices and sometimes even to work at a loss and to resist the formidable competition previously mentioned. This explains the recent decrease of the home poduction, which in its turn is a source of serious embarassment to to the industry, depriving it of the exceptionally good raw material which alone can supply the classical raw silks for the trade and the first class fabrics of the Milan and Como looms. It is one of the chief causes of the decreased exports, which concern more raw silk than the fabrics, as the deficiency in raw material from the country cannot be replaced by Asiatic cocoons.

It will thus be readily understood that all engaged in the silk industry follow with the greatest interest the efforts made to increase silkworm breeding in Italy and especially in the south, where it was once flourishing. During the last twenty years the Italian bibliography on agriculture, silkworms and silk is full of works which treat of this increase and aim at furthering the planting of mulberries and raising worms in Southern Italy. It may be assumed that this object will be attained, for the history of Italian sericulture shows that it has contended with and overcome more than one serious obstacle in the past.

Thus in 1850-55 it received a severe blow from the invasion of pébrine, which carried off half the worms and almost annihilated silkworm breeding in the South . At this time the producers of silkworm eggs of the north of Italy had resort first to Turkey and Anatolia, then to Persia, Turkestan and China, and lastly to Japan, thus saving the national silkworm breeding and silk industry. Meanwhile distinguished scientists investigated the causes of the diseases of worms; Dubini had already discovered *Botrytis bassiana*, the cause of muscadine, in 1832, and later Emilio Cornalia discovered the corpuscles of pébrine and proved the herditary transmission of the disease. Pasteur in France and Gaetano Cantoni in Italy, availing themselves of the discovery, invented the cellular method of preparing silkworm eggs with the aid of microscopical examination, thus allowing the reconstitution of the old Italian breeds. This gave rise to a new industry, the preparation of eggs free from pébrine. At the same time the technique of spinning and weaving made wonderful progress, the industry of silk by- products was founded and our silk fabrics steadily gained ground in foreign markets.

The State on its part favoured the movement by founding the Padova Silkworm Breeding Station under the direction of the famous silkworm expert Verson, and silkworm observatories; it arranged for instruction on the subject to be given in agricultural schools, as well as by the travelling lecturers ; it held special competitions, founded schools of weaving and silk dyeing at Como, and assisted industrial and technical educa-

tion. In addition to all this, private initiative joined in the work, chiefly by instituting cooperative esiccators, that is establishments in which the cocoons of the agricultural members are suffocated, dried and stored, thus avoiding the necessity for selling the fresh produce within a few days (1). A private society, the " Anonima Cooperativa per la Stagionatura delle Sete " of Milan, founded and kept up by itself the laboratory for the study of silks, from which very valuable contributions to the technique of the industry have been and are being made.

Altogether few Italian sources of production and of industrial activity have been the object of so much study and free and successful initiative as silkworm raising and the silk industry.

Among the difficulties mentioned above, must be included a parasite of the mulberry, *Diaspis pentagona*, a most injurious scale insect from Japan which invaded the mulberry plantations in 1890. For its control it became necessary to enact laws rendering obligatory the use of certain insecticide emulsions, but the work of scientists was still more beneficial. Prof. Antonio Berlese discovered an entomophagous parasite, *Prospaltella berlesei*, which now successfully controls the Japanese fruit scale. Meanwhile, however, in many localities numbers of mulberries had perished or were in such a bad state as to induce the farmers, tired with the struggle against so many adverse conditions, to cut them down.

The above-mentioned efforts to improve the conditions of sericulture were not sufficient, in view of the many difficulties which beset it, to attain their aim, and the Government had naturally to take the matter into serious consideration, owing to the great interests involved. After several measures, in January 1907 the Government decided upon an enquiry by a Commission under the presidency first of the Hon. L. Luzzatti and then by the Hon. Senator Cavasola, at present Minister of Agriculture. The Commission presented its report in 1910; this dealt with the conditions of Italian sericulture, the causes of its depressed state and the measures to be adopted. It is naturally impossible to give a résumé of it here; it will be enough to say that the Commission declared in its conclusions that the greatest evil which afflicted the silk industry was the want of organization, and it proposed the foundation of a Silk Institute as an independent body for the object of furthering the progress and the improvement of sericulture. Beside this measure, it recommended suitable provisions for credit, for the rail way tariffs, for the carriage of cocoons, silk and silk fabrics, and for the customs tariffs, with the object of facilitating the importation of raw materials required by the industry. It advocated also the extension of instruction in silkworm rearing and mulberry growing, especially in the colleges at Milan, Perugia and Portici. It demanded especially that the State should aim at obtaining *an increase and a progressive improvement in the production of national raw material, so as to supply completely the Italian*

(1) One of the most important esiccators is that of Cremona, which was founded chiefly by the exertions of Prof. Antonio Sansone, then director of the travelling professorship at Cremona and now Director-general of Forests.

factories and to keep up the character of Italian goods, which cannot be given by the raw material of other countries. Lastly the Commission asked that a complete and accurate study be made of the foreign silk trade and industry. The proposal of the foundation of the Silk Institute was not, however, accepted by Parliament, which nominated a Council for the Silk Interest, allotting to the Ministry of Agriculture £48 000 per annum for the above-mentioned objects, including the sending of special delegates to the East, to some countries in Europe and to New York, with the object of keeping in touch with the trade in raw material and in silken fabrics. The above sum was distributed as follows: For promoting silkworm rearing, mulberry growing, studies on silk, foundation of cooperative associations, etc., £20 000 and £4 000 in the financial year 1912-13. For the intelligence service and statistics £4 000. For the establishment of mulberry groves and distribution of mulberry trees, prizes to agricultural societies and farmers, control of *Diaspis*, etc., £10 000. For the increase of the endowment of the Como school of silk industry, for the new station of Ascoli, for the increase to the contribution to the Padua Station and for the three chairs at Milan, Portici and Perugia, £6 000. For scholarships to special courses of silkworm rearing at the above schools and other forms of propaganda, £4000; for increased subventions to travelling lectureships, £4 000. Lastly, for the first cost of the plant of the newly founded institutions and chairs and for the increase of the plant of the already existing ones £10 000.

The Silk Council was definitely constituted in July 1912 and has now actively entered upon its labours. It has appointed technical delegates in China, Japan, New York and other localities. It has turned its attention to the furtherance of professional instruction and provided for the encouragement of mulberry growing and silkworm rearing in all the regions of Italy; special attention has been paid to the south, which used to produce and still produces cocoons yielding abundance of good silk, notwithstanding the imperfections in the technique of managing the worms. During the 1914 season the Council started the publication of a Bulletin containing information on the cocoon crop in Italy and abroad and on every subject likely to interest the silk market.

The Ministry of Agriculture in its turn, availing itself of schools, travelling lectureships and other kindred institutions and of the above-mentioned funds, has begun a liberal distribution of mulberry trees and of silkworm eggs; it has organized special courses of instruction and has encouraged a number of breeders with an ample distribution of suitable instructions. Among these, special stress is laid on those which tend to teach the methods of diminishing expenses and consequently the cost of mulberry leaves and of cocoons.

As for the former, it has been recognized as advantageous in many instances to replace standard mulberry trees by hedges, low pollards, and so-called mulberry meadows, a kind of coppice which is cut every year and which renders the collection of the leaves much less expensive. In rearing, the breeders are advised, instead of feeding the worms on detached leaves, to give them whole shoots or twigs, as has been practised for a long time past

in Venetia. As regards the lack of housing, especially in the South, it has been shown that the Persian sheds or *tilimbars* are very convenient; these are built of poles and branches of trees at the beginning of the season and are dismounted as soon as the cocoons are gathered. Several tests of the system, especially those carried out at the Portici Agricultural College by Prof. Gustavo Leonardi, have demonstrated its superiority over other systems and its economy, especially under climates favourable to the worms like that of the South of Italy.

The above-mentioned law has provided for the greater and permanent spread of instruction and experimentation by founding a second Silkworm Rearing Station at Ascoli and three new chairs of silkworm rearing and mulberry growing at the Milan, Perugia and Portici Colleges. Many of these institutions are already in full work, and others will soon be founded; with them the whole series of measures for the attainment of the objects above-mentioned will be completed. The Divisions of Industry and Agriculture are actively devoting themselves to the work, whilst the Silk Council in its turn contributes opportune suggestions and expresses the real conditions and requirements of the country. Everything encourages us to hope that two of the most ancient and important sources of wealth, increased and strengthened by their own activity without artificial help and fiscal protection, will soon resume the place they once occupied in Italian public economy.

SECOND PART.

ABSTRACTS

AGRICULTURAL INTELLIGENCE

GENERAL INFORMATION.

DEVELOPMENT OF AGRICULTURE IN DIFFERENT COUNTRIES

870 – **Agriculture in Sweden..** — *Sweden, Historical and Statistical Handbook*, published for the Government by G. GUINCHARD ; second part : *Industries*, pp. 29-232. Stockholm, 1913.

In the year 1910, out of the 5 522 000 inhabitants of Sweden, 2 663 000 or 48.23 per cent., were occupied in agricultural pursuits ; in 1900 the percentage was 53.67 and in 1870, 71.87. Since 1880, in spite of the steady increase of the population, there has been also an absolute decrease in the agricultural population which then numbered 3 078 000 persons.

The cultivated area of the country was divided in 1911 among 359 871 farms, with an average area of about 25 acres under cultivation. The size of the farms has a very wide range. In the official statistics the groups according to size are as follows :

Size-group	Relative number
Up to 5 acres	25 per cent
5 to 50 »	64 »
50 to 250 »	10 »
over 250 »	1 »

As regards the area of cultivated land, small farms up to 25 acres and large ones over 125 acres each account for about ¼ of the total, the other half being occupied by the medium-sized ones. The extensive plains with fertile loam and clay soils in Central and Southern Sweden have relatively many large farms, while small farms are prevalent in the higher or hilly districts in the west and north of the country, on sandy and gravelly soils, where the cultivated land is cut up by mountains, woods and moors.

In general in Sweden, farmers own the land they farm ; in 1911 only a little over 14 per cent. of the whole number of farms were rented. Among the smaller farms renting is particularly uncommon (10 and 13 per cent. in the two smaller size-groups), while in the two groups of larger farms, with over 50 and over 250 acres, it is more frequent (31 and 35 per cent.).

In 1911 the total area of the country, 101 566 950 acres, was divided as follows :

Fields and gardens	9 144 700	acres or	9 per cent.
Meadows	3 226 325	»	3.2 »
Woods	52 828 600	»	52.0 »
Other descriptions	36 367 325	»	35.8 »

The arable area of Sweden has quadrupled in the last century. Table I shows the changes which took place in the areas occupied by the various crops between 1865 and 1911 :

TABLE I. — *Area under chief crops in* 1865 *and* 1911.

	1865	1911	1865	1911
	acres	acres	%	%

Total	5 765 200	9 032 000	100.0	100.0

The relative areas under the various kinds of cereals have changed considerably in the course of time ; barley, which was formerly the cereal most grown, has gradually lost importance, with the exception of Upper Norrland where it takes preference to other grain on account of its earlier ripening. As breadstuff barley has been chiefly replaced by rye; at the beginning of the 19th century the quantity of barley and rye harvested was about equal, while at the end of the century the rye crop was nearly twice the barley. Of late years the area under wheat has grown steadily, without however ceasing to hold the lowest place among the four leading cereals both for area and total yield. Oats have gained most of all in importance, now occupying almost half the area under cereals in the country; the crop is equal to that of barley, rye and wheat together, besides which, the bulk of the increasingly grown mixed grain is oats.

Of less importance in area occupied and in value are pulse crops (peas, beans, and vetches) and buckwheat, which is now grown only to a limited extent in the poorest sandy regions of Schonen.

With the increase in area under cultivation an increase of yield per acre has also taken place: it is due to improvements of the land, more

TABLE II. — *Area and yield of grain and pulse crops.*

abundant and suitable manuring, more thorough tillage, and the introduction of a more intensive rotation. The changes which have taken place in the acreage and yield of the various cereals and pulse crops since 1800 are shown in Table II.

Notwithstanding the increase in the production of grain in Sweden, namely from 598 lbs. per inhabitant at the beginning of the 19th century to 1 045 lbs. at present, among which breadstuffs figure for 205 and 315 lbs. respectively, a good deal of the constantly increasing consumption has to be met by importation.

In most of the twenties of last century the breadstuffs (wheat, rye and barley) harvested were sufficient for the wants of the country and soon an increasing export trade began, at first only with oats, but in the forties with barley, rye and wheat. In 1860, however, most of the exports ceased and the importation of wheat and rye in constantly larger quantities set in ; up to the middle of the eighties this was partly balanced by the exportation of oats, but after that time this also began to slacken, owing to the rising demands of the developing animal husbandry ; the result is that since 1902 the imports have been in excess of the exports by 2 to 3 millions sterling per annum. The condition of the trade is shown in Table III.

The following root crops besides potatoes are grown in Sweden : beets and mangolds, Swedes, turnips and parsnips. Between 1901 and 1910 about 1 450 100 tons of potatoes were grown yearly on 378 693 acres , this gives 614 lbs. per inhabitant, which is not much below the average figure for the west of Europe, namely 682 lbs.; deducting the seed (or about 10 cwt. per acre) there remains available for consumption 535 lbs. per inhabitant. Every year about 100 000 tons are used by the distilleries.

cereals (in metric tons).

The area under sugar-beets has increased from about 45 000 acres in the mid eighties of last century to 75 000 acres in 1911; the average crop for the period 1901-10 was 8 130 000 tons, or 11 tons per acre. The sugar content has steadily increased, the yield of unrefined sugar having risen from 6.6 per cent. in 1870 to 15.72 in 1911.

Forage crops were grown in 1911 on 3 355 227 acres, or 37.1 per cent. of the cultivable land. The forage plants most commonly grown are timothy and red and alsike clovers. The yield of grass leys is, according to official statistics, about 20 to 28 cwt. per acre, making altogether between 3 and 4 million tons; to this must be added the hay from natural meadows, at 8 or 10 cwt. per acre., or about 1 ½ million tons. Accordingly the whole hay crop, not including pastures, amounts to upwards of 5 million tons, worth about £14 000 000, or a third of the value of the total produce of the country.

Sweden possesses a great extent of pastures, but there are no available data as to their area and yield.

The area devoted to the cultivation of plants other than grain, root and forage crops, amounted, in 1911 to only 4038 acres, of which 3783 were under textiles.

The land in Sweden devoted to horticulture is given for the same year at 112 978 acres, or about 1.25 per cent. of the cultivated area. Fruit growing is the principal branch and is carried on intensively in some localities. The growing of flowers under glass has also considerably developed and vegetables are grown all over the country both for private consumption and for sale. Schools for gardeners exist at Alnarp in Schonen, Adelsnäs in Östergötland, Experimentalfältet near Stockholm and Härnosänd in Norrland. Special schools of gardening for women are those at Exper-

näs in Närke and Torshäll in Dalarne. Cooperation in horticulture is in a flourishing condition.

Animal husbandry (1) has been from time immemorial the chief branch of agriculture in Sweden. According to official statistics the live stock in 1911 consisted of the following :

Horses under the age of 3 years	Horses over the age of 3 years	Steers	Bulls	Cows	Cattle under 2 years	Sheeps	Goats	Pigs	Reindeer
493 322	95 163	144 277	52 467	1837 038	655 830	945 709	66 136	951 164	276 084

By the thirties of last century the importantion on a large scale of foreign, especially English, breeds of live stock had already begun and the State promoted breeding by the institution of central breeding farms for cattle and sheep ; these were, however, broken up about the end of the 19th century and the stock sold off. The proceeds were devoted to a "Fund for the improvement of Swedish cattle and sheep". Among the general measures adopted for the promotion of animal husbandry, prize giving is now the most important. There are prizes for horses, cattle, sheep and pigs. In 1911 the amount spent in prizes for cattle was £19 350 of which the State contributes £6 600.

At present the five following breeds of cattle are awarded prizes.

1) The *Fjäll* (North Swedish cattle) in Norrland and Dalarne ; the cows yield about 550 gallons of milk per annum with an average fat content of 3.8 per cent . ; their live-weight is about 770 lbs.

2) The *Swedish Red Poll* in Dalarne, Bohuslän and other districts ; their milk yield and live-weight are about the same as in the Fjäll.

3) The *Ayrshire* in Southern and Central Sweden ; the cows give about 770 gals. of milk containing an average of 3.6 per cent. of fat ; their live-weight is about 1000 lbs.

4) The *Red Spotted Swedish* in Central Sweden ; yearly milk yield about 880 gals. with 3.8 per cent. fat ; average live-weight 1 100 lbs.

5) The *Black Spotted Swedish Lowland* in Southern Sweden : milk yield 990 gals. with 3.3 per cent. fat ; live-weight about 1265 lbs.

In the year 1911, 58 020 animals were exhibited, 50 761 taking prizes. Besides the awarding of prizes the following measures have also largely contributed to the success of Swedish animal husbandry : the institution of herd books, the auctions of breeding cattle, the competitions for the formation of cattle-breeding centres, the record associations and the veterinary and educational services.

In the breeding of horses heavy draught horses occupy a prominent position. To this type belong the Dalbo horse in Dalsland and northern Bohuslän and the North Swedish horse. They are rather small but power-

(1) See also E. O. ARENANDER : "The recent development of Cattle Breeding in Sweden". — *B.* Oct. 1913, pp. 1502-1511. (*Ed.*).

ful, resistant and exceptionally thrifty animals. In order to give the Swedish horse more bulk and strength the following foreign strains of blood have been introduced, especially since the middle eighties of last century: Percherons, Pinzgaus, Clydesdales, Norwegians and Belgians. The first two have not had any notable influence on the native breeds. Clydesdales, which in Wästergöttland laid the foundation of the Levene horse, have had a certain importance, especially in the beet-growing districts; but they are giving place to Belgian Ardennes, which have been crossed with the native breed to produce a compact, powerful horse with lively action (1). In 1901 the studbook for Swedish Ardenne horses was founded; out of the hundred or so stallion and horse-breeding associations existing in the country about seventy aim at the production of an Ardenne type.

Of much less importance than the breeding of draught horses is the breeding of half blood horses, which are chiefly devoted to the production of army remounts. For these there are two stallion depots: Flyinge in Schonen and Strömsholm in Västmanland, with about 230 stallions. Of these about 20 are English Thoroughbreds, the rest Hanoverians and East Prussians. The breeding of Thoroughbreds in Sweden is insignificant. The breeding of poneys gains constantly in importance; the demand for poneys is met by importation from Iceland.

The breeding of pigs has gained much importance since the beginning of this century. The pig-breeding associations and stations are assisted by the State. Only English Large Whites and Swedish or Danish pigs are awarded prizes.

Sheep breeding is constantly losing ground. For the improvement of the sheep Cheviot rams, some imported from Scotland and some raised in Gottland, are used. In Southern and Central Sweden some English breeds, such as Oxford, Shropshire and Southdown, are kept. Merincs, which in the eighteenth century were very numerous, are now reduced to two or three hundred head in Sodermannland and Östergötland.

The breeding of reindeer is more important. In Sweden a distinction is made between the high mountain reindeer and the forest reindeer. The former spend the summer in the high mountain land and only the winter in the woods, while the latter live throughout the year in the woods. The value of the Swedish stock of reindeer may be estimated at about £250 000, while its yearly returns are upwards of £55 000.

Poultry breeding is highly developed in the south of Sweden. There is a considerable exportation of eggs and birds. The number of head of poultry is estimated at 4 250 000. The General Poultry Association founded in 1898 included, in 1910, 23 district associations with 6 601 members. There were also in the same year sixty egg-purchasing cooperative associations within the Län Malmöhus; these collected eggs from 160 receiving stations.

(1) See No. 754, *B.* Aug. 1914. (*Ed.*)

Bee-keeping has also made considerable progress during recent years. The number of hives in 1911 was at least 120 000 ; the yearly output of honey was estimated at 1 320 000 lbs. and that of wax at 23 760 lbs.

Table IV shows the foreign trade in animals and their products in recent years.

Dairying in Sweden, the history of which can be followed back for seven centuries, has developed very considerably since the milk separator was invented in 1878. In 1910 there were 1382 dairies in the country ; of these 542 were cooperative dairies, 457 collecting dairies, 276 estate dairies and 107 estate collecting dairies. Cooperation is most widely diffused in the southern and northern parts of the country, while in Central Sweden the estate and collecting dairies prevail. In 1911 the total amount of milk delivered at the dairies was 252 828 394 gals., of which 30 133 330 gals. were sold as whole milk ; the rest, upwards of 220 000 000 gals., was used in the manufacture of cheese and butter. The dairies producing only butter numbered 845, while 327 produced only cheese, and 208 both

butter and cheese. The amount of butter produced is constantly increasing; it was 57 450 840 lbs. in 1900, 61 598 700 lbs. in 1905 and 72 464 577 lbs. in 1910. The production is most intensive in Schonen and Halland, where in 1910 about half of all the butter produced in the country was made. Of the butter exported, 75.01 per cent. goes to England, 20.74 per cent. to Denmark and only 3.92 per cent. to Germany and 0.33 per cent. to other countries. The preparation of cheese has made slow but steady progress during the last twenty years; the increase is observed only in fat cheeses, the production of the other cheeses being on the decline.

Further assistance to dairying in Sweden is offered by the labours of dairy instructors and advisers, by the schools of dairying, by the dairy stations, exhibitions and the organization of the examinations of butter (the butter that has been examined being distinguished by a special mark).

The Royal Agricultural Department, under the Ministry of Agriculture which was instituted in 1900, is at the head of the State agricultural advisers, of the peat and fishery inspectors and of the 22 agricultural engineers; with the 26 Chambers of Agriculture at present existing, it takes all the public measures calculated to promote agriculture or proposes them to the Ministry.

Sweden possesses at present 15 farming schools, 33 schools of agriculture in which practical and theoretical courses lasting at least 20 weeks are held, two upper housekeeping schools in which women teachers of housekeeping are trained, two agricultural institutes for higher agricultural education (Alnarp and Ultuna), three schools of farriery and one veterinary college (Stockholm).

Further chapters treat of agricultural credit, of the control and experiment services (17 chemical control stations, one State central institution for agricultural experimentation and several other experiment stations connected with the agricultural institutions or founded by associations and chambers of agriculture, 17 seed control stations), of the question of seeds (Society for the Improvement of Agricultural Plants, Swedish General Seed Company and Svalöf Institute (1)), the work of the Swedish Moor Cultivation Society and other agricultural associations, the measures for promoting agricultural book-keeping, the question of agricultural labour, and agricultural legislation in general and that of farm renting in particular.

Forestry is discussed in a section by itself, from which a few figures are here given to show the importance of forestry in Sweden. Of the whole area of the country, 52 per cent. is covered by forest; that is 969 acres per 100 inhabitants, while Russia has only 415 for the same number. The 52 million acres of forest represent a total value of about £85 756 000. Only one-third of the forests are property of the State or of public bodies,

(1) See NILSSON: "The Swedish Institute for the Improvement of Field Crops at Svalöf". — *B.* June 1913, pp. 834-843. (*Ed.*).

the rest being private property. In 1911, 1 329 million cub. ft. of wood were cut ; in 1913 the value of wood imported amounted to £1 049 000 against £16 595 000 exported.

RURAL HYGIENE

871 – **Control of Beri-Beri: Curative Action of Autolysed Yeast Against Avian Polyneuritis.** (1) — COOPER, EVELYN ASHLEY (Beit Memorial Research Fellow, Lister Institute) in *The Biochemical Journal*, Vol. VIII, No. 3, pp. 250-252. Cambridge, June 1914.

The autolysis of yeast was obtained by placing pressed brewers' yeast in a flask in a hot room (35° C.) for 36 hours, when the yeast was rapidly converted into a brown fluid. This was filtered and the residue washed with a little water. Pigeons affected with polyneuritis were readily cured by 3 cc. of this liquid.

Experiments were also made with air-dried yeast, which had been stored for six weeks ; to this some water was added and it was then allowed to autolyse at 35° C. for 48 hours ; the filtrate was found equally curative.

The writer summarizes the results obtained as follows:

1. By the autolysis of brewers' yeast a solution can be obtained which possesses as marked curative properties towards avian polyneuritis as the original yeast.

2. The solution retains its curative power for at last eight weeks and when given orally to birds in doses 10 times as great as the minimum curing dose has no toxic action.

3. An air-dried yeast retains its curative power after storage for two years in a dry tin, and still autolyses after storage for four months.

The writer concludes that the autolysis of brewers' yeast should afford a simple and inexpensive method of preparing a non-toxic solution suitable for the oral treatment of human beri-beri.

AGRICULTURAL EDUCATION

872 – **American Black Flies.** — NALLOCH, Y. R., in *U. S. Department of Agriculture, Bureau of Entomology, Technical Series*, No. 26, pp. 72 + 6 plates. Washington. April 6, 1914.

The *Simulidae* are of considerable economic importance as parasites of domestic animals and man. The writer gives a classification and scientific description of the American species in all phases of their life cycle, based on a study of the collections in the United States National Museum. He distinguishes 5 species of *Prosimulium*, one of *Parasimulium* and 29 of *Similium*. A bibliography of 26 works on the subject is appended.

873 – **Agricultural Schools in Panama.** — *Daily Consular and Trade Reports*, Year 17, No. 172, p. 476. Washington, July 24, 1914.

Two agricultural schools are to be established in Panama. One of the schools will be located near New Gorgona. The Government is also contemplating the establishment of an agricultural experiment station.

(1) See also No. 1130, *B.* Aug. 1912. (*Ed.*).

874 – **The Experiment Farm at Genale, Italian Somaliland.** — ONOR, R. (Agricultural Adviser at Genale) in *Giornale di Agricoltura della Domenica*, Year XXIV, No. 30. Piacenza, July 26, 1914.

The fundamental technical problem in the agriculture of Benadir is that of irrigation. When that is overcome one may say that, apart from questions of practical convenience, almost every tropical crop is possible. On the other hand the draught animals are liable to serious parasitic diseases, so that the questions of cultivation of the land and transport become an additional problem. Further, in addition to these and other technical problems of first-rate importance, is the question of the economic value of the various crops.

In view of these facts the Government decided on the formation of an experiment farm at Genale, to which the Governor added four farms to be allotted to four families of Italians with a view to facilitating a preliminary colonization experiment. In February 1912 the first huts were built, and the station is now assuming its normal aspect with brick buildings constructed locally.

The mechanical elevation of the water for irrigation, which has been provided for at Genale by centrifugal pumps worked by oil engines, the study of the possible utilization of the wind, and the application of motor power to agricultural work and transport, are all questions for investigation which will entail considerable funds. Further, the administrative side of the farm will render assistance by providing information of great practical value. The book-keeping, which during the initial period was, owing to the opportunity offered, concerned only with certain items of outlay, is now carried out like that of any private enterprise.

The progress of the scheme has not so far allowed well organized experiments to be conducted, especially as the largest share of attention had to be given to crops which seemed likely to be of the greatest economic importance in Benadir. Among the plants already studied and those under experiment are the following :

I. Starch-producing plants : *Manihot utilissima*, *Dioscorea Batatas*.

II. Cereals : oats, maize, millet, barley and Indian upland rice.

III. Rubber plants : *Manihot Glaziovii*, *M. dichotoma*, *Funtumia elastica*, *Parthenium argentatum*.

IV. Dye and tannin plants : *Bixa orellana*, acacias, *Carthamus tinctorius*.

V. Spices : *Coffea liberica*, *Zingiber officinale*.

VI. Textile plants : *Fourcroya gigantea*, *Agave Sisalana*, *Corchorus capsularis*, various cottons, *Eriodendron anfractuosum* (kapok), *Hibiscus Sabdariffa*.

VII. Oil crops : coconut, earthnut, sesame, castor-oil.

VIII. Sugar crops : sugarcane, Minnesota sorghum.

IX. Fruits : *Citrus* spp. (orange, lemon, tangerine, grape-fruit), *Anona* (*muricata*, *Cherimolia*), *Mangifera indica*, olive, guava, bananas, papaw, pineapple.

X. Narcotic plants : tobacco.

XI. Timber trees and various : *Inga dulcis, Poinciana regia, Terminalia Catappa,* tamarind, *Eucalyptus Lehmanni, E. citriodora, Cedula odorata, Cassia florida, Casuarina equisetifolia, C. tenuissima,* bamboos, *Parkinsonia,* mulberry.

XII. Vegetables: French beans, *Dolichos,* cowpea, soy bean, capsicum, egg-plants, onions, cabbage, chicory, beetroot, *Hibiscus esculentus,* cucumbers, etc.

XIII. Leguminous forage plants : lucerne, sulla, sainfoin.

AGRICULTURAL INSTITUTIONS

875 – **The Reorganization of the Experimental Garden at Hamma, near Algiers.** — *Bulletin de l'office du Gouvernment Général de l'Algérie,* Year 20, No. 12, pp. 194-195. Algiers, June 15, 1914.

Several years ago the experimental garden at Hamma, which had been leased to a financial company in 1883, was taken over by the Algerian administration and reorganized on a rational system with a view to its better utilization. With this object two decrees were issued on June 5, 1914, the first cancelling the previous lease and approving the necessary equipment, the second defining the reorganization of the garden.

According to article 1 of the second decree, the experimental garden at Hamma is to serve the purpose of a nursery for the production and distribution of native crops and as a garden for scientific studies and the acclimatization of exotic plants.

The staff of the garden consists of administrator, head gardener, and clerk. The governing body consists of a permanent technical commission, comprising the following :

The Director of the Botanical Department.
The Professor of Botany.
The Director of the Pasteur Institute.
The Chief of the Forestry Research Station.
The Chief of the Agricultural Department of Algiers.
The Delegate of the Algerian Horticultural Society.

The garden collaborates with the Departments of Phytopathology, Forestry and Entomolgy, the Faculties of the University of Algiers, and, on advice from the technical commission, all other public services which require it. A museum of natural history for North Africa, the necessary laboratories and a small zoological park may be added, and a department of horticultural instruction will be organized for the education of working gardeners and grafters.

CROPS AND CULTIVATION.

SOIL PHYSICS, CHEMISTRY AND MICROBIOLOGY

876 – **A New Method of Determining the Density and Porosity of Soil and Rocks.** — Truka, Rudolf (Tábor, Bohemia) in *Internationale Mitteilungen für Bodenkunde,* Vol. IV, Part 4-5, pp. 363-387. Berlin, 1914.

The writer has devised a new method for the determination of the specific gravity of soils and rocks, based on the researches of Dr. Slavik. Its novelty consists in detaching a lump of earth from the interior of a lar-

er block without subjecting it to pressure or in any way altering its natural tate. The small lump is dried at 100° to 103° C., then plunged in liquid araffin at a temperature of 40 to 50° C., so that it becomes covered with very thin layer of paraffin. The volume of the sample is determined by isplacement of water in an apparatus specially designed by the writer, who escribes it in great detail.

The method is applicable to all types of adhesive soils and the writer continuing his studies with a view to devising a method suitable for andy soils. An examination of the results obtained by this and other ıethods has led the writer to the following conclusions :

A. *Specific gravity.* — 1) If the density of a soil is to be used for etermining its physical properties, a more exact method is required.

2) Those methods in which a given volume of soil is obtained by lling a standard measure, or by sedimentation in water, should be bandoned, since they do not take into account the stratification of ıe soil.

3) Methods involving the sampling of the soil by means of cylinders tubes should also be abandoned, since the experimental error is too reat.

4) The only method that can be recommended is one which consists taking lumps of earth showing the natural stratification unchanged, ıereby reducing the error to a minimum.

B. *Porosity.* — 1) For the porosity to be an exact indicator of the rcperties of the soil, it must take into account the natural stratification the land.

2) Any disturbance of the natural lie of the soil in sampling is inadmis-ble, as it will lead to changes in the porosity.

3) The determination of the porosity by means of a lump of soil showing ıe natural stratification is the only method which gives results agreeing ith practical experience.

4) Porosity cannot be considered alone in determining the value of a ven soil ; other properties must be taken into account.

7 – **A New Method for the Determination of Soil Acidity.** — Truog, E. (Wisconsin, Experiment Station) in *Science*, Vol. XL, No. 1024, pp. 246-248. Garrison, N. Y. August 14, 1914.

Acid soils boiled with zinc sulphide and water liberate sulphuretted ydrogen, traces of which can be easily detected with lead acetate paper. ı this besis the following method of determining soil acidity was evolved : gms. of soil are placed in a 300 cc. Erlenmeyer flask with 1 gm. of calcium loride, 0.1 gm. of zinc sulphide and 100 cc. of water.; the mixture is oroughly shaken and heated over a flame ; after the contents of the flask ve boiled one minute, a strip of moistened lead acetate paper is placed er the month of the flask and the boiling continued two minutes more, ıen the paper is removed. If the soil be acid the paper will be darkened the under side, the shade obtained varying with the degree of acidity ›m almost white to black, and the percentage acidity may be estimated means of a standard colour scale.

This test is more delicate than the litmus test, is extremely simple t carry out and has proved very reliable ; in no case have alkaline soils give a positive reaction, even when they had undergone previous anaerobi fermentation. Experiments are now in progress to make the method mor accurately quantitative by titrating the liberated hydrogen sulphide wit iodine solution.

PERMANENT IMPROVEMENTS. DRAINAGE AND IRRIGATION

878 – **The Ombrone Diversion for the Reclamation of the Plain of Grosseto Italy.** — Luiggi, Luigi, in *Giornale del Genio Civile*, Year LII, pp. 254-260. Rome May 31, 1914.

The Ombrone diversion in the province of Grosseto, Italy, is one of th most important hydraulic works now in course of construction.

It will be capable of conveying 21 200 cubic feet of water per second and in case of need even 24 700 cu. ft., whilst the Cavour Canal (so far th largest in Italy) conveys only 3885 cu. ft., the Ganges Canal 6710 cu. ft feet, and the Euphrates diversion (1) (hitherto the largest in the world 14 125 cu. ft.

The object of the Ombrone diversion is not irrigation, as in the above mentioned schemes, but the utilization of the silt carried down by th water for reclaiming, by means of warping, the swamps which the protru sion of the river mouth has produced in the neighbourhood of Grosseto

The flood water sometimes contains for about 24 hours as much a 10 per cent. of silt, and on the average there are six good floods every year

In order to utilize this material to the best adavantage, it is necessary to waste no time in securing the greatest quantity of water when it ha its maximum load of silt and to fill all the depressions as speedily as pos sible ; hence the necessity of a large intake with rapidly acting sluices.

The works consist in : 1) a submergible weir across the bed of the rive at the head of the canal ; 2) a head regulator or barrage ; 3) a channe between the weir and the regulator ; 4) the main canal for the flood wa ter ; 5) distributing secondary channels ; 6) channels for draining off th clear water after the silt has been deposited ; 7) accessory works for th power plant to work the sluices and for the electric lighting of Grosseto storehouses, bridges, etc.

The submergible weir is 502 feet long. It is a mass of concrete face with ashlar. The vertical section of its surface is a sinusoid curve whic prevents the formation of vortices. It was built in 1879 and has successfull withstood the heaviest floods.

The regulator barrage has seven openings from 15 ft. 3 in. to 17 ft. 9 i wide and 20 ft. 7 in. high, closed by sluice gates worked by electric powe which can be completely raised or lowered, two at a time, in 8 minute The piers of the archways are 3 ft. 8 in. thick.

The main canal is about 180 feet wide at the bottom and is capab of conveying 21 200 cubic feet of water per second with a depth of wat of 17 ft. 4 in. and a velocity of 7 ft. 8 in. per second, or 24 700 cu. ft. wit a depth of 18ft. 4 in. and a velocity of 8 ft. 4 in. These high velociti

(1) See No. 414, *B.* May 1914. (*Ed.*).

are necessary firstly to keep the dimensions of the canal within reasonable limits and secondly to prevent any untimely deposit of silt.

Close to the regulator two buildings have been erected, one for two groups of 40 HP oil motors which drive the dynamos and a 20 HP motor for the workshops and electric light, etc., and the other as a storehouse, workshop and dwelling house for the workmen.

At the side of the canal between the weir and the regulator there is another building with a one-arch regulator for a power channel for the electric lighting of the city of Grosseto and a grain mill. This channel conveys 176 cu. ft. of water per second.

The main diversion or warping canal is about 10 ½ miles in length; for the first 2625 feet it is lined with masonry walls about 164 ft. apart. The rest of the canal is between embankments; it is 213 ft. wide at the water level and 178 ft. at the bottom, in which a small channel has been excavated to drain the canal when not in use, so as to prevent the breeding of mosquitoes. The canal is crossed by seven bridges and feeds the secondary distributing channels which convey the water to the various sections. Provision is also made for the drainage of the adjoining country.

It is calculated that in 24 hours 1236 million cubic feet of water can be collected to fill all the warping sections and that the passage of muddy water and discharge of clear water can be continued without interruption as long as the flood lasts.

The depth of the silt deposited by the floods is about 4 inches per year, but the swampy bottom, consisting of marine mud and peat, will subside under the weight of the silt; consequently the warping will be slow; it is, however, believed that the whole area of 12 350 acres will be completely reclaimed in about 30 years and will then provide excellent soil for farming purposes. Meanwhile the outside belt of the depression is already reclaimed and public health at Grosseto has already much improved.

The cost of the intake and canal is estimated at £ 160 000 and that of the whole work, including the drainage channels and regularization of rivers and a navigable canal, at £ 800 000.

79 – **The Composition and Value of Bat Guano.** — MILLER, C. F. (Bureau of Soils, U. S. Department of Agriculture, Washington) in *The Journal of Industrial and Engineering Chemistry*, Vol. 6, No. 8, pp. 664-665. Easton, Pa., August 1914. MANURES AND MANURING

The following results of a series of analyses of bat guano were obtained by the Bureau of Soils.

The notable variations of composition are due to: *a*) the presence of foreign matter, such as rock fragments, etc. (the Porto Rico samples were very rich in lime); *b*) the loss of useful constituents by washing out and by the decomposition and volatilization of nitrogen compounds.

The sample from Haiti is a pure bat guano of recent formation and practically undecomposed. It is calculated that this deposit contains about 000 tons valued at about £ 5 600, taking the price per ton as £ 8 approx., based on its chemical composition. This deposit exceeds the average in both quantity and quality.

Analyses of Bat Guano (percentage of dry matter).

Locality	Nitrogen	Phosphoric acid	Potash	Volatile matter

No precise data relating to the area of bat guano deposits in the United States exist, but they are known to be very extensive.

880 – **The Solubility of the Various Constituents of Basic Slag.** — SIROT, MAURICE and JORET, GEORGES (Yonne Agricultural Station) in *Journal d'Agriculture Pratique* Year 78, Vol. I, No. 25, p. 78. Paris, June 18, 1914.

Besides phosphoric acid, basic slag contains other elements (magnesia, sulphur, manganese, iron, etc.), whose usefulness as soluble chemical manures has been recognized for some years.

The writers have endeavoured to find out to what extent these elements are soluble, both by Wagner's reagent and by solution in various organic acids of such concentration that the acidity of the solution is equal to that of 2 per cent. citric acid (Wagner's reagent). The method was the same as that employed in determining the citric-soluble phosphoric acid.

From their very numerous analyses, the writers have found that all the elements studied (silica, phosphoric acid, lime, magnesia, sulphur, iron and manganese) exist in a form soluble in various weak acids; the degree of solubility varies according to the fineness of the slag or to the actual solubility of the salts formed (citrates, malates, lactates, etc.).

The degree of solubility of the different elements varies as follows:

	per cent
phosphoric acid	24 to 87.2
lime	48.4 to 89.4
magnesia	3.1 to 67.6
iron	10.8 to 41.4
manganese	7.7 to 39.7

Citric and malic acids have the greatest power of solution, and lactic, acetic, tartaric and oxalic acids follow in order.

In the slags studied there are few insoluble silicates. The silica is very soluble in weak acids, citric, lactic and malic dissolving about 90 per

cent. of the total. It appears that the solubility of this element varies with that of the phosphoric acid, as would be expected if these two elements are in a state of combination as silicophosphate, as many writers affirm. The solubility of iron and manganese also appears to vary in the same proportions.

In conclusion, basic slag can be considered not only as a phosphatic manure but also as a compound manure.

881 – **Measures for Meeting the Shortage of Potash Manures in Great Britain.** — *Leaflet of the Board of Agriculture and Fisheries.* London, August 1914.

The Board of Agriculture and Fisheries desire to draw the attention of farmers and gardeners to the need for seeking new sources of potash manures, since the existing stock is very small and no further importation is possible for the present.

The chief natural sources of potash immediately available are: 1) seaweed, and 2) weeds, prunings, hedge-clippings, brushwood, leaves and vegetable refuse generally.

Seaweed is already extensively used as a manure on the coasts, and all who have access to this source of supply should collect it in quantity. Broad weed (*Laminaria*) may be used direct as a manure; grassy weed and tangle (*Fucus*, etc.) should be dried and burnt wherever possible. A ton of fresh seaweed should yield 20 to 30 lbs. of potash, or sufficient to manure from a quarter to half an acre of potatoes.

Inland farmers and gardeners may obtain potash by burning all kinds of vegetable refuse not suitable for direct application to the soil. The percentage of potash in vegetation varies very widely; among ordinary weeds for example, thistles might yield 5 per cent. and nettles 2.5 per cent. of their weight as potash; timber contains very little potash, cordwood a considerable quantity, and brushwood still more; ordinary wood ashes might contain from 5 per cent. to 10 per cent. according to their source. Ashes from the burning of weeds, prunings, hedge-clippings, etc., may contain from 10 to 15 per cent. of potash, i. e., corresponding to an equal weight of kainit, which last spring sold at about £ 2 10*s* per ton.

It is absolutely essential, in the absence of full supplies of farmyard manure, that potash should be supplied to such crops as potatoes and (on light soils) turnips, and that it should be available in gardens for potatoes, carrots, parsnips, onions and many other crops.

In many districts farmers might advantageously employ unemployed labourers in the collection and burning of all vegetable refuse. The ashes should be stored in a dry place and applied in the following spring.

882 – **Coloration of the Seed-Coat of Cowpeas.** — MANN, ALBERT (Plant Morphologist, Bureau of Plant Industry, U. S. Dept. of Agriculture) in *Journal of Agricultural Research*, Vol. II, No. 1, pp. 33-56 + 2 figs. Washington, April 15, 1914.

This study was undertaken to determine the possible relationship between the arrangement of the various layers of pigment and the heredity of colour in the seed coat, and to verify the supposition that colours optically alike are, in some cases, different in the constitution of the pigment

and place of deposit. The subject is dealt with under the following heads : Methods of Preparation, Morphology of the Seed Coat, Pigmentation of the Basal Colour Layer, Pigmentation of the Palisade Layer, Seeds Destitute of Pigmentation, Classification of Colour Factors in Cowpeas, Classification based on Distribution and Kinds of Pigments (1. Cowpeas having no pigment in the palisade layer ; 2. cowpeas having only anthocyanin in the palisade layer ; 3. cowpeas having only a melanin-like pigment in the palisade layer ; 4. cowpeas having both a melanin-like pigment and anthocyanin in the palisade layer).

The writer summarises the results as follows. The greatly diversified colour schemes of the different varieties of cowpeas may therefore be reduced to two factors : 1) an extremely uniform basal colour, ranging from very pale yellow to deep copper red, but found to be in all cases due to a melanin-like pigment deposited in the basal colour layer, the differences in tint being unquestionably caused by differences in quantity rather than in character of the pigment present ; and 2) a superimposition upon this basal colour of variously arranged pigment areas in the palisade layer, the outer layer of the seed coat, the pigments here being of only two kinds, first, a melanin-like pigment very generally identical in colour and behaviour to that found in the basal layer, and, second, an anthocyanin pigment, either associated with this or found in separate cells.

This anthocyanin pigment may be of a red or blue colour according as the reaction is acid or alkaline, and these two colours may be found in the same cells or in separate cells. Finally, according as only one or more than one or all of these pigments are present in the palisade layer, or according as they are uniformly distributed throughout its cells or are variously localised in large or small areas of its cells, we get the remarkably diversified blotching, streaking, speckling, marbling or monochrome colorations which characterise the different varieties of cowpeas.

In cases where the seed coat is white or cream coloured, or has a certain white area, or even where there is merely a slight speckling, the palisade cells show great distortion of outline and unevenness in the cell cavity. Again, in most parti-coloured cowpeas of strongly contrasted tints, the strongly coloured areas have perfectly regular, symmetrical palisade cells, while the lighter areas are more or less strongly contorted in form and irregular in the cell cavity. In other words there is a decided correlation between the morphology of the palisade cells and the suppression of the pigments in these cells.

85 - **Palms Indigenous to Cuba.** — BECCARI, ODOARDO, in *Pomona College Journal of Economic Botany*, Vol. II, No. 2, pp. 253-276, and No. 4, pp. 351-377 ; Vol. III, No. 1, pp. 391-417. Claremont, California, March and December 1912 ; February 1913.

List and botanical description, accompanied by figures, of palms indigenous to Cuba and neighbouring islands. Twenty-five species are described, of which two belong to the family *Cocoineae*, six to *Areceae*, and the majority of the rest to *Corypheae*. The writer concludes with an account of the mode of growth of the trunk of palms.

884 – **The Influence of Pressure on the Structure of Roots.** — MOLLIARD, MARIN, in *Revue Générale de Botanique*, Vol. 25 (bis), pp. 529-538. Paris, 1914.

The roots of plants growing in soils on schist formation often penetrate between two strata and become subjected to considerable pressure, which results in malformation. The writer summarises the anatomical characters of such roots as follows :

1). The cells are narrower.

2). The living cells are only slightly deformed, whilst the older tissues, such as the wood vessels, are flattened out.

3). Cell division ceases beyond a certain pressure, but without the life of the cells being destroyed.

4). The xylem and phloem elements grow chiefly in a direction parallel to the plane of the pressure.

5). Differentiation of secreting canals may cease.

6). The fibrous tissues are largely or entirely suppressed.

7). The two extremities of the compressed portion of the root become hypertrophied.

These observations were made on material of *Carlina corymbosa*, *Oenanthe Crocata*, *Plantago maritima* and *Hedera Helix*.

885 – **The Aroma of Hops : Studies of the Essential Oil and its relation to Geographic Distribution of Hops.** – RABAK, FRANK (Chemical Biologist, Drug-Plant and Poisonous Plant Investigations, Bureau of Plant Industry, U. S. Department of Agriculture), in *Journal of Agricultural Research*, Vol. II, No. 2, pp. 115-159, + 14 figs. Washington, D. C., May 1914.

The writer has made determinations of the following properties : specific gravity, optical rotation, refractive index, solubility in pure or dilute alcohol, boiling point, ester value, acidity, saponification index. Comparisons have been made of hops from the United States (California, Oregon, Washington, New York) with hops from Bohemia (Saaz) from authenticated sources during four consecutive years.

The volatile oil was prepared by distillation in a current of vapour. The average yield of essential oil varies considerably for a given locality from one year to another. The specific gravity of the essential oil from different Californian hops was almost constant during the same season and varied very little from one year to another . A similar observation was made with regard to the refractive index. The averages of numerous determinations obtained during several years are given in the following table. The data relating to Californian hops are from samples from five different sources.

The writer concludes from his results that the volatile oil of hops consists chiefly of : 1) myrcene ; 2) esters consisting of compounds of heptoic (œnanthylic), octoic (or caprylic), nonoic (or pelargonic) acids in combination with myrcenol (alcohol) ; 3) humulene ; 4) traces of free acid ; 5) formaldehyde. The various essential oils examined contained different proportions of ester, myrcene and humulene. Although not much importance is attached to the two latter constituents, the variations of strength of ester are very significant in relation to the aroma.

The chief chemical and physical properties of the essential oil of hops.

Origin	Essential oil, per cent.	Specific gravity	Refractive Index at 20° C.	Volume of ess. oil. soluble in 3 vols. of alcohol at 94° C. (1909)	Index of acidity	Ester value	Index of Saponification
California .	0.324	0.8326	1.4775	0.8	1.41	45.6	47.0
Oregon....	0.290	0.8385	1.4745	1.0	2.70	58.8	61.5
New York.	0.192	0.8554	1.4753	0.8	3.25	50.9	54.2
Washington	0.370	0.8482	1.4748	0.9	1.25	52.8	54.0
Imported .	3.310	0.8433	1.4862	0.75	2.02	23.5	25.5

Important differences in the constitution of the essential oils occur not only in hops of the same season and from different districts, but also from the same districts during several seasons. These differences appear very prominently in the curves of the chemical and physical properties. The curves of fractional distillation representing a partial quantitative separation of the principal constituents show very clearly the relation between the hops of a particular district during the different seasons. The curves of optical rotation also show this relation very clearly. Generally, the physical properties (fractionation, specific gravity, and optical rotation) show the existence of strong resemblances between the essential oils of the same type and strong differences between oils of different type.

Since the esters are the most important constituents affecting the aroma of hops, the various hops have been compared by means of the ester values of their essential oils after distillation. The curves of the strength of ester of different essential oils and their fractions show at once the different geographical distributions. All hops from countries other than North America were always difficient in esters.

The essential oils of hops from California are very similar from one year to another with regard to their physical and chemical properties. The hops from the various parts of California are very analogous and give parallel curves each year. The essential oils of hops from Oregon and Washington are very analogous, but show slight differences from those of California. The hops from New York State resemble foreign varieties with regard to essential oil, but are richer in esters. Arranged in the order of increasing strength in esters they are as follows: imported hops, Californian, Washington, New York, Oregon, the last three being almost alike.

It has not been possible to establish any relation between the ester value of the essential oil and the quality of the hops, though this value shows a distinct relation to the place of origin in every case. A bibliography of twenty-seven works is appended.

886 – **Fenugreek Seeds.** — WUNSCHERDORFF (Chief of works of the Faculty of Medicine and Pharmacy at Algiers), in *Journal de Pharmacie et de Chimie*, Year 106, 7th Series, Vol. X, No. 4, pp. 152-155. Paris, August 16, 1914.

Fenugreek seeds are exceptionally rich in nitrogen and phosphorus, the former in the form of albuminoids, the latter in the form of phytin, nucleo-albumin, and especially lecithin (1.5 to 1.7 %) which is present in greater quantity than in any other seed. The flour obtained from the decorticated seeds contains 5.81 % of nitrogen, corresponding to 36.3 % of albuminoid matter, 1.042 % of phosphoric acid, of which 0.135 % is in the form of lecithin, 0.758 % as phytin, and 0.149 % as nucleo-albumin. These seeds are therefore of high nutritive value. They were used by the ancients in recuperating the constitution and are now used by the natives of North Africa as a protection against disease, an extract being used as a febrifuge. The writer confirms their food value but doubts their medicinal value. The bitter flavour and disagreeable odour after eating are much against their use. The writer has found that this disagreeable odour is due to a diastatic action taking place during the final stage of ripening of the grain, and that it disappears on germination. Treatment with boiling alcohol and rapid drying at low temperatures destroys the odour and enables them to be preserved indefinitely in air-tight tins.

887 – **The Assimilation of Atmospheric Nitrogen by Plants.** — KÖVESSI, FRANÇOIS, in *Revue générale de Botanique*, Vol. 25 *bis*. (Researches in Vegetable Biology : dedicated to GASTON BONNIER by his pupils and friends on the occasion of the 25th anniversary of the foundation of the Laboratory of Plant Biology at Fontainebleau), pp. 405-415. Paris, 1914.

The writer confirms the previous conclusions concerning the utilization of the free nitrogen of the air by plants (1). Plants were grown under the two following conditions : 1) in an atmosphere without nitrogen (oxygenated) ; 2) in the open air. The two series gave the same reactions, showing the presence of protein in the hairs, particularly in the specialized hairs studied by JAMIESON, and by ZEMPLÉN and ROTH, who attribute to them the power of absorbing and fixing nitrogen from the air.

Various protein reactions were applied, from the results of which the writer draws the following conclusion : The presence of protein in the hairs of plants grown in a nitrogen-free atmosphere shows that it is due to cell growth and normal nutrition, and not to a direct assimilation of atmospheric nitrogen. Thus the theory of Jamieson, Zemplén and Roth, that the protein in the hairs is formed only from atmospheric nitrogen, is untenable.

888 – **Physiological Researches on the Germination of the Pollen of *Vitis vinifera*.** — GARINO CANINA, E., in *Le Stazioni Sperimentali Agrarie Italiane*, Vol. XLVII, Part 7, pp. 480-492. Modena, 1914.

From a study on the germination of vine pollen, the following conclusions have been drawn :

1) The pollen grains of the vine require an acid medium for develop-

(1) See No. 1113, *B.* April 1911. (*Ed.*).

ment, in accordance with the strongly acid reaction of the sap of this plant.

2) The most suitable medium for laboratory experiments is one containing 15 per cent. saccharose, 2 per cent. gelatin, and tartaric acid in the proportion 1 : 4000.

3) Prolonged rainy weather, by diluting the stigmatic secretion, may cause the pollen grains and tubes to burst, as is the case when germination is effected artificially in distilled water.

4) Temperatures outside the limits of 14° C. and 35° C. during the flowering period produce sterility, owing to the absence of germination below 14° C. and to the abnormal development of the pollen tube above 35° C.

5) Many of the fungicides used on vines are injurious to the pollen grains.

6). The grower should have no difficulty in choosing between a possible danger of sterility and the certainty of infection by oidium or mildew.

PLANTS BREEDING

889 – **Thirteen Years of Wheat Selection.** — HUTCHESON, T. B. (Associate Agronomist, University of Minnesota), in *The American Naturalist*, Vol. XLVIII, No. 572, pp. 459-466 + 3 tables. Lancaster, Pa., August 1914.

In 1901 the Minnesota Agricultural Experiment Station planted a number of varieties of wheat from the *polonicum*, *spelta*, *turgidum*, *durum*, and *vulgare* types. Six of these varieties (one each of *turgidum*, *vulgare*, *spelta* and *durum*, and two of *polonicum*) have been grown continuously and selected by the centgener method. This method consists in planting one hundred selected kernels from each plant, at equal depths and at equal distances apart in separate plots. Careful notes are taken of the plants of each centgener, and at harvest five or more of the highest yielding plants are selected, from which the seeds for planting the next year are taken. From these five best plants, from five to ten of the best heads are selected and thrashed together. One hundred of the largest and plumpest kernels are selected and planted in the centgener test next year. This operation is continued from year to year.

In 1908, an experiment was planned with the object of developing a strain of wheat which would have a minimum amount of culm exposed between the base of the spike and the upper leaf sheath, *i. e.* a short-necked variety of wheat. The ultimate purpose of this was to reduce the area of the stem exposed to the black stem rust, which does not attack that portion of the stem enclosed in the leaf-sheath. For this work individual plants were selected which had short necks and the seeds from these were planted in separate centgeners. A continuous selection of short-necked plants was made during the succeeding years.

Each centgener was started from a single head in 1901, and since wheat is normally self-fertilised, these heads have bred true to type ever since. Thirteen years of selection in one pure line is the longest period of continuous selection yet reported for a self-fertilised plant, thus making these data of considerable importance.

Tables are given showing the results of selection for increased yield (1901-1913), for increased height (1901-1913) and for short neck (1909-1913). From the data presented in these tables it is evident that there has been no permanent gain for these thirteen years of selection, either in yield per plant, height of plant, or shortening of neck-length. Only the expected seasonal variations occur, which were the same, with regard to production, as in the continuous open field experiments without selection.

A comparison of the yield of each variety for the first five years of the test with that of the last five years is shown in the accompanying table, which shows that there is no significant difference in yield for these two periods.

Variety.	First 5-year period.		Last 5-year period.	
	Height. in.	Yield. gms.	Height. in.	Yield. gms.
Hedgerow (*turgidum*)	41.6	2.67	38.4	2.34
Russian (*vulgare*)	38.0	1.99	35.4	2.18
Spelt (*spelta*)	40.0	2.51	39.2	2.40
Kamouka (*durum*)	36.4	2.01	35.8	1.97
Polish I (*polonicum*)	39.9	1.54	37.4	1.61
Polish II (»)	33.4	1.62	33.4	1.31
Average . . .	38.2	2.06	36.5	1.97

From the practical breeder's standpoint permanent improvement in pure lines of small grain, if possible, is certainly not rapid or apt to be very marked. It is probable that much more rapid progress could be made by segregating pure lines from mixed populations and combining the desirable characters of these lines by hybridisation.

890 – **Note on the Selection of Maize in Cambodia.** — De Flacourt, Martin (Chief of Agricultural and Commercial Service in Cambodia), in *Bulletin économique de l'Indo-Chine*, Year 17, No. 107, pp. 215-218. Hanoi Haiphong, March-April, 1914.

Maize is extensively grown in Cambodia chiefly as food for the inhabitants, and it generally precedes rice in the rotation. There are two chief varieties : one with orange yellow grains, the other with milky white grains, the vegetative periods being 90 and 105 days respectively.

The writer proposes selecting local varieties with a view to improving their earliness. These two varieties show considerable variation as regards coloration of the grains and number of secondary tillers, and sometimes show pale green or white striations on the stem and leaves. These variations cannot be explained by hybridisation alone, but would seem to indicate a tendency to mutation amongst some individual plants.

In these experiments the writer found that the variation was increased by exposing the ripe ears freed from the sheath for several days, thus

causing a cracking of the grains similar to that produced by the mechanical process employed by BLARINGHEM. The present pedigrees are too short to enable conclusions to be drawn.

It was also found that the secondary shoots, in many cases, flower at the same time as the main shoot, and though some 20 to 23 days younger than the latter, they ripen their grains at the same time, thus having a shorter vegetative period. The inflorescences of the secondary shoots are of three different forms: 1) they are exclusively unisexual, 2) the female inflorescence is normal in type but surrounded at its base by small ears, 3) the terminal panicle carries both male and female flowers. Seed is selected only from the best grains produced by the normal inflorescences of the secondary shoots, and it is found that the earliness of maturity of these seeds is inherited by the descendants.

Plants were also raised from seeds from the abnormal inflorescences of the last two types; they produced perfectly normal male and female inflorescences with the same degree of earliness of maturity.

AGRICULTURAL SEEDS

891 – **Innovation in the Danish Trade in Seeds of Root Crops.** — *From a Communication by* H. HELWEG, *Director of Experiments at Copenhagen.*

In Denmark the State has for a number of years carried out trials of root crops, for which any Danish seed breeder can enter his strains of seed. According to the results the strains are divided into three classes. The names of the breeders of the first class seeds are published. Owing to the great demand for seeds on the part of the trade, prices rise very high and this stimulates the breeders to further exertions. Thus 10 *s* a pound is now paid for pedigree mangold seeds and 20 *s* a pound for turnip and swede seeds.

This cooperation of State, breeder and seedsman has already led to an increase in the yield of Danish root crops.

Of late years the practice has been introduced of selling seeds of root crops with a guarantee as to their quality, as has long been done for grass seeds.

For both root-crop seeds and grass seeds the value of the crop depends upon the genuineness of the seed, but with this difference, that the genuineness of grass seed can be recognized by examination, while the quality and strain of root-crop seeds cannot; the analysis of the latter carried out by the seed control stations has therefore little value, whereas in the case of grass seeds it is so useful that it has become customary to base the price upon it. It is further to be noted that the analysis of a parcel of grass seeds can be controlled by another examination in spring, while the quality of the root-crop seeds can only be checked in the autumn by an expert examination of the roots in the field in which the seed was sown in the spring.

Complaints as to the quality of the seeds sown in spring are allowed up to the 15th of October of the same year.

In the spring of 1912 the guarantee for genuineness of Danish root-crop seeds was introduced into the home trade and in 1913 into the foreign trade. Not all the wholesale seedsmen have adopted the guarantee system

in their transactions, but they must henceforward mention it expressly on their business papers, etc.

For the settlement of possible disputes concerning the guarantee, an official (of the Weights and Measures Bureau) takes an average sample from the seeds sold under such guarantee and sends it to the State Commissioner for root crops, who has all the samples sent in sown in a control field recognized by the State. Complaints from abroad are to be brought before the Maritime and Commercial Tribunal of Copenhagen, which appoints two or three experts to examine the roots produced in the above field by the seed in question, and if the seeds delivered do not correspond to their description the amount of compensation due is determined on the result of the test made in the experiment field.

892 – **The Longevity of Some Common Seeds.** — EASTHAM, ALFRED (Chief Seed Analyst, Department of Agriculture of Canada, Seed Branch) in *The Agricultural Gazette of Canada*, Vol. I, No. 7, pp. 544-546. Ottawa, July 1914.

Researches on the longevity of seeds were begun in 1903 and will be continued until the vitality of the seeds has been entirely lost. Seeds of

	Germinating capacity after:			
	1 yr.	5 yrs.	7 yrs.	10 yrs.
Timothy:				
Average of 12 samples harvested in 1902	97	90	83	56
Average of 12 samples harvested in 1903	93	90	85	52
Red clover:				
Average of 12 samples harvested in 1902	97	76	61	44
Average of 12 samples harvested in 1903	96	75	68	43
Alsike clover:				
Average of 12 samples harvested in 1902	93	79	66	45
Average of 12 samples harvested in 1903	93	81	72	45
			after 10 yrs.	after 13 yrs.
Oats:				
Average of 53 samples harvested in 1900 (1)	94	95	93.5	91
Average of 64 samples harvested in 1901	98	97	96	—
Average of 63 samples harvested in 1902	95	97	97	—

(1) From the various provinces of Canada.

high germinative capacity were chosen and stored in sealed boxes in the Seed Branch Laboratory of the Department of Agriculture. The results are shown in the accompanying table.

CEREAL AND PULSE CROPS

893 – **The Influence of External Physical Agents on the Germination of Wheat.** — 1. LOYER, HENRI. – 2. RIVIÈRE, C. — *Bulletin de la Société Nationale d'Acclimatation de France*, Year 61, No. 14, pp. 447-456. Paris, July 15, 1914.

I. — The writer states that the influence of physical agents on germination requires a more precise investigation and that many problems remain to be solved in regard to aeration, moisture and temperature. For example : the limits of rarefaction and pressure between which germination is possible, the gradual reduction of germinative power, the maximum and minimum quantities of water favourable to germination, and the correlation of data relating to the duration of germination in relation to temperature. The writer points out that the temperature data obtained by the methods of RÉAUMUR, DE GASPARIN, DE CANDOLLE, TISSERAND are not concordant, since they show great differences for the same vegetative period of the same plant. He proposes a method of his own which appears to give better results.

The sum-totals of the daily means of the squares of the hourly temperatures always give the same result for the germinative period of the same plant. In the case of wheat, for example, the number always approximates to 1500, provided that the squares of temperatures above 20° C. are reckoned as 400 and that only the temperatures between 0° and 20° are included in the actual values.

The writer considers that these generalisations are common to all plants and intends to verify them in cases other than wheat.

II. — The following comments have been made by M. C. RIVIÈRE.

These experiments have the advantage of being carried out under precisely controlled conditions, the same plant being used throughout, since each variety requires certain variable meteorological conditions to complete its development. The results are interesting, but some indication, however approximate, should be given of the meteorological conditions affecting germination, such as soil temperature, illumination and humidity.

Rise of temperature, for example, does not always coincide with increased illumination, and the more rapid development of wheat in northern Europe near the arctic regions is due more to increased illumination, than to the temperature. Thus, the intensity of light during the night should be taken into account. Further, what method of computation can take into account all meteorological influences ?

There are also meteorological influences which are difficult to define and determine. Since our determinations of meteorological conditions are as yet only rudimentary compared with the complexity of the subject, all conclusions should be considered as arbitrary only. The method of M. LOYER will tend to narrow down the problem. It is possible to determine the number of calories necessary for the germination of wheat by experiments *in vitro* with temperatures controlled and automatically recorded, but the results thus obtained are so far removed

from natural conditions that they are useless to determine the actual meteorological conditions conducive to good or bad germination. This is the problem which still awaits solution.

894 – **Studies on the Pollination of Lucerne in its Relation to Seed Production.** — PIPER, C. V.; EVANS, MORGAN W.; MCKEE, ROLAND, and MORSE, W. J., in *Bulletin of the U. S. Department of Agriculture*, No. 75, pp. 32 + 1 fig. Washington, April 8, 1914.

In the regions of the United States where lucerne is grown for seed, the yield varies considerably from one season to another. Thus, in Milk Valley, Montana, in some seasons the yield has reached 10 to 12 bus. per acre, whilst in others it has been practically nil.

With a view to finding the cause of this difficulty the Department of Agriculture in 1906 undertook a series of experiments at several stations. The problem was found to be a most complex one, depending not only on the abundance of insects for pollination, but also on the climatic conditions. Under certain climatic conditions autogamous pollination is an uncertain factor from one season to another and among different individual plants. The factors or conditions favouring the production of seed vary during the season, as is seen from the occurrence of pods amongst the mature plants. On several occasions, especially during the first cut, it has been seen that artificial pollination by agitation of the stamens does not result in fructification.

The writers reviw the work of previous authorities on the structure and pollination of the flower of lucerne, showing conclusions at variance with each other. Only in some cases are direct attempts made to determine the relation between pollination and the quantity of seed harvested. The prevailing opinion is that pollination by insects is of vital importance, and that if they are not present in sufficient numbers, the yield of seed is reduced. The importance of the climatic conditions is generally recognized, and it is pointed out that commercial seed is produced in regions with a semi-arid climate, at least during the ripening period.

The flowers of lucerne may be pollinated at any time from the opening of the flower to the fall of the petals. Pollination generally takes place after the release of the staminal tube, which is effected by a special mechanism. The staminal tube is held by two opposite lateral protuberances inside the keel. Heavy insects such as the bumble bee are able to press the sides of the keel apart, thus liberating the staminal tube. Generally, however, the operation is effected by the insect inserting its proboscis between the posterior edges of the keel. More often the two posterior appendages of the wings, which meet above the staminal tube, are displaced, thus causing an indirect distension of the keel. The presence of this spring-like mechanism has been observed in twenty species of *Medicago*, also in *Alysicarpus*, *Trigonella*, *Indigofera* and *Genista*. The writers have not been able to confirm BURKILL'S theory, that the release of the staminal tube causes a rupture of the stigmatic cells and promotes fertilization. Liberating the staminal tube by artificial means, so as not to stimulate or rupture the stigmatic cells by contact, gives as good results as natural pollination.

Flowers which are artificially exploded and thereby self-fertilized produce an abundant crop of seeds. In a series of experiments on 77 plants conducted in 7 different places, 9074 flowers produced 2784 fruits (or 30.66 per cent.) when mechanically self-fertilized, whilst 8939 flowers on the same plants fertilized under natural conditions yielded 1499 fruits (or 16.76 per cent.). The fruits from flowers artificially exploded contained an average of 1.72 seeds each, whilst the fruits of flowers naturally fertilized contained 2.22 seeds.

Cross-pollination among flowers of the same plant is not more productive of seeds than self-fertilization, but pollen from other plants increases the proportion of fruits and the number of seeds per fruit. There is no considerable difference between the pollen of like or of dissimiliar varieties.

The explosion of lucerne flowers normally takes place automatically, but may be caused by insects or other agents. Flowers which fail to open rarely produce fruits and seeds. Two plants were observed at Chinook, Mont., in 1909; one had 57 flowers, of which 33 exploded automatically and set 21 fruits; the other had 64 flowers, of which 36 exploded automatically and set 16 fruits. The percentages of fruits formed from these flowers were therefore 37 and 25 respectively. These figures are as high as those obtained under natural conditions in the fields. In a similar experiment conducted at Pullman, Wash., in 1910, only 21 out of 775 flowers left to themselves produced seed, or 2.7 per cent., against 13.15 per cent. in the open.

There is considerable variation in the rapidity with which the flowers of lucerne explode automatically or by means of exterior agents, and in their subsequent fructification. The number of fruits is not proportional to the number of flowers, since the largest infloresences are less fertile than the smaller ones.

Automatic fertilization of the flowers takes place more frequently during warm sunny weather and is influenced considerably by the humidity. Pollination can be immediately effected by placing the open flowers at the focus of a converging lens or by exposing them to the sun on a warm day. Insects are the natual agents of cross-fertilization of lucerne, but good yields of seed can be obtained in places where they are rare. Bumble-bees and *Megachiles* are the most effective insects for effecting the dispersal of the pollen. Bees collect honey from these flowers, but effect pollination in only a few cases. Nocturnal insects are of negligible importance. There is no evidence to show that butterflies are able to effect pollination; wind and rain are of slight importance.

Automatic explosion of the flower and consequent self-pollination is as effective in producing seed as insect pollinizers, at least in the Western States. This conclusion agrees with the observation that excellent yields of seed are obtained in regions where bumble-bees and other suitable insects are rare.

895 - **Alfalfa in the United States.** — BROOKS, WILLIAM P., in *Massachusetts Agricultural Experiment Station, Bulletin* No. 154, pp. 147-171 + 2 tables. Amherst, Mass., June 1914.

This is a bulletin of instruction and propaganda intended for practical farmers. Part of the directions are based upon the experimental results obtained either by the writer at the Amherst Agricultural Experiment Station or by thirty-three farmers in different parts of the State.

Alfalfa is now successfully grown in most parts of the United States and in a few parts of Canada. It is popularly supposed that alfalfa is much superior in nutritive value to clovers, but so far as can be determined by chemical analyses made at the Amherst Station and determinations of digestibility made there and in other stations, this does not appear to be the case, as may be seen from the following tables :

TABLE I. — *Composition of Clover and Alfalfa Hays.*

	Water %	Ash %	Protein %	Fibre %	Nitrogen free extract %	Fat %
Alfalfa hay	13.24	6.38	13.98	28.48	34.70	1.40
Alsike clover hay	15.00	9.70	14.00	23.10	36.10	2.10
Medium red clover hay	15.00	9.70	13.30	24.30	37.20	2.50

TABLE II. — *Digestible Nutrients and Energy Values* (*).

	Protein (lbs. in 100)	Fibre (lbs. in 100)	N-free extract (lbs. in 100)	Fat (lbs. in 100)	Net energy value (Therms)
Alfalfa hay	10.2	13.9	24.4	0.5	34.9
Alsike clover hay	9.2	11.6	23.8	0.8	34.6
Medium red clover hay	7.7	13.1	24.2	1.4	35.6

(*) Based upon average results in the United States.

The writer does not recommend the direct application of manure in preparing the soil for alfalfa, but advises instead the free use of it on the preceding crops. Sometimes, however, the direct application of potash, lime and phosphatic fertilizers may be advisable. In the writer's experiments potash in the form of sulphate appeared much superior to potash in the form of chloride.

Some varieties of alfalfa introduced from Siberia by the South Dakota Experiment Station have not yet been sufficiently tested. The best seeds of common alfalfa grown in The United States are those from the northern districts ; Grimm's alfalfa is a selected strain which originated in

Minnesota and is noted for hardiness and productiveness (1). In some experiments conducted by the writer with Grimm and common alfalfa, the former yielded an average produce in 3 cuts per year for two years, of 3.982 tons per acre against 3.261 tons of the latter, or a difference of about 22 per cent. in favour of the Grimm.

The variegated alfalfa is said to be a cross between common alfalfa and yellow lucerne. This variety is said to be more hardy than ordinary alfalfa and adapted to poorer soils : it has, however, a tendency to decumbent growth, and a lower feeding value.

Hitherto few diseases have proved troublesome to alfalfa in Massachusetts; the only important ones are leaf-spot (*Pseudopeziza Medicaginis*) and dodder.

Two experiments in inoculation with " Farmogerm " culture (prepared by the Earp-Thomas Farmogerm Co., Bloomfield, N. J.) were made and gave good results on land which was put under lucerne for the first time.

CROPS YIELDING OILS, DYES AND TANNINS

896 – **Methods of Propagation of Olives** (2). — CAMPBELL, C., in *Le Stazioni Sperimentali Agrarie Italiane*, Vol. XLVII, Part 4, pp. 297-307. Modena, 1914.

The writer draws the attention of olive growers to the importance of the methods of propagation. The seeds of the wild varieties of olive have the highest germinating power, but the growth of cuttings (as shown by the writer's experiments) is more vigorous in the case of cultivated varieties and improves as the number of asexual generations increases.

Of the various methods of asexual reproduction, *e. g.* by cuttings, from "ovoli" (3) and by grafting, the last-named method is destined to be of the greatest importance in the future. Reproduction from seed is seldom practised, since the number of seeds which germinate is small, and each stock requires subsequent grafting. The writer remarks that it is possible to improve the germination of the seeds, which is more vigorous in the hardier and semi-wild varieties. The seeds from trees grown directly from seeds are more vigorous in germination than seeds obtained from grafted trees. New varieties obtained in this way, using seeds of the best varieties, will yield seeds with a higher percentage of germination. Since it is necessary to choose vigorous plants as stocks, especially for arid and infertile soils, the writer recommends the sowing of seeds of cultivated varieties so as to produce stocks more suitable for receiving the grafts of their own varieties or others of similar vigour. It will then be possible to undertake on an extensive scale the selection of different varieties, at the same time obtaining useful stocks.

(1) See No. 2106, *B.* July 1911.

(2) See Nos. 2668 and 2669, *B.* Aug.-Sept.-Oct. 1911; No. 1046, *B.* Sept. 1913.

(3) Excrescences formed at the botton of the trunk; these are cut off and planted in the ground like cuttings. (*Ed*)

897 – **Olive Growing in Syria.** — AARONSOHN, A. (Director of the Jewish Agricultural Experiment Station, Haïfa, Palestine), in *Revue Agricole et Viticole de l'Afrique du Nord*, Year 12, No. 120, pp. 607-609 + 3 figs. Algiers, June 27, 1914.

Olives are generally well looked after in Syria, and particularly so about Damascus. The exorbitant prices of irrigated land in this neighbourhood make intensive methods a necessity, and the olive comes in for its full share of attention. While in Palestine grafting is carried out on wild stocks, at Damascus (as at Sfax, for example) cuttings from old trees are grown on their own roots; to promote the growth of shoots from the old stems, the trees are earthed up. Grafting is only performed when it is desired to change the variety.

In preparing the land the soil is not deeply dug over, but very large holes are prepared for the trees, and a layer of stones is placed in the bottom for drainage.

Often very old trees are transplanted. They are cut back almost to the trunk, or at any rate to the oldest branches, and the stumps are dressed with a mixture of clay and dung; the trunk is surrounded by bundles of straw or reeds and a layer of clay and cow-dung. Trees treated like this may remain inactive for two or three years, but once they begin to grow, they develop rapidly and when irrigated begin to fruit in 3 or 4 years.

The trees are planted 16 to 22 yds. apart. When they reach several centuries old, young fruit trees (chiefly apricots of late years) are planted between the rows. When the fruit trees come into bearing, the old olives are removed, realizing about £ 2 each as timber.

The variety most commonly grown is the Dân, with small fruit: the Massa' abi yields large fruit suitable for preserving; the J' lette yields fruit which is consumed in the green state.

Analyses carried out at the Haïfa Experiment Station gave the following figures:

	gms.
Average weight of an olive	3.37
Weight of kernels from 100 gms. of olives	21.75
» oil » »	27.97
» pulp » »	78.75

Pruning, which is little else than trimming, is practised in the Damascus district. The fruit is knocked down by means of long poles.

898 – **Olive Growing in in the District of Tizi-Ouzou, Algeria.** — HIPPOLYTE, L., in *Revue Agricole et Viticole*, Year 12, No. 124, pp. 88-91. Algiers, July 25, 1914.

The western and eastern slopes of the Djurjura chain of mountains are covered with ancient olive groves, the majority of which belong to the Kabyles. The French colonists, encouraged by the bounties for planting and grafting olives granted by the Algerian government, have also begun to plant. The cultivation practised in Kabylia is only ploughing and digging. The importance of pruning is not understood by the native and is seldom practised and then without method. Manures are not applied, and the collection of the fruits is effected by means of poles 2 to 3 yds.

long, which damage the fruits and branches, thus reducing the value of the next year's crop. The writer has introduced a sort of wooden comb, used in some parts of Italy, which enables the fruits to be collected with less damage to the trees.

In the case of the very bushy trees growing in an almost natural condition in the mountains, the first thing to be done is a good thinning. The harvesting of the fruit should be regulated for each district, as the growers are apt to start picking too early, with the result that an inferior oil is produced.

There are two varieties of olives in Kabylia, the Chembal and the Rougette, the latter being more common. The western slope of the Djurjura is favoured by abundant rain, averaging 45 to 50 inches per annum. These conditions are very favourable to the future welfare of the industry in this region. The adoption of modern rational methods would result in immediate improvements and a yearly crop instead of one every other year.

899 – **The *Aleurites* of Tonking.** — LEMARIÉ, CH., in *Bulletin économique de l'Indo-Chine*, Year 17, No. 107, pp. 144-150. Hanoï-Haiphong, March-April, 1914.

The writer gives a description and botanical analysis of the species of *Aleurites* of Tonking, with references to others from China and Japan. " Cây-trau " of Tonking was first described as *A. cordata* Muel. Arg.

Eberhardt recorded *A. Fordii* Hemsl. as occurring in the remote province of Tonking. The only species found by the writer in the Delta and forest regions are *A. triloba* Forst. (*A. moluccana* Willd.) or "cây-lai ", and *A. montana* Wils. or " cây-trau ", of the latter of which he gives a botanical description.

E. H. Wilson (*Bulletin of the Imperial Institute*, Vol. XI, No. 3), mentioned that the species which yield a drying oil used for waterproofing objects, varnish, linoleum and rubber substitutes, etc., occur on the continent, while the Japanese species, *A. cordata* Muel. Arg., yields a burning oil.

Enormous quantities of drying oil are exported to Europe and America. Thus, in 1900, more than 330 328 pikuls (about 44 million lbs.) of oil obtained from *A. Fordii* were exported from Hankow, valued at 2 559 344 Haikwan taels (about £ 320 000), and in 1910 as much as 757 959 pikuls (about 100 million lbs.) valued at 6 449 421 taels (or £800 000). The exports from Outcheon during the same period increased from 24 469 pikuls (or 3 million lbs.) of oil from *A. montana*, valued at 146 813 taels (or £19 000), to 52 106 pikuls (7 million lbs.)

A. montana Wils. is limited to the subtropical regions in the south-west of China, from Fukien to Annam. *A. Fordii* Hemsl., which yields more than $^{9}/_{10}$ of the total production of oil, belongs to the warm temperate regions of the Yangtse basin. *A. montana* is much more productive in Fukien than in Tonking, where the writer suggests improvement of the variety by selection. He also recommends experiments with *A. Fordii* on the high plateaus of Tonking, as this species is more productive and the fruits are devoid of a ligneous seed-coat.

900 — **The Cultivation of the Sugarcane in the South of Spain.** — *Royal Botanic Gardens, Kew, Bulletin of Miscellaneous Information*, No. 4, pp. 147-150. London, 1914. SUGAR CROPS

This article is based on information received from the British Consul at Malaga.

Sugarcane is cultivated in the sheltered valleys between Estepona and Adra. The most profitable varieties are: Blanca, sometimes called Amercana, imported by the Arabs; Marada (violet) and Negra (black), probably the same variety: Negra is said to have been imported from Cuba; Canna cristalline, larger than the preceding but less rich in sugar; Striée, of inferior quality; Algarrobena, now almost entirely abandoned.

The preparation of the land consists in heavy manuring and careful cultivation, breaking of clods, levelling, preparation of furrows 35 inches wide and about 8 inches deep, for the planting of the sprouted cuttings in March and April. They are planted in 3 lines so that the cuttings of one line alternate with those of the adjacent lines. They are covered with a light layer of soil and gradually earthed up as they grow until the ground is level again. The land is kept free from weeds and in July or August guano or chemical manures are applied followed by irrigation for 15 to 20 days until harvest. The plantation is renewed every 7 to 8 years or 10 to 12 years. The use of a complete chemical manure has become very widespread of late years, as much as 1350 lbs. per acre being applied once or twice during the season.

The average yield is 20 tons p. acre and the average sugar content for the district is 14 % and at Adra only 8 %.

901 — **Sugar-Beet Experiments in Ireland.** — *Department of Agriculture and Technica. Instruction for Ireland, Journal*, Vol. XIV, No. 3, pp. 471-482 + 4 figs. Dublin April 1914.

In 1911 the Department of Agriculture and Technical Instruction for Ireland commenced a series of sugar-beet experiments with a view: 1) to comparing the relative yields and quality of roots grown close together in rows on the flat in accordance with continental practice, and of those grown wider apart on drills or ridges, so that after-cultivation was facilitated; and 2) to affording information as to the yields of this crop in the state in which it is purchased by sugar factories, *i. e.*, of roots properly topped and cleaned.

In the 1911 experiments the farmers reported very adversely on the systems of growing sugar-beet on the flat, because it was more costly and the crop more difficult to lift than when the beet was grown on drills. In order to ascertain whether the requirements of a sugar factory for roots grown almost entirely below the surface of the soil could be met by cultivating the crop on moulded-up drills, a third plot cultivated in this manner was included in the trials in 1912. Furthermore, in 1912 half of each plot was top-dressed with nitrate of soda. The experiments in 1912 were conducted at twelve centres in eleven counties.

In 1913 the experiments of 1912 were repeated: *a*) on drills 27 inches wide; *b*) on drills 27 inches wide — the crop being moulded up after hoeing;

c) in rows 18 inches apart on the flat; *d*) with and without nitrate of soda at the rate of 1 ½ cwt. per acre.

The area of each plot was one-tenth statute acre: the variety of sugar-beet used was Klein-Wanzleben Original Z.

The average yields of the three seasons 1911-13 (30 experiments in all) were as follows:

Ordinary drills:

Gross weight of roots	15 tons 9 cwt. per acre
Factory weight of roots	11 » 1 » »
Sugar content	17 per cent.

On the flat:

Gross weight of roots	16 tons 12 cwt. per acre
Factory weight of roots	13 » 2 » »
Sugar content	17.5 per cent.

From the above it is evident that the better crop in point of yield and also of sugar content was that cultivated on the flat, and that, moreover, the superiority of the roots on the flat would, at a price of £1 per ton on the farm, more than recoup the extra cost of labour involved in this method of cultivation.

The average yields in 1912 and 1913 are shown in the following table:

Plots	Average annual yield of roots per acre				Ratio of factory weight to gross weight as percentage	Average sugar content, per cent.	Average coefficient of purity (apparent)
	Gross weight		Factory weight				
	tons	cwt.	tons	cwt.			
Ordinary drills:							
a) Without nitrate of soda	13	6	9	8	68.1	16.5	89.45
b) With » »	15	1	10	3	67.4	16.1	89.24
Moulded-up drills:							
a) Without nitrate . . .	14	1	10	3	72.0	16.3	89.42
b) With » . . .	15	11	11	4	72.0	16.2	89.55
On the flat:							
a) Without nitrate . . .	14	14	10	17	73.8	17.0	89.60
b) With » . . .	16	10	12	1	73.0	16.5	89.28

From the above table it will be seen that, on the average of the two seasons, the flat plots *a* and *b* produced yields (factory weight) only 14 and 17 cwt. respectively per acre higher than the moulded-up drill plots *a* and *b*, and that the sugar content of the roots on the former plots was only 0.7 per cent. and 0.3 per cent. respectively higher than that of the roots on the latter. These increments in yield and sugar content would by

no means be sufficient to compensate for the extra outlay in labour on the lat plots. It may therefore be inferred that of the three methods of cultivation that of moulding up ordinary drills is best adapted to Irish conditions.

It will be noticed also in the above table that the average increases in yield (factory weight) due to the application of nitrate of soda were as follows :

On ordinary drills	15	cwt.	per acre
On moulded-up drills	21	»	»
On the flat	24	»	»

and that, on the average, the use of nitrate of soda slightly reduced the sugar content of the roots (the reductions being 0.4, 0.1 and 0.5 per cent. respectively). Nitrate of soda had little, though varying, effect on the purity of the juice.

From the foregoing it would appear that the application of nitrate of soda to sugar-beet would not prove remunerative on fields manured as the experiment plots of 1912-13 had been. Some of them had 15 tons of farmyard manure to the acre and 1 cwt. sulphate of ammonia, 3 cwt. of superphosphate and 6 cwt. of kainit, and others only chemicals, namely 1 ½ cwt. sulphate of ammonia, 4 ½ cwt. superphosphate and 6 cwt. kainit.

In some localities the sugar-beet plots were grown alongside mangolds with a view to comparing the relative yields. The general averages of nine experiments in the three years 1911-13, the yields of the best plots being taken, were the following :

Sugar-beets (gross weight) . .	17	tons	9	cwt.	per acre
» (factory weight) .	13	»	10	»	»
Mangolds	28	»	18	»	»

The average yield of mangolds at the same time was 19 tons 3 cwt. per acre. This shows also that the farmers who carried out these sugar-beet experiments were among the best. The inference to be drawn from these facts is that, even when cultivated in the best manner, the factory weight of a sugar-beet crop in Ireland cannot be expected to exceed about half the yield of a well-managed crop of mangolds.

902 – ***Coffea excelsa* and its Cultivation.** — CHEVALIER, AUG., in *Journal dAgriculture Tropicale*, Year 14, No. 157, pp. 193-196. Paris, July 31, 1914.

STIMULANT, AROMATIC, NARCOTIC, AND MEDICINAL CROPS

The writer discovered this species of coffee in Central Africa and distributed seeds to several experiment stations, including those in Tonking, Java, French Guinea and the Belgian Congo.

Native climate. — *C. excelsa* is found in the wild state at altitudes of 2 200 ft. in a climate which is dry for six months of the year and has a rainfall of at least 40 inches during the remaining six months. The summer temperature is tropical, whilst in December and January it falls below 10° C. at night. This type of climate occurs in a number of countries. It has been shown that this species succeeds well in equatorial regions, so that its cultivation is possible over wide areas.

Quality. — The coffee obtained from Central Africa showed a satisfactory strength in caffein, and though somewhat bitter it had an excellent flavour.

Introduction in Tonking and Java. — In Tonking its growth has been remarkable and entirely free from insect and fungoid pests. The bean is small and uniform in size and it is hoped to sell it in competition with Arabian coffee blended with Mocha. Numerous specimens have been planted in Java in the Experiment Station at Bangilan near Malang and in the Tjikeumeuth Garden near Buitenzorg. Field cultivation has also been begun in the Dutch East Indies.

Selection. — This species is being improved by M. P. J. S. Cramer. It shows variation in almost all its botanical characters. In appearance it is less luxuriant than *C. liberica,* though it is hardier and earlier.

Cultivation. — This species is particularly robust in Java. It commences to flower in the second year and yields a crop of berries in the third year. The trees should be planted at least 12 ft. apart each way. Each tree is planted in the centre of a square plot cultivated and made to slope in the opposite direction to the general slope of the land and forming a hollow at the lower end, so as to prevent erosion of the surface soil. Young plants of "lamtoro" (*Leucaena glauca*) are planted on the border of each square and periodically pruned so as to prevent the growth of old shoots. Stumps of *Leucaena* 16 inches high are planted at the four corners of the squares at the same time as the coffee plants. They are allowed to grow freely until the fifth year, when they are cut down; as the coffee plants now cover the ground the *Leucaena* along the borders of the squares and some of those at the angles are removed so as not to shade the coffee too much.

Yields. — At Bangilan an annual yield of 616 lbs. per acre or about 3 lbs. per tree has been obtained. M. Cramer mentions the plantation at Kedatong (South Sumatra) where 54 plants of *C. excelsa* of 4 to 5 years growth yielded 7 lbs. per tree.

Market Value. — The value of the coffee approaches that of Liberian coffee and according to M. Boom it amounts to about £ 20 per acre. The beans require particular care since they are enclosed within a thin skin which must be completely removed before the highest prices can be obtained. Unfortunately only a small supply of the best strains exists and it is only at Bangilan that a uniform collection has been seen by the writer.

903 – **Studies on the Fertilization of Hops.** — TOURNOIS, JULIEN, in *Annales des Sciences Naturelles, Botanique,* Vol. XIX, No. 2 and 3, pp. 49-491 — 5 plates. Paris, June 1914.

Investigations of the various phenomena in the sexual reproduction of *Humulus Lupulus* and *H. japonicus.*

I. *Appearance of flowers and differentiation of the sexual organs.* — The time of flowering depends strictly on external factors; changes, for example of illumination, may cause considerable variation in the duration of the vegetative period.

The species of *Humulus* are generally dioecious, though apparently monoecious individuals occasionally appear. The transformation of dioecious plants is brought about by particular conditions, especially those

which diminish the transpiration of plants, or tend to lower the osmotic pressure. It appears that a lowering of the osmotic pressure of male plants may determine the appearance of female organs or flowers and that an increase of osmotic pressure in female plants may provoke, though more rarely, the development of male organs or flowers.

II. *Fertilization and formation of the embryo.* — The ovule of the common hop may be fertilized by foreign pollen, such as that of hemp and of Japanese hop, but in these cases the resulting seeds contain only irregular abortive embryos.

III. *Formation and constitution of the fruit or cone of the common hop.* — Fertilization is not essential to the development of the cones, but it stimulates their growth. The various morphological characters of the cone which form the basis of classification of hops, are liable to variation under different conditions and are of no more value than vegetative characters in determining the varieties. Consequently the species *H. Lupulus* is to be considered homogeneous, notwithstanding the innumerable varieties of cultivated hops that have been described.

This monograph comprises 7 chapters and contains a very extensive bibliography. It concludes with generalizations concerning the determination of sex and the phenomena following pollination of the common hop with pollen from very different species. The following information on the different varieties of cultivated common hop is taken from Chapters VI and VII.

The influence of fertilization on the development of the cones is seen in their more rapid growth and greater size. The yield, excluding seeds, is doubled. The bracts of unfertilized cones are more adherent and by remaining intact during manipulation they retain the lupulin to a greater extent, whilst the fertile cones readily drop their bracts with a view to seed dispersal. It is generally believed that fertilization results in a lowering of lupulin content. The writer, however, is of opinion that the number of glands will remain the same in both types of cone and that only reduction in the relative number of glands owing to the increase in surface area of the bracts would account for the loss of strength. The only advantage, but a very important one from a commercial point of view, is the increased yield of cones after fertilization. The chief disadvantages are: greater fragility of the cones and loss of lupulin, and perhaps also reduction in strength of lupulin.

In Belgium and America, and to some extent in England, it is the custom to plant one male hop for every two or three hundred female plants, whilst in Germany, Bohemia, the East of France and Burgundy all male hops are carefully destroyed and often the local authorities forbid their cultivation. It will only be of advantage to the grower to plant male hops in his fields so long as the increased crops are not compensated for by a lower price for the dried hops.

Male hops should be planted in countries where a cool and damp climate retards the more complete utilization of the plant reserves and where

the growth of the cones is retarded by unfavourable conditions, such as extreme drought or attacks of aphis.

In reviewing the characters of the different varieties, it is only possible to compare specimens of the same variety from different districts. The characters of the cone are as follows : aroma, the character most considered by the brewers, but which has not yet been put on a proper scientific basis : shape of the cones, which varies on the same plant : percentage of seeds, indicating the extent of fertilization : the shape of the bracts, biometric measurements of which might form a suitable basis for classification ; the presence of leaves in the cones, an anomaly which appears frequently in certain varieties and which occurs in other varieties in certain favourable seasons. The varieties in which this abnormality appears most frequently yield products of good quality, but are less productive, and when the character is too pronounced there is an excess of material devoid of lupulin, which may even import an inferior taste to the beer.

Other characters which are noted are : the productivity, depending chiefly on the cultivation ; the degree of precocity, depending on illumination and general climatic conditions ; the colour of the stems and shoots, which does not appear to be a fixed specific character.

None of the characters studied appear to be hereditary and they are of no use in defining species or varieties. Each of the cultivated forms appears to correspond to a single individual or to a small number of individuals divided into innumerable parts by means of setts. It is therefore concluded that the specials *Humulus Lupulus* is very homogeneous and that the various cultivated forms (of which BRAUNGART has enumerated 200 from all parts of the world) are only individuals with slight differences.

904 – **Essential Oil of *Ocymum pilosum* Roxb.** — BHADURI KSHITIBHUSAN, in *The Journal of the American Chemical Society*, Vol. XXXVI, No. 8, pp. 1772-1773. Washington, D. C., August 1914.

The essential oil is found in every part of the plant including the seeds, from which, however, it can only be obtained by distillation when they are fresh. The essential oil obtained by distillation in a current of steam is a very mobile liquid, of a light yellow colour ; on exposure to the air it volatilizes leaving behind a resinous mass possessing a smell almost identical with that of the essential oil of lemon-grass. Its specific gravity is 0.8872 at 25.5° C ; its refractive index is 1.4843 or 40° 12' at 24.5° C. ; laevogyre, with specific rotary power $[\alpha]$ D = - 4° 10' 14" at 24.5° C.

Its chemical reactions prove that the essential oil contains aldehydes (75 per cent. by volume, of which 41 per cent. is citral and 34 per cent. citronellal), cineol, limonene, and very small quantities of thymol ; it does not contain free acids ; on being treated with strong mineral acids it evolves the smell of camphor.

905 – **Medicinal Plants in Tunis.** — CUÉNOD, A., in *Bulletin de la Société d'Horticulture de Tunisie*, Year 13, No. 82, pp. 186-189. Tunis, May 15, 1914.

The natural habitat and uses of the following plants are indicated : *Adonis microcarpa*, *Aloe vera*, *Aceras anthropophora*, *Althaea officinalis*, *Anethum graveolens*, *Apium graveolens*, *Artemisia arborescens*, *Borago offi-*

cinalis, Callitris quadrivalvis, Colchicum autumnale, Lavandula multifida, Mandragora autumnalis, Matricaria aurea, Melissa officinalis, Mentha viridis, Papaver somniferum, Pinus halepensis, Rosmarinus officinalis, Sinapis alba, Thapsia garganica, Trigonella Foenum-graecum, Thymus capitatus, Urginea maritima, Verbena officinalis.

906 – **A New Cover Crop: *Dolichos Hosei.*** — CRAIB, W. G., in *Royal Botanic Gardens, Kew, Bulletin of Miscellaneous Information*, No. 2, pp. 76-77. London, 1914. VARIOUS CROPS

The writer gives a botanical description of a new species, *Dolichos Hosei* Craib, obtained from the Experimental Plantation, Kuala Lumpur, F. M. S. The value of this plant was first noted by Mr. E. Hose, who found it a great success as a cover crop at Sarawak, Borneo.

The plant is indigenous in Borneo. It thrives on all soils but, prefers a sandy loam. It forms a thick dense growth about 6 inches deep and when planted 3 feet apart in six months it prevents the washing of the soil. Seed is difficult to obtain and propagation is readily effected by means of cuttings.

907 – **Studies on the Chemical Composition of Mulberry Trees in Japan.** — KAWASE, S., and SAITO, R., in *Bulletin de l'Association séricicole du Japon*, Year 1, No. 8, pp. 7-11. Tokio, April 1, 1914.

The writers give the results of their experiments carried out since 1912 at the special School of Sericulture at Uéda.

I. — *Chemical changes during the growth of mulberry leaves.*

As the result of numerous analyses the following conclusions have been drawn :

1). The percentage of water decreases in proportion to the development of the leaves, whilst the percentage of dry matter increases.

2). The percentage of protein in the dry matter and the fresh leaves decreases in proportion to the development of the leaves.

3). The percentage of crude fibre in the dry matter and fresh leaves increases enormously in proportion as the leaves develop.

4). The percentage of nitrogen-free extract increases as the leaves develop.

5). The percentage of the various nitrogen compounds, albuminoid, ammoniacal, amino, etc., diminishes as the leaves develop.

II. — *Differences in the chemical composition of leaves on standard and dwarf trees.* — Experiments were conducted on only one variety, *Komaki*, and show that :

1). The percentage of crude fat, protein and lime is higher in leaves of standards than in those of dwarfs. The percentage of nitrogen-free extract is higher in the leaves of standards. The quantity of phosphoric acid and ash is almost constant.

2). The composition of the leaves on young branches shows no considerable differences in the two types of trees.

3). In the case of old branches, the percentage of crude protein, fat and ash is higher in standards than in dwarfs, but the percentage of nitrogen-free extract and crude fibre is higher in the case of dwarf trees.

III. *Manner of calculating the quantity of manure suitable for the mulberry* This is based on the results of the preceding analyses and is only strictl applicable to this one variety Komaki. Other investigations with differen varieties of mulberries under different conditions are in course of progres in order to determine more general conclusions.

FRUIT GROWING

908 – **The Cultivation of European Fruit Trees in Upper Tonking.** — CHEVALIE AUGUSTE, in *Bulletin économique de l'Indo-Chine*, Year 17, No. 107, pp. 107-113. Hano Haiphong, March-April 1914.

The region to the north of the delta of the Red river in Tonking ha a temperate climate during the greater part of the year, whilst in th uplands it is distinctly cold during the three months November to January During the months from April to July the temperature rises considerably especially at altitudes less than 1000 ft. The climate, however, is favourabl to the growth of many European plants, including the following fruit trees

Citrus s· p. (oranges, lemons, mandarins, pomeloes). Numerous varietie occur near Tonking. The better varieties are propagated by means of air layering. Grafting is never practised by the Annamese, but they under stand the methods of growing dwarf trees, and sometimes treat citrus tree in this way.

The *persimmon* appears to have been introduced a considerable time but is not yet very widely distributed. It produces many excellent fruits The writer observed two varieties: one, small and seedless, the other muc larger and containing 5 or 6 seeds.

The *pomegranate* was introduced before the French occupation, bu it is chiefly cultivated as an ornamental plant.

Peaches are widely distributed, especially in the north and east, and ar often found half wild. It is chiefly cultivated for its flowers rather tha its fruits, which are generally of inferior value. A variety of bette quality is found the mountainous region inhabited by the Thôs, west o Lao Kay, and in Yunnan on the frontier. The acclimatisation of goo European varieties has already been succeessfully attempted at Cha-F at altitudes between 4000 and 5000 ft.

Plums exist in a wild state near the Chinese frontier. There are tw varieties in the Langsom district, one resembling the mirabelle and the oth the common plum. Another species of wild plum was met with in th Lang Biang mountains.

The *pear* (*Pyrus sinensis*) is commonly cultivated in the South of Chi in the district of Langsom (Tonking). Its fruits are handsome in appea ance, but of poor quality. There is little prospect of improvement b selection, but something might be done by hybridisation and graftin (*e. g.* on the wild stock of the Langsom district).

Apples are not grown by the natives in Tonking, but Yunnan alread sends them to Hanoi. French varieties have been acclimatised at Cha-P A species of wild apple (*Pyrus Doumeri* Bois) has been found in Annam south of Tonking, on the uplands of Lang-Biang: this should be usef as a stock for grafting European varieties.

The European *vine* was apparently unknown in Tonking before the French occupation. It does not give good results and is often attacked by disease, notably oidium. In the *Flore d'Indo-Chine* (Vol. I, Part 8, 1912) M. GAGNEPAIN records 4 species of *Vitis*, two of which, *V. balanseana* Planch. and *V. pentagona* Diels and Gilg., occur chiefly in Tonking and produce edible grapes.

Figs have been successfully introduced and thrive in Tonking even in the Delta region. They multiply readily and yield an abundance of fruit.

Several species of *blackberry* are found in the wild state in Tonking and in the south of China. The *raspberry* has been successfuly introduced and fruits freely.

Red currants and *gooseberries* have also been introduced by M. Miéville at Cha-Pa, and produced fruits during 1913. Other fruits introduced are apricots, quinces, nectarines and walnuts.

The *sweet chestnut* probably exists in certain parts of Yunnan, but it has not been recorded in Tonking. Several wild species of *Castanopsis* occur and one of them is cultivated for its fruits.

Several varieties of *strawberries* are cultivated on a large scale by native market gardeners near Hanoi. The writer found a wild strawberry at Cha-Pa producing fruits without either flavour or smell and another producing fairly tasty white fruits.

It appears that almost all the fruits of the temperate zone can be cultivated in Tonking, but the productive plants are scarcely introduced or are represented by species or varieties different from those cultivated in Europe and generally inferior. The natural advantages of Tonking over those of other neighbouring countries, will enable it to supply European fruits to the markets of the Far East. The imported French varieties do not always maintain their qualities ; the flavour is always different, sometimes improved, but generally inferior. The improvements require a long time and are generally the result of new varieties obtained from seed. Researches on the acclimatisation of suitable European fruits can be carried out only by a properly constituted Agricultural Service.

909 – **The Propagation of the Date Palm.** — CORNELL, RALPH, in *Pomona College, Journal of Economic Botany*, Vol. III, No. 1, pp. 418-423 + 3 figs. Claremont, Cal., February 1913.

The first date palms were imported by the United States Department of Agriculture twenty-five years ago, but it is only recently that the propogation of this palm in the arid regions of the south-west has assumed commercial importance. At the present time private enterprise has planted a nursery of 15 000 palms in the Colorado desert. The cultivation of this palm is limited to this region, Chuckarvalla, Mesa de Palo Verde, Imperial Valley, Yuma, Arizona and the region of Phoenix and the Salt River Valley.

The shoots or suckers, which may weigh anything from 10 to 50 lbs., are severed from the parent tree by means of heavy chisels specially made for the purpose. After painting the severed butt ends of the shoots, their tops are trimmed and the whole plant is wrapped and sewed in a covering

of palm fibre preparatory to shipment. They are often packed in boxes to facilitate handling on their long journey, during which they must be kept sufficiently moist to present excessive drying, but not so damp as to encourage mould or rot. At the end of their journey the Department of Agriculture requires that they be immersed for two different periods of 15 minutes each in an insecticide of given formula. They must then be planted in nursery form in an isolated place at least 1000 ft. from any other date palms and remain thus quarantined for 12 months. Before the planting takes place they are left exposed to the burning heat of the sun for two days so as to dry them thoroughly and stop any fungous growth that may have started. The young palms are planted so as to lean slightly toward the prevailing wind, in rows 4 feet apart and 3 feet apart in the rows. They must be kept continually moist and are generally watered every other day for the first six weeks. After this time the frequency of the irrigations may be gradually diminished as the young shoots establish themselves in their new home, but the plants should never be allowed to approach a state of dryness. The rooting process is slow and requires 8 or 9 months, sometimes even a year. The percentage of survivals varies considerably, but is generally considered satisfactory.

910 – **Date Palms from Irak.** — POPENOE, PAUL B., in *Pomona College of Agriculture Journal of Economic Botany*, Vol. III, No. 2, pp. 459-477. Claremont, Cal., May 1913.

Irak contains the largest area in the world under date cultivation, and its produce, known as Persian Gulf dates, has monopolised the North American markets for a long time. Nevertheless, when date cultivation began to assume economic importance in California, the material for the new plantations was imported from Algeria, as being more easily accessible. Most of the varieties thus obtained ripen late and the harvest in certain districts is often damaged by rain. Further, they reach the markets after they become dominated by the produce from Irak. It is therefore of great importance to obtain early varieties ripening in August and September. The Department of Agriculture obtained several such varieties from Irak in 1913.

In obtaining these varieties the writer visited Oman, Busreh and Bagdad during the winter of 1912-13. He catalogued and described 112 varieties previously unknown, and about 9000 suckers were shipped for propagation.

A description of the above varieties is given in this article.

911 – **New Fruits on North American Markets.** — *The Journal of Heredity*, Vol. IV No. 4, pp. 179-184 + 3 figs. Washington, April 1914.

The so-called "Pili nuts" which have been sold on American markets for many years at about 28 cents per lb. are the fruits of *Canarium ovatum* and *C. luzonicum* from the Philippines, and to a less extent of *C. commune* from the Dutch East Indies. The first two species exist in a wild state, while the third is cultivated. These trees (which also yield an oleo-resin) would be difficult to acclimatise in the United States but would be more suitable to Central and South America.

The Paradise nut is the fruit of various species of *Lecythis*, chief

L. Zabucajo, cultivated in Brazil, Venezuela, and Guiana. It is sold in the United States at about 80 cents per lb.

The Queensland nut is the fruit of *Macadamia ternifolia* and is already being experimented with in the south of California and other warmer regions of the United States, where it promises to become of considerable industrial importance.

912 – **The Influence of Chemical Manures on the Keeping Qualities of Pears.** — RIVIÈRE, GUSTAVE, and BAILHACHE, GABRIEL, in *Journal de la Société Nationale d'Horticulture de France*, 4th Series, Vol. XV, pp. 435-438. Paris, June 1914.

These experiments were conducted with pears of the variety Passe-Crassane, from July 5 to August 30, 1913. A row of 12 trees was chosen, four of which were used as a control and received no application; the next four trees received 10 litres of water each week and the remaining four received 10 litres of a solution containing 1 gm. of the double phosphate of potash and ammonia per litre. The fruit was harvested on October 18 and stored until fully matured, when it was analysed. The results were as follows.

1) In each group the number of fruits per tree was approximately the same (22 to 25); the volumes and weights varied slightly (383, 333 and 366 gms.).

2) The application of manures does not injure the keeping qualities of this variety (Passe-Crassane), since the fruit of the manured trees remained good longer than that of the others.

3) Manuring did not affect the chemical composition of the fruits to any considerable extent.

913 – ***Eremocitrus*, New Genus of Citrus Trees from Australia.** — SWINGLE, WALTER E., in *Journal of Agricultural Research*, Vol. II, No. 2, pp. 85-100 + 7 figs. + 1 table. Washington, May 1914.

The writer gives the botanical description, distribution, morphology phylogeny and mode of culture (grafting, hybridising and selection), of *Eremocitrus glauca* Swingle (syn : *Triphasia glauca* Lindl. ; *Atalantia glauca* Benth.) indigenous in the north-east of Australia. It is a spiny shrub, showing a marked morphological adaptation to desert conditions and characterised by a winter resting-stage and absolute resistance to cold. Its fruits are small, pyriform or roundish, and edible. It grafts easily with all common cultivated citrus trees.

914 – **Hybrid Direct-Bearers in the Côtes-du-Rhône District (France) in 1913.** — DESMOULINS, AMÉDÉE, and VILLARD, VICTOR, in *Le Progrès Agricole et Viticole*, Year 35, Nos. 29 and 30, pp. 81-89 and 108-111. Paris, July 19 and 26, 1914.

After a series of observations made in 1913 on Couderc, Seibel and other hybrids, the writers conclude that among the many varieties obtained by hybridizing there are a certain number which are decidedly valuable. The recent hybrids obtained are much superior to the earlier ones, as the writers have seen in studying the question during the last fifteen years. Nevertheless the writers do not think it possible at present to utilize hybrid direct-bearers for the great wines, which for the moment

must limit themselves to fine local grafted stocks. On the other hand these hybrids may be adavantageously employed in districts which produce only common wines ; thanks to them the production of fairly good wines of current consumption becomes steadily more reliable and its cost price cheaper.

Their functions, according to M. Couderc, are : 1) to allow the vine to be grown in localities in which it is not the principal crop ; 2) to get a crop in years in which there is much mildew and wine is dear (a kind of insurance) ; 3) diminish expenses when wines are cheap.

As for the question whether these hybrid direct-bearers are to be grown on their own roots or grafted, the writers believe that there is evidently more safety in grafting them, but that the following direct-bearers may be grown on their own roots on the soils mentioned below :

1. *On very dry soils* : Couderc 123-11, C. 7120, C. 202-75, C. 106-46, C. 272-60, Seibel 1000, Berthille-Seyve 450.

2. *In medium soils* : Seibel 2007, Castel 1028, Castel 13-706, Gaillard 157, Berthille-Seyve 618.

3. *In good soils* (wheat soils) : first the varieties mentioned above as suitable for medium soils, and then Seibel 1, S. 128, S. 880, S. 2660, S. 2653, S. 4111, Malègue 474-5.

The writers have also studied the dates of shooting of direct-bearers, which it is important to know, since spring frosts may injure vines which open early. It is evident that in districts liable to late frosts, other conditions being equal, late varieties are to be preferred. The susceptibility of a variety to spring frosts is not necessarily due to early shooting, as other factors may modify this sensibility. The time at which the buds open is also affected by various factors, but at the same time should be considered in the choice of a hybrid.

By measuring for each variety at the same period (15th to 22nd of April) the same number of shoots and taking the average of such measurements, the writers have established for each hybrid the average length of the shoots, by means of which they could measure the difference in shooting of the varieties under comparison. The results of these measurements are here given :

Length of shoots between 15th and 22nd of April	Group
1 or 2 cm.	late
3 or 4 cm.	medium
5 or 6 cm.	early
7 cm. or more	very early

STRY 915 — **The Alpine Limits of Forest Growth.** — D'ALVERNY, A., in *Annales de la Science Agronomique*, Year 3, No. 6, pp. 273-294. Paris, June 1914.

The question as to why the upper limits of forest growth are higher in the centre of mountain groups than on the outside has still reeceived no satisfactory answer.

The two principal explanations attempted are based on temperature and atmospheric precipitations respectively. FLAHAULT inclines to the latter

factor and in order to explain the phenomenon, distinguishes between the subalpine belt with maximum precipitation, and the alpine region proper. The great moisture-laden currents of air which strike the mountain ranges follow the average slope of the continent inland; the parallel layers, laden with varying amounts of moisture, rise gradually as they approach the high mountain masses. But the maximum of precipitation supposed by this theory is not at all demonstrated; all that the records show is that the first chains of mountains act as a screen to the inner masses and prevent a greater rainfall there. It is further to be noted that Flahault's botanical characterization of the subalpine zone (presence of *Pinus Cembra*, *P. uncinata*, *Larix europea* and *Picea excelsa*) is somewhat artificial; in particular, spruce agrees more nearly with silver fir in not reaching the tree-limit where this is highest.

According to Dr. MAREK the alpine limits of forest growth are lower where the annual sum of precipitations is highest. This conclusion, which seems paradoxical and in contradiction with the laws of plant biology and with current observation, is nevertheless justified if instead of considering only moisture it be admitted that other factors contribute to this result. Since all the study which has been based on the influence of temperature has yielded insufficient results not agreeing with each other, Dr. Marek sees in the factor light the one which more especially justifies the paradoxical aspect of his law. The factor light must therefore be studied with attention in its effects and must be subjected to accurate measurements (1).

The study of alpine limits would be more complete if the three essential factors of plant life—light, moisture and heat—were all considered together. It would then be seen that trees begin to fail where, owing to the want of heat, and notwithstanding the light, growth becomes so slow that it does not counteract the effect of drought. They disappear when the time is too short for the seedlings to produce during the growing season a sufficient formation of wood to afford protection against the injury caused by cold.

The fruiting of trees diminishes as their situation becomes colder, and this decrease is more marked in clouded and moist positions. It is thus evident that the warm and sunny localities of the central ranges are more advantageous than the spurs or outer chains; this is one of the most important reasons of the difference of level of the alpine limits of forest vegetation.

LIVE STOCK AND BREEDING.

916 – **Studies on the Toxicity of Cicuta or Water Hemlock.** — MARSH, C. DWIGHT, and CLAWSON, A. B. (Bureau of Plant Industry); and MARSH, HADLEIGH (Bureau of Animal Industry); in *Bulletin of the U. S. Department of Agriculture*, No. 69, 27 pp. + 4 plates. Washington, March 1914. HYGIENE

The writers give an introductory account of the historical works dealing with *Cicuta*, a list of its poisonous species, its resemblance to *Conium*, and its pathological effects.

(1) See also No. 893, above. (*Ed.*).

Experiments were conducted in 1910 and 1911 with specimens of *Cicuta occidentalis* occurring in irrigated land in the Ohio Creek Valley, Colorado. Sheep and young cattle were used to determine: 1) whether the plant is poisonous in summer and early autumn; 2) the danger to live stock from eating hay containing *Cicuta*; 3) the symptoms and effects of *Cicuta* poisoning.

The conclusions of the writers are as follows:

1. The synptoms of *Cicuta* poisoning are characterized by nausea, pain and violent convulsions. The prominent lesions, as found in autopsies, are congestion of the lungs, kidneys, and central nervous system, with inflammation of the alimentary canal.

2. So far as is known all the higher animals are susceptible to *Cicuta* poisoning.

3. A very small quantity of the root may be fatal, but the amount varies with the season and the period of time during which it is eaten. The plant is very poisonous at all stages of its growth.

4. The toxic principle is largely confined to the rootstock; the tops under ordinary circumstances are not poisonous and neither the tops nor the seeds are dangerous when present in hay.

5. The best remedy is an emetic; hypodermic injections of morphin (from 1 ½ to 3 or even 10 grains in the case of larger animals) are recommended to control the convulsions.

The following species of *Cicuta* are reported as poisonous: *C. maculata, C. bulbifera, C. vagans. C. Bolanderi, C. occidentalis, C. californica, C. Curtisii, C. Douglasii, C. purpurea, C. tenuifolia* and *C. virosa.* There is every reason to believe that all species of *Cicuta* are poisonous, and possibly all equally so.

A full bibliography of *Cicuta*, comprising 49 works, is appended.

917 – **Experimental Investigations into the Cause of Pernicious Anaemia or Typhoid Anaemia in Horses.** — SEYDERHELM, K. R. (Director of the Municipal Slaughterhouse, Strassburg) and SEYDERHELM, R., in *Berliner Tierärztliche Wochenschrift*, Year XXX, No. 34, pp. 609-612. Berlin, August 20, 1914.

CARRÉ and VALLÉE demonstrated and VON OSTERLAG and MAREK confirmed that infective pernicious anaemia in the horse is caused by an ultra-visible virus present in the blood, faeces and urine. There remained, however, some doubts as to the manner in which infection took place, as it was observed that in order to procure infection by food soiled with excrements such quantities of these were necessary as to preclude its happening in practice. It was further observed that only in very rare instances did healthy horses contract the disease through living alongside of sick ones. On the other hand it has been observed that very often the appearance of the disease followed on the horses being put out to graze. Consequently the hypothesis has been advanced of the existence of an intermediate host of the pathogenic agent. Various writers have suspected intestinal parasites, flies, and ticks of playing the part of intermediate hosts, but none were able to demonstrate the fact.

The writers of this paper proposed to demonstrate experimentally the existence of such an intermediate host. In the autopsies of 85 horses affected by pernicious anaemia they *always* found larvae of *Gastrophilus* on the mucous membrane of the stomach. An intravenous injection of an extract of *Gastrophilus* collected from a horse affected by pernicious anaemia caused a very rapid poisoning — followed by death in 12 minutes — of a horse; post-mortem examination showed violent haemorrhagic inflammation. The extract was perfectly harmless for other domestic animals, such as cattle, sheep, rabbits, fowls, guinea-pigs, etc., but not for the ass.

The writers showed that the larvae of *Gastrophilus* contain a hitherto unknown animal poison that they call oestrin (östrin), which is characterized by its being poisonous only for horses and asses. Injections in doses inferior to the mortal dose cause intense motor excitement of all the muscles and fever; the next day a considerable decrease of haemoglobin and of erythrocytes is observed. The activity of the extract is not diminished by high temperatures or by the presence of various chemical conditions, whence the conclusion is drawn that the hypothesis of its containing micro-organisms is to be set aside. Another fact points to this view, namely that the disease appears without a preceding period of incubation. Repeated injections of weak doses cause the animal at last to suffer persistently from pernicious anaemia, with all its characters, and then to die. The serum of the blood of horsees affected by pernicious anaemia following upon injections of extract of *Gastrophilus* larvae, when injected into healthy horses, causes perncious anaemia, which in its turn can be transmitted to other healthy horses by injection. The writers conclude that the cause of the disease is oestrin secreted by *Gastrophilus* larvae.

Not all horses which are hosts of *Gastrophilus* are affected by pernicious anaemia; but all the extracts of larvae are poisonous, even those taken from healthy animals. While the extracts of larvae of *Gastrophilus equi* are relatively of low toxicity, those of *G. haemorrhoidalis* are much more so. In horses affected by pernicious anaemia the writers almost always found *G. haemorrhoidalis*, besides *G. equi* and *G. nasalis*; while in healthy horses the former is usually absent.

The discovery of the writers affords an explanation of the following clinical observations on the natural infection:

1. The disease appears in its acute form mostly from May to October, that is during the period in which Oestrids fly about and deposit their eggs on horses.

2. The intensity of the disease varies from one year to another; the number of Oestrids also varies from year to year, probably according to the season.

3. The appearance of the disease is almost always connected with the animals being turned out to graze.

4. The disease is hardly ever propagated from diseased horses to healthy horses near them.

5. The disease never appears in horses that are regularly groomed, for instance military horses.

The disease may be treated by the expulsion of the *Gastrophilus* larvae only when it is incipient. The writers investigated whether antibodies were formed against oestrin and succeeded in obtaining a highly efficient curative and preventive serum.

Pernicious anaemia of horses may thus be controlled prophylactically by the destruction of Oestrids.

After prolonged dosing with the extract containing oestrin at first only transitory symptoms appear ; then the horses begin to be sickly and at a certain stage the disease becomes more serious, even without further injections, and leads inevitably to increasing anaemia, to high fever and then death. In this latter period the blood contains an agent that transmits the disease to healthy horses. The nature of this body cannot be determined with certainty, but judging from its behaviour to physical and chemical agents it possesses properties which differ from those of oestrin. In the first place it is unstable under the action of heat. It might be a substance that could be represented by a chemical formula and that is liberated by oestrin from certain parts of the horse's tissue and has the property of acting on the healthy tissues in the same way as oestrin itself, namely of liberating from the tissues a compound similar to itself. Thus the " ultra-visible virus " of the pernicious anaemia of the horse would be a product of anomalous metabolism formed during the course of the disease and which, transmitted to a healthy horse, sets up the pathogenic conditions which cause the same metabolic product to be formed. The process may thus be repeated indefinitely. The research work carried on at the Breslau Chemical and Physiological Institute confirms this hypothesis.

In Japan also investigations have been carried out (by SHIGA and others) into the pernicious anaemia of horses during the last five years on 980 horses and other domestic animals. They have proved that the disease is transmissible to pigs, that infection by means of faeces and urine has no practical importance, and that the appearance of the disease is connected with the presence of winged insects. By means of only *one* inoculation of *Gastrophilus* larvae it was not found possible to cause the disease. The results obtained by the Japanese commission thus agree with those of the writers.

918 – **Microphylaria in Horses affected by Haemorrhagical Boils.** — ROMANOVITCH (Veterinary Laboratory, Petrograd) in *Comptes Rendus hebdomadaires des séances de la Société de Biologie*, Vol. LXXVII, No. 26, pp. 390-391. Paris, July 24, 1914

Horses in Southern Russia are often infested by *Filaria haemorragica*. This parasite lives in the subcutaneous connective tissue and causes the formation of haemorrhagic boils on the surface of the skin ; when these break a certain amount of bleeding takes place.

On examining drops of the blood the presence of a non-sheathed microphylaria was observed ; when fixed on the object glass by the alcohol and ether mixture this measured 150 to 224 μ in length. It tapers towards its posterior extremity which ends in a longish tail.

The blood from the heamorrhagical boils contains also eggs, which enclose completely developed embryos. The shells of the eggs are very thin, and easily coloured.

In the blood taken from the jugular vein of horses affected by these boils the same microphylaria was always found.

The writer examined five horses suffering from these boils and three healthy ones from the same district. In the former he always found microphylariae, while the latter were free from them; from this he concludes that the microphylaria in question is the embryo of *Filaria haemorragica*.

919 – **Effect of Low Temperatures on the Bacilli of Anthrax. — Contribution to the Study of the Treatment of Meat Superficially Infected by Anthrax Bacilli.** POPPE, KURT (Veterinärabteilung des Kaiserlichen Gesundheitsamts) in *Zeitschrift für Fleisch- und Milchhygiene*, Year XXIV, Part 21, pp. 485-489 + 1 fig. Berlin, August 1, 1914.

The frequent appearance of localized anthrax in pigs has given a special importance to the question of judging the fitness as food of pigs thus affected, as well as of the flesh of animals that have been slaughtered together with such pigs, and which has come into contact with them.

According to the legislation at present in force in Germany pigs affected by localized anthrax are seized and declared unfit for human food, and the meat and offal that comes into direct or indirect contact with animals affected, or suspected of being affected, by localized anthrax or with their flesh, is for the most part likewise seized and declared unfit for human food or only fit under certain conditions.

In Prussia a Ministerial Order of April 12, 1913, provides that the last-mentioned meat may be exempted from seizure when upon examination it appears that no germs of anthrax have been conveyed to it. Similar legislative provisions have been adopted in most of the other German States.

The fact that the flesh of healthy pigs which becomes infected superficially at the slaughter-house is mostly treated with the same severity as diseased meats, led to investigating whether, besides the treatment with steam, low temperatures would render it harmless.

After referring to the purely scientific researches of Pictet and Young, Allan Mac Fayden and Belli (who experimented at the temperature of liquefied air) and to the more practical ones of Klepzoff, who concluded that *Bac. anthracis* may be rapidly killed by very low temperatures and in some days at higher temperatures (in 12 days at - 24° C, - 11.2° F.), the writer describes his own experiments, which consisted in keeping cultures of *Bac. authracis* in pieces of superficially infected meat, blood and organs of infected animals in ventilated cold storage at the average temeprature of - 15° C. (+ 5° F.) with average moisture of 75 to 80 per cent. The details of the experimental results are collected into tables from which the writer concludes that anthrax bacilli on meat and in cultures do not lose any of their vitality or virulence even after two weeks' storage at - 15° C. Consequently, even prolonged refrigeration does not render meat superficially infected with anthrax bacilli harmless.

920 – **Vaccination against Hog Cholera** (1). — CRAIG, R. A., and WHITING, R. A., in *Purdue University Agricultural Experiment Station, Bulletin* No. 173, Vol. XVII, pp. 441-474. Lafayette, Indiana, March 1914.

The purpose of this bulletin is to inform farmers as to the nature of hog cholera and the methods of controlling this disease. The disease exists in all sections of the United States, but is especially prevalent in the corn-raising States, where it is considered to be the disease of greatest economic importance. In Indiana alone the annual loss from this cause amounts to about $3 000 000, excluding the loss resulting from the marketing of young hogs in neighbourhoods where the disease is prevalent. In 19 years (1894 to 1912) 58 800 409 pigs were raised in Indiana, and of these 6 754 771 died of cholera.

In 1908 Drs. Dorset and Niles, of the Bureau of Animal Industry, demonstrated the method of producing an anticholera serum and its application. A number of State laboratories for the production of anti-sera were then established. For the production of a laboratory virus it is best to use young thrifty hogs weighing from 80 to 100 lbs. They should be inoculated with 2 or 3 cc. of hog-cholera blood of sufficient virulence to kill a susceptible hog in from 8 to 14 days, but preferably in 8 to 10 days. When the hog has developed fatal symptoms of disease, it is killed by cutting the carotid artery near the base of the neck. In order to increase the quantity of virus that may be secured from a hog showing fatal symptoms of hog-cholera, from 10 to 15 cc. per lb. of body-weight of a sterile physiological salt solution are injected into the peritoneal cavity of the hog two to three hours before it is bled. After the hog has bled, the solution is removed by tapping the peritoneal cavity with a side-neck cattle trocar. The lesions of hog cholera should be marked and acute in character; blood from virus hogs showing fatal symptoms of disease within 6 days following exposure and those showing lesions of septicaemia in the liver, spleen and skin, should be rejected.

The immune hogs used for the production of serum should weigh from 150 to 175 lbs., since after several re-hyperimmunizations covering a period of from 4 to 6 months the animal may double in weight and become difficult to handle. The injections should be intra-muscular or subcutaneous in the region of the thighs or shoulders. From 10 to 12 cc. of blood per lb. of body-weight are injected on two occasions with an interval of one week between them.

In the intra-peritoneal method, 10 cc. of cholera blood per lb. of body-weight are injected into the peritoneal cavity. This method is not recommended owing to the inferior serum produced.

In the intravenous method, 5 or 6 cc. of virus per lb. of body-weight are injected into the vein of the ear. The injection may be made once, or twice with an interval of one week.

The virulent salt solution recovered from the abdominal cavity of the cholera hog is about one half as virulent as the cholera blood and should

(1) See also original article by Dr. Hutyra: « Protective Inoculation against Swine Fever in Hungary ». — *B.* June 1914, pp. 707-712. (*Ed.*).

be used in double the quantity. It is advisable to inject the virus intramuscularly in the proportion of 20 cc. per lb. of body-weight.

The hyperimmunised animals are ready for bleeding in from 10 to 14 days after injection of the virus. At each bleeding, which is effected on the tail, 6 cc. of blood per lb. of body-weight may be removed, but the animals should not be bled more than three times at weekly intervals before re-hyperimmunising. This process requires only one half the quantity of cholera blood used for the first injection, and the animal should not be re-hyperimmunised the same day it is bled. It is ready for bleeding in a week or ten days after re-injection with the virus. The bleedings and injections can be practised until the tail becomes so short that it cannot be handled. The hyperimmune animal is then bled to death by cutting the blood vessels near the base of the neck, but it is advisable to re-immunise before making this final bleeding.

The hyperimmune blood is defibrinated and preserved by adding one-tenth of its volume of 5 per cent. solution of phenol. Before being used for vaccination purposes it should be carefully tested for potency and the presence of septic organisms.

The vaccination of a hog by the single method consists in giving it anti-hog-cholera serum, which confers immunity not longer than four weeks. Vaccination by the double method consists in giving an injection of anti-hog-cholera serum and one of cholera blood. The writers recommend the following doses of anti-serum: for pigs weighing from 50 to 100 lbs., one half cc. per lb. of body-weight: for pigs weighing from 100 to 300 lbs., from 50 to 90 cc. In using cholera blood: pigs weighing less than 100 lbs. receive 1 cc. and pigs weighing more than 100 lbs. 1 ½ to 2 cc.

During the period July 1908 to March 1914 the State of Indiana produced 9 881 998 cc. of serum; this was used for the vaccination of 247 049 hogs; the percentage loss in the healthy herds was 2.39, whilst that of the infected herds was 9.02.

An extract of the law relating to the prevention, spread and control of swine disease in Indiana is appended.

921 – **The Influence of Food Poor in Lime on the Composition of Growing Bones.** — WEISER, STEPHAN, in *Biochemische Zeitschrift*, Vol. 66, Part 1-2-3, pp. 95-114. Berlin, July 29, 1914. ANATOMY AND PHYSIOLOGY

The writer kept a group of three young pigs, from the 15th of January to the 1st of October, on food rich in lime and another perfectly similar group on rations poor in this substance. After the animals were slaughtered, the bones were analysed; it was found that a food poor in lime diminished the development of the animals to such an extent that from the beginning their increase in weight was about 20 per cent. less than that of the pigs fed on food rich in lime. The prolonged want of lime always caused the appetite to diminish and consequently the live-weight also.

The pigs that had not been fed enough lime had in general deformed pliable bones, thinner and easier to cut than those of the other lot. The differences in growth and weight of the skeletons, however, could not be determined. Out of the total weight of the body of the pigs poor in lime,

the weight of the fresh bones and of the dry matter represented a greater percentage (14.29 and 5.05 per cent.) than in the other lot (8.74 and 3.91 per cent. respectively).

The bones of the lot lacking lime contained considerably more water and much less ash than those of the others, but their fat content was nearly the same.

The differences in the ash content were least in the bones of the skull and greatest in the ribs. In the pigs deficient in lime, out of the total ash content of the skeleton a greater proportion was found in the skull than was the case with the other lot.

The bone-ash of the former is considerably poorer in CaO than that of the latter; a difference in the same direction, though smaller, was observed also in the $P_2 O_5$ content.

The essential difference between the composition of the bone-ash of animals deficient in lime and that of animals rich in lime is that the former includes considerable quantities of alkalies ($Na_2 O$, $K_2 O$).

FEEDS AND FEEDING

922 – **Investigations into Factors affecting the Handling of Wheat Hay, including a Study of its Digestibiiity.** — PERKINS, A. J.; PHILLIPS, J. H.; SPAFFORD, W. J., and MAY, N. S., in *The Journal of the Department of Agriculture of South Australia*, Vol. XVII, No. 7, pp. 720-755. Adelaide, 1914.

The experiments of 1912 and 1913 confirm the conclusions of 1911 (1) and include feeding trials.

King's White wheat was grown on half-acre plots which were cut at intervals of one week from the 10th of October to the 20th of November. The results are given in Tables I-V.

TABLE I.

Details of seven cuts of hay taken between full bloom and ripeness.

Date of Cutting	Yield per acre			Moisture	Loss of weight on drying	Percentage of ears by wt. in hay with 10 % moisture
	tons.	cwt.	lbs.	per cent.	per cent.	
1. — Oct. 10	1	17	86	11.31	71.33	12.26

Fibre	46.99	32.42	30.12
Carbohydrates and fat	61.56	62.91	59.94
Albuminoid ratio	1 : 19	1 : 15.25	1 : 12.24

Conclusions.

1. The yield of dry fodder from wheat varies according to the period of cutting; the average relative yield per cutting during the flowering period is as follows:

Days after flowering	Percentage dry fodder
6	20.31
13	24.02
21	36.04
28	32.62
35	21.90
42 (grain ripe)	14.24

The maximum yield is obtained by cutting 3 weeks after the period of full flower, when the grains leave the milky stage. This is the case with early wheat grown in a climate requiring six weeks between flowering and maturity.

2. There is a greater increase in weight in the ears than in the stem and leaves during the three weeks following the flowering period. At the end of three weeks the weight of the ear continues to increase, whilst that of the stem and leaves begins to decrease, and two weeks before maturity actually weighs less than at the flowering period. The following figures show the average (1911 and 1912) percentage increase in weight after the flowerring period.

Days after flowering	Ear	Stem and leaves
0	100.00	100.00
6	137.77	118.28
13	153.10	119.98
21	246.75	120.48
28	321.05	106.70
35	337.00	92.54
42 (grain ripe)	340.40	83.33

Cutting the crop after the grains have passed the milky stage results in a loss of nutritive substances and a badly balanced hay, and unless harvested at least two weeks before maturation the hay deteriorates considerably.

3. The relative differences in chemical composition of the crop cut at different stages are as follows: *a*) a progressive diminution in the percentage of ash and a corresponding increase in organic matter during maturation *b*) the percentages of albuminoid substances tend to increase during the first three weeks, then diminish until complete maturation of the grains; (*c*) the percentage of fatty matter appears to remain constant during the whole period; *d*) the percentage of carbohydrate in the ear increases regularly during the six weeks (being 50 per cent. of the dry matter at flowering and 72 per cent. on maturation), and it is balanced by a corresponding decrease in the stems and leaves; *e*) conversely, while the percentage of cellulose gradually increases in the stems and leaves (from 32 per cent. at flower

ng to 42 per cent. on maturation), it decreases in the ear (from 30 per ent. at flowering to 13 per cent. on maturation).

4. There is a considerable loss of dry matter in the grains during he two or three last weeks, reaching 22.9 per cent. of the highest yield n 1911 and 6.41 per cent. in 1912. This loss is undoubtedly due chiefly o the breaking of the leaves and partly to the separation of grains or ther accidents, such as a lowering or suspension of the assimilatory function, or washing out of the porous tissues by rain. The annual loss of nineral matter (20.51 per cent. in 1912-13) was considerably greater than hat of the organic matter (5.34 per cent.); from this it is concluded that migration of mineral substance towards the root takes place as maturation proceeds.

5. The loss of weight on drying decreases as the time of cutting pproaches the ripening stage. In the case of the 1st, 4th, and 7th cuts t was respectively 71.45, 47.44 and 24.04 per cent. of the green weight luring the flowering period, and less than ¼ of the green weight after naturity.

6. The percentage moisture in the hay varies slightly according to he conditions of drying. Generally hay cut early retains more moisture han hay cut late. South Australian wheat hay has an average of 10 per cent. of moisture.

7. The loss of weight of hay allowed to dry naturally in the fields s not exclusively due to the evaporation of moisture. The writers consider that at least 1.5 per cent. of this loss is due to the decomposition of organic matter, such as carbohydrates. Comparing the composition of the plant with that of the hay dried *in situ*, and assuming both to have contained the same proportions of water, the writers found a loss of 4.05 per cent. of dry weight, or 1.66 per cent. of the green weight, which they listribute as follows: protein matter 0.10, fatty matter 0.03, cellulose 0.33, carbohydrates 1.20.

Digestibility experiments on horses showed that wheat hay cut at he flowering period is more digestible than hay cut later and that the digestibility diminishes in proportion to the lateness of the cutting. There s a difference of 12 per cent, in the digestibility of hay cut at the flowering period and that cut when the grain is ripe. The decrease in digestibility s more noticeable in the case of the albuminoid and cellulose constituents and less so for the mineral matter and carbohydrates. The ratio of the digestible nitrogenous matter to the digestible non-nitrogenous matter s higher in the case of hay cut early, owing to the greater digestibility of he albuminoids in early hay and the predominance of carbohydrates n hay cut late.

Thus, there is everything to lose and nothing to gain in postponing he cutting of the crop until the grain begins to harden. The practice of judging the value of hay from its colour is fully justified, a distinct green being the best colour.

923 – **Bacteriological Research on Ensilaged Forage.** — GORINI, COSTANTINO, in *Bollettino dell'Associazione Italiana dell'industria dello zucchero e dell'alcool*, Year, VII, No. 4, pp. 83-90. Bologna, July 1914.

The bacteriological researches carried out by the writer (1) justify the suggestion, which he made in 1907, that selected lactic ferments should be added to ensilaged forage. This is all the more so as the forage from butyric silos, though it may be considered as successful, presents some disadvantages. It must especially be noted that intestinal troubles are observed in the cattle fed on such ensilage, and that this forage is to be avoided in dairies, not only for the odours and flavours which it may impart to milk and butter, and especially to the bacterial flora, of a gas-forming nature, which may cause cheese made with such milk to swell.

924 – **Live Stock Feeding Experiments in Ireland, 1912-13.** — *Department of Agriculture and Technical Instruction for Ireland, Journal*, Vol. XIV, No. 3, pp. 456-470. Dublin, April 1914.

These experiments are in continuation of those begun in 1912. (*Journal*, Vol. XIII, No. 3).

1. — Pig Feeding Experiments.

Series I. *Comparison of potatoes and meal.*

The object of these experiments was to determine if pigs can be fattened successfully without potatoes. During the past two seasons the experiment was conducted with 148 pigs at 20 centres distributed throughout 13 counties. The average age of the pigs was 13 ½ weeks and the duration of the experiment 108 days. At each centre the pigs were divided into two lots. Lot 1 received a certain quantity of potatoes in addition to other foods (maize, pollard and separated milk), whilst lot 2 was given an extra pound of the meal mixture in place of every 4 lbs. of potatoes fed to lot 1.

The results obtained are set forth in Table I.

Whilst these figures show that the average daily gain in live-weight was practically the same for each lot of pigs, nevertheless, in respect to rate of increase in live-weight, cost of producing a given increase in live-weight and quality of pork, the pigs fed on meal alone were slightly, but fairly uniformly, superior to the pigs which received potatoes. The question as to whether potatoes should be sold or fed to pigs depends largely upon the current prices of potatoes and meal respectively. It is very doubtful whether it is economical to feed pigs on saleable potatoes if they can be sold for one-fourth the value of meal, in addition to the cost of marketing.

Series II. *Barley meal compared with maize meal.*

This experiment was conducted with 106 pigs at 15 centres. The average age of the pigs at the commencement was 13 weeks and the duration of the experiment 100 days.

The results obtained are set forth in Table II.

(1) See No. 541, *B.* June 1914. (*Ed.*)

TABLE I.

Food.	Price per cwt.	Quantities. Lot 1.	Quantities. Lot 2.
	s. d.	cwt. lbs.	cwt. lbs.
Maize meal	7 6	141 21	220 92
Pollard	7 0	89 101	146 26
Oat meal	12 0	0 84	0 84
Potatoes	2 0	524 28	— —
Separated milk	1d. per gallon.	3247 gallons	3 247 gallons
Linseed cake	10 6	2 28	2 28
Table refuse.	— —	— —	— —
Total cost of food	— —	£155 10 s.	£149 13s.
Average increase in live-weight	— —	1 cwt. 50 lbs	1 cwt 54 lbs
Cost of producing 1 cwt. live-weight increase	— —	£1 9s 1d.	£1 7 3d.

TABLE II.

Food.	Price per cwt.	Quantities. Lot 1.	Quantities. Lot 2.
	s. d.	cwt. lbs.	cwt. lbs.
Barley meal	7 0	134 99	— —
Maize meal	7 6	—	135 23
Potatoes	2 0	339 9	335 65
Swedes	8s per ton	35 0	35 0
Separated milk	1d per gallon	1 062 gallons	1 051 gallons
Linseed cake	10 6	2 0	2 0
Table refuse	— —	— —	— —
Cost of food	— —	£87 15s 10d	£90 17s 8d
Average live-weight increase	— —	1 cwt. 34 lbs.	1 cwt. 37 lbs.
Cost of producing 1 cwt. live-weight increase	— —	£1 5s 6d	£1 5s 10d

In two experiments where swedes were fed instead of potatoes, the pigs made very slow progress, the average daily increase scarcely exceeding one pound per head. The results of these experiments appear to indicate that maize is worth approximately 10s per ton more than barley meal for pig feeding. As regards quality of pork, barley meal seems to be slightly superior to maize meal. It should be noted that the estimated

cost of production is based on the cost of the food only . In practice, many other items, such as attendance, fuel, risk and interest on capital have to be considered.

2. — Calf Feeding Experiment.

This experiment was designed to compare the value of oat meal and wheat meal respectively, when used in conjunction with maize meal and ground linseed for calf feeding. It has been carried out during the past two seasons at 31 centres. 244 calves were selected and divided into two lots ; their average age at the commencement was seven weeks and the experiment lasted 117 days.

The results are given in Table III.

TABLE III.

Food.	Price per cwt.	Quantities.	
		Lot 1.	Lot 2.
	s. *d.*	cwt. lbs.	cwt. lbs.
Oat meal mixture	14 0	105 92	— —
Wheat meal mixture	13 0	— —	105 83
Linseed cake	10 6	31 72	31 72
Whole milk	5 *d.* per gallon	91 gallons	91 gallons.
Separated milk	1 *d.* per gallon	18 765 gallons	18 765 gallons
Total cost of food	—	£170 15*s* 5*d*	£16 5*s* 8*d*
Live-weight increase (mean)	—	1 cwt. 78 lbs.	1 cwt. 77 lbs.
Cost of production of 1 cwt. of increase	—	16*s* 6*d*	16*s* 1*d*

In the above estimates no account is taken of the value of the hay consumed or the grazing, but these items are the same for both lots. On the whole, there was no appreciable difference in the health or appearance of the two lots of calves. The difference in the cost of production is so small that it would appear that the two meal mixtures are of practically equal value at the prices mentioned.

III. — Cattle Feeding Experiments.

Experiment A. — Cattle on grass.

This experiment has been conducted at 14 centres with two lots of 62 cattle each. Lot 1 received a mixture of home-grown concentrated foods, whilst lot 2 received a corresponding quantity of imported foods.

The mixture were made up as follows :

Home-grown.	*Imported.*
1 part wheat meal.	1 part maize meal.
1 ½ parts barley meal.	2 parts undecorticated cotton cake.
2 parts ground oats.	

At the beginning of the experiment 3 lbs. of the above mixtures were given per head daily; this amount was afterwards increased to 4 and finally to 5 lbs. towards the end of the fattening period. The average duration of the experiment was 79 days.

The results are set forth in Table IV.

TABLE IV.

Food.	Price per cwt.	Quantities. Lot 1.	Lot 2.
	s. d.	cwt. lbs.	cwt. lbs.
Home-grown:			
Wheat meal	8 0	43 60	— —
Barley meal	7 0	65 34	— —
Ground oats	6 8	87 8	— —
Imported:			
Maize meal	7 6	— —	65 34
Undecorticated cotton cake	6 6	— —	130 68
		£ s d	£ s d
Cost of food:			
Concentrated	— —	69 5 10	66 18 9
Grazing	— —	69 19	69 19 5
Total	— —	139 8 3	136 18 2
Manurial value	— —	7 3 7	13 2 3
Total cost of food less manurial value	— —	132 1 8	123 15 11
Total increase of live-weight	— —	117 cwt. 102 lbs.	117 cwt. 102 lbs.
Cost of producing one cwt. live-weight increase	— —	£1 2s 5d	£1 1s 5d

The average results of these experiments show that the increase in live-weight made by the two lots of cattle was identical, but the cost of production was somewhat in favour of the imported foods.

Experiment B. — Stall-fed cattle.

This experiment was carried out at 21 centres with 176 cattle in 2 lots. Lot 1 received the same home-grown foods as in the preceding experiment, whilst lot 2 received a mixture of 1 part decorticated cotton cake and 2 parts maize meal. At 15 centres, part of the decorticated cotton cake was replaced by linseed cake during the finishing period.

At the beginning of the experiment 3 lbs. of concentrated food were given daily, and this quantity was gradually increased, until in some cases as much as 10 lbs. were supplied. The average duration of the experiment was 82 days.

The results are set forth in Table V.

TABLE V.

Food.	Price pee cwt.	Quantities.	
		Lot 1.	Lot 2.
	s. d.	cwt. lbs.	cwt. lbs.
Home grown:			
Wheat meal	8 0	90 54	— —
Barley meal	7 0	135 81	— —
Ground oats	6 8	180 108	— —
Imported:			
Maize meal	7 6	— —	271 50
Decorticated cotton cake	9 6	— —	144 25
Linseed cake	10 6	— —	21 56
Bulky food:	per ton.	tons. cwts. qrs.	tons. cwts. qrs.
Roots	8 0	256 1 3	256 1 8
Hay	40 0	26 5 2	26 5 2
Straw	30 0	14 8 3	14 8 3
Cost of food.		£ s d	£ s d
Concentrated	— —	144 0 5	167 6 6
Bulky foods	— —	176 12 9	176 12 9
Total	— —	320 13 2	343 19 3
Value of manure produced	— —	14 18 1	26 12 0
Cost of food less manurial value	— —	305 15 1	317 7 3
Total live-weight increase	— —	112 cwt. 40 lbs	118 cwt. 72 lbs.
Cost of producing 1 cwt. of live-weight increase.	— —	£ 2 14*s* 5*d*	£ 2 13*s* 6*d*

The average live-weight increase was one-tenth pound per head daily in favour of the imported foods, and the cost of production per cwt. live-weight increase was 11*d* in favour of the imported foods.

Considered as a whole these experiments show that for all practical purposes no superiority can be claimed for either class of concentrated foods at the prices quoted.

BREEDING

925 – **Preliminary Notes on the Heredity of Certain Characters in a Cross between Silky and Yokohama Fowls.** — BONHOTE, J. L., in *The Cairo Scientific Journal*, Vol. VIII, No. 91, pp. 83-89. Alexandria, April 1914.

The writer received from M. Debruil, of Melu , Fra ce, a pair of fowls which were the offspri g of a male Silky a d a female Duckwing Yokohama; the cross had bee made i the hope of obtai i g birds combi i g the texture of feathers of th Silky with the length of feathers of the Yokohoma, with a view to using the feathers as substitutes for

"ospreys", etc., the writer bred from these two birds to study the inheritance of the characters involved.

The characters of the parent birds were: *Silky* (male), dark-fleshed, white, with short silky feathers, rose comb, five-toed, with feathered legs and a small crest; *Yokohama* (female), white-fleshed, Duckwing, with long normal feathers, a single comb, four-toed, clean legs and no crest.

The two birds of the F_1 generation were uniform (sex excepted) and showed a practically complete dominance in almost all cases, *e. i.* dark fleshed, coloured plumage ("black-red"), normal feathering, long-tailed (especially in the male), clean legs, crested. The carriage of the tail-feathers was intermediate between that of the parents. The male had five toes and the hen only four.

The F_2 generation is considered in two groups. The first group, consisting of 96 individuals, deals only with those characters such as colour of flesh and feathers, simple or rose comb, 4 or 5 toes, which are visible at birth and on which statistics concerning all the chickens hatched are available. Of these 66 pigmented flesh and 30 non-pigmented; 71 were coloured and 25 white, (expectation 72:24) but very few were pure white; the majority showed some red pigmented feathers on the saddle, the coloured portions being sharply divided from the rest. It is evident that these chickens are not pure recessives but contain a certain amount of pigment. 30 chickens hatched from eggs of these individuals showed the same characters, giving no really coloured ones. The writer suggests that this form of coloration is the initial stage of the "pile" type of coloration found in other breeds of fowls.

No "Duckwing" character appeared in the F_2 generation, all the individuals being of the "black-red" type, but of two kinds, one having black breasts with a few red feathers, the other red breasts with a few black feathers.

With regard to character of comb, 83 had rose combs and 13 single combs. The ratio of five-toed individuals to four-toed was 64 : 32. The inheritance of both these characters was complicated by intermediate forms.

The characters of the second group, *viz.* silky or normal feathering, long or short feathers, clean or feather legged, crested or not, were studied in 24 individuals reared to maturity. Of these 18 were normal and 6 silky. The flight feathers and tail feathers are only silky at their ends and practically normal at their bases. The length of feathering is difficult to determine and apparently not inherited in a strictly Mendelian manner. No two birds were alike in this respect, but the writer by adopting a provisional standard, divided the birds when six months old into two groups of 19 long and 5 short, thus showing that the long-feathered type is dominant. The real character which determines the length of the feather is the growing period of the feather follicle and this is undoubtedly influenced by the food, environment and individual vigour of each bird, so that when this character is blended with the normal it is only to be expected that the actual length of feather in the progeny would be largely dependent on the indi-

vidual when the environment remains constant. Sixteen individuals were clean-legged and 8 feathered, but, of the 8 feathered ones, 4 were only half feathered and therefore almost certainly heterozygous, thus giving 20 dominants and 4 recessives. The crest was developed in these crosses, being present in 21 individuals and absent in only 3.

Thus, the Mendelian expectations with regard to each character have been largely realised. The writer remarks that recessives are more frequent among females, owing to the absorption of more of their mitial vigour, on their sex, and that recessive characters more usually associated with the female can be produced in males by an artificial reduction of vigour. Also if colour may be to a certain extent an indication of vigour, we shall expect to find a higher percentage of recessive characters among white birds than among the coloured ones.

Of these 24 birds, 10 were males and 14 females, 19 coloured and 5 white.

The 10 males showed 13 recessive, 6 heterozygous and 61 dominant characters ; the 14 females showed 24 recessive, 14 heterozygous and 42 dominant characters. The 19 coloured individuals showed (xcludi g the white or coloured as characters) 22 recessive, 14 heterozygous and 133 dominant characters ; the 5 white individuals showed 10 recessive. 6 heterozygous and 19 dominant.

These results show that on the average the females have 0.41 more recessive characters than the males, and the whites 0.74 more recessive characters than the coloured.

The writer therefore concludes that the Mendelian proportions are to a certain extent affected by vigour and that it is practically possible to increase the number of individuals possessing a certain character by attention to such details as the food, temperature, age of the breeding stock and time of year at which breeding takes place.

926 – **Studies on Inheritance in Pigeons: Hereditary Relations of the Principal Colours.** — Cole, L. J., in *Agricultural Experiment Station of the Rhode Island State College, Bulletin* No. 158, pp. 313-380 + 4 plates. Kingston, R. I., May 1914.

These investigations were begun at the Rhode Island Agricultural Experiment Station in 1907, to determine the mode of inheritance of coat colour in birds. Previous work on inheritance in birds (fowls and canaries) has not given data as definite as in the case of mammals. In the case of fowls this was undoubtedly due to the complications introduced by coloured patterns originating in different colour schemes for each feather. Pigeons have been chosen because it is possible to select strains of uniform colour and free from pattern complications.

In most of the studies with fowls, crosses were made with very different breeds showing very marked differences in a large number of characters thus resulting in confusion. The writer has considered it more advisable to confine his observations to certain well-defined differences in the same breed (Tumblers). It also appeared less probable that similar characters would behave differently in the same breed.

The primary colours of pigeons are : red, yellow, black, brown, blue, silver, and white. These experiments have shown that these colours are produced by only two types of pigment, black and red. Red is the fundamental colour of pigeons and probably also of fowls and the majority of mammals. The red factor is always present, but it only determines the colour of the bird in the absence of an inhibiting factor or of a dominant factor such as the factor for black. For the full manifestation of these two colours an intensifying factor is necessary. When this factor (I) is absent, the colour is of a lighter shade and red becomes yellow, whilst black becomes dun. The I factor is definitely sex-linked in its inheritance. "Duns" are easily obtained by crossing birds having the B factor with birds lacking the I factor, *e.g.* black × yellow.

Thus, mating a yellow cock (bbii) with a black hen (BBIi) heterozygous for I, will produce black cocks and dun hens, since the factor I is limited to the males. In the reciprocal cross all the F_1 generation will be black and duns will appear in the F_2 generation.

The blue colour of the wild pigeon (*Columba livia*) is due to the optical effect of black pigment aggregated into clumps. In the black birds the pigment is uniformly distributed. This is accounted for by supposing the presence of a spreading factor (S), the absence of which results in the blue colour. Silver colour is regarded as a diluted blue and is therefore black minus the factors I and s. White is due to the absence of pigment and the reflection of light. Pure whites are fairly common but rarely breed true, and the mode of inheritance is very complex. Colour is dominant over white but not entirely. Pure white should undoubtedly be considered as the extreme reduction of mottling. As a provisional hypothesis white may be considered as due to the presence of an indefinite number of factors preventing the formation of pigment. Thus the quantity of white depends on the number of these factors present.

The marking of the plumage of pigeons may be of the following types: 1) splashes or intermingling of white and coloured feathers without definite patterns; 2) special patterns, *i. e.* a combination of white and coloured areas forming a more or less definite marking ; 3) check, light triangular markings on the wings ; 4) grizzling, *i. e.* barbs partially white and partially coloured ; 5) mealiness, due to the whole or partial replacement of white by red ; 6) frosting, due to the presence of white distal margins on the contour feathers.

It is possible that a particular portion of the plumage may be represented by homozygous factors, such as W_1, W_2, etc.

The frequent reappearance of the blue colour of the wild rock pigeon (*Columba livia*) is due to the recurrence of the particular combination of factors present in this type.

In the experiments on the dominance of black over red, the F_2 ratio was nearer 2:1 than 3:1. This was not due to the absence of homozygous dominants, but rather to the tendency toward the production of different ratios in different families or strains. All the results show a slight excess

of red offspring above the normal expectation of a pure dominant and recessive.

In the experiment on the inheritance of the I factor the crossing of heterozygous individuals always gave the 3 : 1 ratio ; the cross between the heterozygous F_1 and the recessive parent always gave the ratio 1:1, thus showing that the factor for intensification of colour segregates in a strictly Mendelian fashion.

Various matings between birds of different colours gave results according to expectation. In general the offspring tend to be grouped around the parental mean with respect to amount of colour in the plumage. The evidence points to the conclusion that a number of factors are concerned in the production of white and splashed birds.

STOCK RAISING : ORGANIZATION AND ENCOURAGEMENT

927 – **Animal Husbandry in Sardinia in Connection with Environment.** — DORIA, MARIO, (Director of the Royal Horse-Breeding Station of Ploaghe) in *Il moderno Zooiatra*, Series V, Year III, No. 7, pp. 313-326. Bologna, July 31, 1914.

In Sardinia, where agriculture is still mostly extensive, live stock is the most important source of income. The animals are generally bred wholly in the open.

Horses. — The Sardinian horse, descended from African and Asiatic breeds, has had a period of celebrity, which came to an end chiefly through too close in-breeding. According to the writer, when the State founded the stallion depots and stations, a great mistake was made in not taking the native horse into account, and of using among others English stallions ; these increased the stature of the animals but at the expense of their muscle and the harmony of their shape. The cross of the Sardinian (Oriental) with the English horse has led to a great variation of forms, so that no uniform local breed exists. The horses of Gallura and of Anglona have most English blood, and form a distinct type. According to the writer the stallions to be adopted for the improvement of Sardinian horses should be of pure Oriental breeds, which, like the native Oriental crosses, have the advantage also of being better stock getters than the English stallions.

Cattle. — Cattle breeding has made much progress of late years in Sardinia. There are three breeds of cattle in the island : the plain breed, imported from Sicily, the Schwytz (brown variety) on the hills and in the best pasture lands ; the Sardinian or mountain breed, which has remained in its primitive state, not having been subjected to any crossing. It inhabits the mountains especially of Gallura, of the Fonni plateau and of Fonni, Orgosolo and Aritzo. The plain breed lives in the so-called *planargia* and the Campidano towards Oristano ; it is especially suitable as a draught animal ; the meat is good, but not much sought after on the markets. The small mountain breed is a good draught animal for rough and stony localities ; it does not yield much milk; its flesh is excellent, though but little streaked with fat. The Schwytz breed has given origin to the Swiss-Sardinian breed, which is raised all over the island and gives excellent products, as for instance at Oristano, Macomer, Ozieri, Nulvi, Ploaghe, Mores, Bonorva, etc. The Schwytz breed has proved the best for the improvement of Sardinian cattle, though the excess of new blood, if not accompanied by improve-

ments in the pastures and in the treatment, sometimes causes stunted development and a decrease in the yield of meat and milk. For this reason the writer deprecates the use of a pure-bred bull beyond the third or fourth generation, after which cross-bred bulls should be used unless special reasons suggest recourse to a pure bull again.

Sheep. — Grazing is the most important industry in Sardinia. There are two breeds in the island, one in the plains and the other in the mountains. On the plateau of Bitti and in the districts of Fonni, Orgosolo, etc., there is a small hardy breed with roughish and short wool, which does not yield much milk ; it passes the winter in the plains or on the hills. In the hills and in the richest pastures the sheep are a cross derived from the mountain breed and the Campidano breed, which is only an importation from Algeria, Tunis and the plains of Apulia. It is bred pure in the fine plains of the Campidano of Oristano. The introduction of a certain amount of the blood of this breed into the mountain breed produces sheep of a suitable stature, yielding good wool and flesh and a fair quantity of milk (an average of 1 ½ to 2 pints per day in spring and in favourable winters). Further crossing gives a much larger sheep which yields more meat but at the expense of the yield in milk and wool. It would therefore be advantageous to practice alternate crossing, that is using Campidano or Apulian rams for two or three generations and then cross-bred rams.

Pigs. — Pig breeding is also flourishing in Sardinia ; it is chiefly a small industry of the poor, but there are also extensive herds on the mountainous and wooded parts of the island. The principal pig-breeding centres are Bono, Bolotana, Silanus, Monti, Buddusò and the Gallura region, which is also mountainous and rich in woods. Pig breeding is practised more or less all over the island. In the chief centres the local breed has been crossed with the Caserta, the Verona and Yorkshire crossbreds. Such pigs are frequently met with in the cuntry about Ozieri, Mores, Pattada, Nulvi and Ploaghe. The Sardinian breed still bears a considerable resemblance in build to the wild boar ; crossing it with other breeds has much improved its flesh, increased its weight and caused measles to disappear from many herds. The crosses at the age of two years weigh 440 to 550 lbs. dead weight ; the pork and hams are excellent. The pigs are fed on buttermilk, whey and bran up to the age of five or six months, after which they are tied up in sties to be fattened. Sometimes the want of exercise and cleanliness causes a form of rheumatic arthritis, on the appearance of which the animals have to be slaughtered immediately.

928 — **Report of the Dickinson County Cow-Testing Association : Results of the First Year** — REED, O. E., in *Kansas State Agricultural College Experiment Station, Circular* No. 35, 8 pp. Topeka, Kansas, 1914. CATTLE

The records of the Association contain a complete account of the performances of 134 cows during a period of 12 months. The average annual production of these cows was 6019 lbs. of milk and 246 lbs. of butter-fat, while the average Kansas cow produces only 100 lbs. of butter-fat. The average cost of feed was $ 35.59 per cow per annum and the value of the butter-fat produced was $ 90.48, leaving a net profit per cow of $ 54.89,

assuming that the calf and manure produced are liberal compensation for the labour and risk.

The best cow (a Holstein) produced 546 lbs. of butter-fat in 11 months ; the poorest cow in the same herd produced only 175 lbs. of fat, whilst the poorest cow in the Association produced only 59 lbs. at a cost of $ 33.23. The ten best cows made an average rofit of $ 96.43, which is more than six times the average profit made by the ten poorest. With one exception, the ten best cows were dairy-bred animals, while there was only one of the ten poorest that showed any trace of dairy blood in its pedigree. The ten poorest cows made an average of only 119 lbs. of butter-fat for the year, at a profit of $ 15.23. The profitableness of these poor cows appears still less when one considers that most of them calved in the spring and produced milk only while on grass, thus greatly cheapening their rations. Further, the value of the calves and manure from this batch of cows would not fully compensate for the labour expended, while in the case of the ten best cows it would be an additional source of profit.

Some of the cows with low records of milk production were handicapped by being allowed to remain dry several months of the year and are capable of much better performances under better conditions. It is generally true that many good milch cows are allowed to go dry longer than is necessary and it should be borne in mind that a cow returns the greatest profit when kept in milk throughout the greater part of the year.

SHEEP

929 – **The Breeding of Karakul Sheep in the United States** (1). — YOUNG, C. C., in *The Journal of Heredity*, Vol. V, No. 4, pp. 170-178 + 3 figs. Washington, April 1914.

The first importation of Karakul sheep into the United States was made in 1909, when the writer brought 10 ewes and 5 rams from Bokhara to Wichita Falls, Texas. In 1913 a second batch of 17 was received from Central Asia. Of the first importation only two gave birth to lamb which had thick curly fleeces. The writer found that among the imported sheep and rams, some had thick coarse fibres in their fleeces whilst others had a layer of short fine, reddish wool under the fleece, which was without gloss and resembled Merino wool under the microscope. The animals imported from Bokhara gave lambs with thick curly fleeces, whilst the lambs belonging to the second importation had open fleeces worth little more than fur. The writer is of opinion that the fineness of the wool of the latter group of sheep is due to admixture with some Afghan breed possessing fine wool, and he proposes to call them the Afghan Karakul breed. It is easy to eliminate the fine wool characters in one or two generations by using a ram entirely free from fine wool.

Crosses between Karakul rams and Merino and Shropshire ewes do not produce good fleeces, but good results were obtained with Lincoln Longwool crosses and with red fat-tailed Persian sheep (*Ovis steatopygia*). which are free from short wool. The Persian sheep only produces curly-wooled lambs when crossed with the Astrakhan breeds and its wool is wrongly classed as fur in commerce.

(1) See also No. 282 *B.* March 1913 ; No. 653 *B.* July 1914. (*Ed.*).

There are six classes of sheep in Central Asia called Karakul by the Russians, and Arabi by the inhabitants of Bokhara, and they all derive the black pigmentation, the tendency to close curly wool and their glossy fleeces, from the small black Danadar sheep, now almost extinct.

These are: 1) the Large Arabi or Duzbai sheep; 2) Small Arabi; 3) Medium Arabi, a hybrid between 1 and 2; 4) Grey Shiraz; 5) Zigois (these five classes are not very numerous); 6) Afghan Karakuls, which unfortunately constitute 90 per cent. of the fur classes of Bokhara, since, though they are hardy and produce excellent flesh like the other races, they only yield a fur of inferior quality unless crossed with rams of the other breeds. The small Arabi is the best breed and the Duzbai is quite satisfactory and makes a good cross with our common sheep, increasing the weight and improving the quality of the flesh. The writer is of opinion that the Afghan sheep is the ancestral form of the Merino.

Sheep imported from Bokhara, besides being seldom free from fine wool, are too often inbred, since they come from small districts in the neighbourhood of railway stations (Tjardjui, Kara-Kul, Bokhara). The Karakul sheep imported into Russia, Germany and Austria are of very small value.

GOATS

930 – **The Age of Goats according to their Teeth.** — SCHEUNPFLUG, in *Berliner Tierärztliche Wochenschrift*, Year 30, No. 28, pp. 503-504. Berlin, July 9, 1914.

Most of the data at present available on the age of goats according to their teeth present considerable discrepancy and do not correspond to actual facts, for, as the present investigation proves, the appearance and the replacing of the teeth takes place generally earlier than the above data state.

According to the observations of Dr. Scheunpflug the central incisors are replaced at 14 to 16 months; goats which have their central permanent incisors up are, as a rule, upwards of one year old and seldom upwards of 23 months.

The 2nd pair of incisors change in general at 19 to 22 months. Goats that have their 2nd pair of permanent incisors up are above 17 months old and but rarely over 34 months.

The 3rd pair are replaced mostly at 21 to 26 months and generally between 23 and 24 months. After the 3rd pair of permanent incisors are up the animals are, as a rule, above 19 and under 36 months old. Exceptionally however they may be older.

The corner incisors are generally replaced at between 29 and 38 months, most frequently between 32 and 36 months and in some cases even later than 38 months. Goats with the corner permanent incisors up are mostly upwards of 28 months old. (In judging the age by the jaws of dead animals the appearance of the third molars has also to be taken into consideration, as well as when only the first three pairs of permanent incisors are up).

In most cases the permanent teeth are all up at 2 $^3/_4$ to 3 years.

In practice, in judging the age of goats by their incisors it may be assumed that in general the central pair are replaced at the age of 1 $^1/_4$

years, the 2nd pair at 1 $^{3}/_{4}$, the 3rd pair at 2 and the corner pair between 2 $^{3}/_{4}$ and 3 years. Thus the intervals between the replacement of each pair of incisors are about 6 months, about 3 months, and 9 months (more precisely from 6 to 12 months) respectively.

It sometimes happens that the two permanent incisors of a pair do not appear at the same time; if only one is up, the age, should be reckoned a month less than if both are up.

The lack of permanent incisors, especially of the central pair, is in most cases due to oligodonty, which in some localities has been frequently observed.

In determining the age by the jaws of dead animals valuable data are furnished by the molars also, all the more so as the periods of their appearance and replacement in goats have a more restricted range than is the case with the incisors.

According to Dr. Scheunpflug the appearance of the molars in the lower jaw generally precedes that in the upper jaw. At the age of 3 months the first molar appears in the lower jaw and at 4 months the corresponding tooth in the upper jaw.

At the age of 5 ½ months the first upper and lower molars are in wear. In some cases the second molars pierce through the gums in the lower jaw shortly before the eighth month, as a rule however, between 8 and 9 months, seldom later. In the upper jaw they appear between 8 and 10 months.

At 12 months the second molars are in wear. The change of the premolars takes place at from 17 to 20 months and at the same time in the upper and lower jaws. Sometimes one temporary molar is cut first, sometimes the other, as the replacing depends only upon accessory circumstances.

After the replacing of the above temporary molars, in general after these are in wear, the third molars are cut. They appear between 18 and 21 months, apparently a little later in the upper jaw than in the lower one.

All the third molars are up at between 18 and 24 months, and in wear not before 26 months. At the cutting of the third molars, it must be noted, in general the 2nd and sometimes the 3rd pair of incisors are replaced.

Oligodonty of the molars was observed by the writer only in the 3rd pair.

The data found in the literature on the replacing of the teeth in sheep are compared with the writer's observations on goats. It appears that the termination of the period during which the incisors are replaced is nearly the same in goats as in early-maturing sheep (especially according to the data of Cornevin and Lesbre). There is nevertheless a small difference in that the period between the replacing of the first and second pairs of incisors in sheep is about two months shorter than in goats. On the other hand the interval between the 2nd and 3rd pairs is shorter in goats.

The temporary molars are certainly replaced earlier in goats than in sheep, as, according to the writer, the premolars are replaced in goats

shortly before the cutting of the third molar, while in sheep this happens only after the cutting of the latter or at the same time.

931 – **The Rearing of Reindeer in Alaska** (1). — CHUBBUCK, LEVI (Office of Farm Management, Bureau of Plant Industry, U. S. Department of Agriculture), in *The Journal of Heredity*, Vol. V, No. 4, pp. 149-154 + 3 figs. Washington, April 1914. REINDEER

The introduction of the European reindeer into Alaska was recommended by Prof. S. F. Baird in 1851, notwithstanding the fact that the indigenous American caribou is capable of domestication. This suggestion was also made by Townsend in 1867, and in 1892 Dr. Sheldon Jackson, agent-general of the Bureau of Education in Alaska, introduced a small herd of domesticated European reindeer, which was followed by others. As a result of breeding, their number now reaches 40 000 and has transformed the native people from hunters and fishermen to herdsmen.

The reindeer indigenous to North America are: *Rangifer arcticus* (Barren-ground Caribou), inhabiting the extreme north, and *R. caribou* (Woodland Caribou) in the wooded region south of the former. This latter species differs slightly from that of the old world (*R. tarandus*). Apparently no attempt has been made to domesticate it, though it is fertile when crossed with the domestic reindeer; this character is valuable, since the native species are larger and stronger than the imported species which appears to show signs of degeneration. The present area of undeveloped land in Alaska that would be suitable for rearing reindeer is estimated at 100 000 square miles, capable of supporting 10 million deer. The most suitable region is north of the Yukon river. The reindeer lichen (*Cladonia rangiferina*) occurs throughout the arctic region of Alaska, in the Seward peninsula, in the tundras of the west and in the mountains of the Alaska chain and of the Alaska peninsula.

Reindeer do not require shelter; in fact they require no care beyond watching. Almost half of the present herds are in the Seward peninsula and the remainder are distributed as far as Point Barrow on the Arctic Ocean in the Alaska peninsula and to Tanana towards the Yukon river. They belong to Eskimos, Indians and a few Laplanders; the latter were brought over with the animals by missionaries to teach the care of the reindeer. Some herds belong to the Government. The Alaska Division of the U. S. Bureau of Education, Department of the Interior, looks after all the herds, through the masters of the Government native schools.

In 1911 a hundred carcasses were sent from Norne to Seattle and sold for 75 cts. per lb. Up to the present the Alaska markets have consumed all the reindeer flesh which is produced. A dressed carcass averages about 130 lbs. in weight; the butcher buys the dressed carcasses at about 25 cents per lb. The most suitable age for slaughtering the animals is 7 or 8 years, *i. e.* after they have been worked for 5 or 6 years. The cows are rarely milked in Alaska; any milk obtained is consumed fresh after dilution with water or as cheese; butter is never made, since the fat has a rancid flavour. There is a heavy loss amongst the young animals ow-

(1) See also No. 1186, *B.* Oct. 1913 (Reindeer in Newfoundland). (*Ed*).

ing to the unscientific method of rearing introduced by the Laplanders and the tundra fires, so that the rate of increase of the reindeer is only half that of herds of cattle.

POULTRY

932 – **Winter Egg Records in Ireland.** — *Department of Agriculture and Technical Instruction for Ireland, Journal*, Vol. XIV, No. 3, pp. 546-547. Dublin, April 1914.

The data presented are from records kept in Ireland under the control of the Department.

TABLE I. — *Average number of eggs per hen during the six months October to March.*

Breed.	1908-09	1909-10	1910-11	1911-12	1912-13	1913-14
White Leghorn	44.3	39 7	41 5	45.1	42.4	47.4
Brown Leghorn	40.7	42.1	37.9	49.3	51.8	38.1
Black Leghorn	—	—	—	—	64.3	—
Minorca	32.8	38.0	48.3	48.3	86.3	60.5
Buff Orpington	54.5	42.4	45 2	42.6	49.1	58.6
White Orpington	50.7	48 7	54 1	52.6	44.1	38.6
White Wyandotte	56.6	34.2	45.2	45.8	42.9	33.9
Faverolle	42.5	41.5	35.7	28.8	42.2	34.9
Plymouth Rock	35.9	39.2	45 5	36.5	43.1	38.8
Ancona	—	—	—	64.9	—	—
Houdan	59.2	58.5	62.5	58.0	75.8	46.4
Andalusian	—	71.3	—	—	—	—
Rhode-Island Red	—	—	63.9	61.9	49.1	48.4
Light Sussex	31.6	32.1	39.8	41.8	38.4	49.7
Red Sussex					—	32.5
Mixed pure breeds	39.7	—	—	—	—	—
Mixed breeds	40 8	41.9	40 5	41.6	43 7	42.4
Average	42 3	40.7	42.7	41.8	44.2	42.2

TABLE II. — *Variations in different strains of the same breed.*

Breeds	Average of all flocks	Average of the best flock	Average of the worst flock
White Leghorn	47.4	75.0	31.5
White Wyandotte	33.9	53.3	22.0
Faverolle	34.9	57.8	21.2
Plymouth Rock	38.8	60.8	20.9
Rhode-Island Red	48.4	59.1	28 7
Light Sussex	49.7	72.4	38.3
Mixed breds	42.4	78.6	16.9

Omitting the breeds of which the returns relate to less than 100 birds, the following is the order : Light Sussex, Rhode Island Red, White Leghorn, Plymouth Rock, Faverolle, White Wyandotte.

The egg-laying capacity of the different strains of the same breeds varies considerably, as shown in Table II.

933 – **Attempts at Breeding the Great White Heron and the Buff-Backed Heron (Cattle Egret) in Madagascar.** — GUILHELM, in *Colonie de Madagascar et Dépendances, Bulletin Économique,* Year 13, No. 4, pp. 472-476. Antananarivo, 1913.

With a view to protecting the great white heron and the buff-backed heron in Madagascar, an Order was issued on May 3, 1913, forbidding their being shot in the island. These two species are valuable for their plumage and the second is a very useful bird, as it feeds almost exclusively upon cattle ticks, which often spread contagious diseases. The writer, having observed that the Malagasy kept birds caught young in a state of perfect domesticity, thought of the possibility of breeding them economically. He tried keeping them in cages and fed them with raw meat and fish. His attempts have been successful, and the cutting of the feathers has been found more advantageous than plucking them.. M. Guilhelm thinks that breeding these birds would be especially suitable in the northern and north-eastern provinces of Madagascar.

934 – **New Research on the Visual Power of Bees.** — VON HESS, in *Die Naturwissenschaften,* Year 2, Part 34-35, pp. 836-838. Berlin, August 28, 1914. BEES

The writer reports upon a series of experiments, all of which agree in proving that it is quite out of the question to think that bees have a sense of colour in any way comparable with that possessed by man.

935 - **Apiculture in Ireland.** — *Daily Consular and Trade Reports,* Year 17, No. 167, p. 342. Washington, July 18, 1914.

The importance of apiculture in Ireland may be judged from the following statistics of production :

	Average 1901-1910	1911
	lbs.	lbs.
In hives with removable combs:		
Run honey	69 291	91 450
Section honey	262 253	422 862
Total	331 544	514 312
In other hives:		
Run honey	89 123	69 254
Section honey	29 004	27 737
Total	118 127	96 991
Grand total	449 671	611 303

Of the 611 303 lbs. produced in 1911, the two eastern Provinces of Ireland supplied the bulk, Ulster giving 204 784 lbs., while Leinster furnished 181 354 lbs.; the westen Provinces (Munster and Connaught) supplied 132 387 and 92 778 lbs. respectively.

The abundance of vegetation and flowering plants has always had a tendency to encourage the production of honey in Ireland.

The usual price paid to producers for comb honey is 9*d*. per lb., while the retail price is 1*d* to 2*d* higher.

Under the Bee Pest Prevention Act (Ireland, 1908) any swarms infected with disease of whatever description may be ordered to be destroyed by local committees of agriculture, with the approval of their respective county councils. Compensation is rendered for all such enforced destruction, and in 1913 the aggregate sum set aside for this purpose was approximately. £ 257.

936 — **Collection and Exportation of the Wax of Wild Bees in the African Colonies.** — MICHEL, E. (Agricultural Engineer at the Ministry of the Colonies) in *Bulletin agricole du Congo Belge*, Vol. V, No. 2, pp. 385-395 + 6 figs. Brussels, June 1914.

This paper contains information on the wild bees' honey in the African colonies, a description of the native methods of bee-keeping in the Belgian Congo, in the Sudan and in Tunis, and of the improved methods of separating wax (melting by solar heat, in a stove, in boiling water).

The trade in wild beeswax is constantly increasing in most of the African colonies, especially in Gambia, Gold Coast, Nigeria, Angola, Sudan, Uganda, British East Africa, German East Africa, Mozambique. A few years ago the exportation of wax from these countries was almost insignificant, while now it amounts to thousands of tons. Wax occupies the third place in the export trade of Angola (Benguela supplying 90 per cent. of the exports of the whole province). Angola exports every year 600 or 700 tons of wax; Mozambique about 100; Portuguese Guinea 50. The wax is exported in cakes weighing 253 to 264 lbs. each. The quantities of wax exported during the last few years from German East Africa and from the British African colonies are given by the following table

Colonies	Year	Exports of wax	
		weight lbs.	value £
German East Africa	1911	802 347	40 488
Gambia	1912	29 498	1 154
Nigeria	1913	12 862	385
Uganda	1912–1913	263 408	—
British East Africa	1912–1913	139 207	7 522
Nyasaland	1912–1913	110 609	5 478
Sudan	1912	43 704	2 379

Wild beeswax when well purified is comparable to European wax. The Central Administration of the Belgian Congo had some samples of wax from the colony examined, and among them many of good quality were found. Bees are widely spread in the Belgian Congo ; the natives extract honey but do not make any use of the wax, the value of which is unknown to them.

FARM ENGINEERING.

937 **Stump Burning to Reclaim "Logged-off Lands".** — ALLISON, LE ROY W., in *Engineering Record*, Vol. 70, No. 4, pp. 95-96. New York, July 23, 1914.

AGRICULTURAL MACHINERY AND IMPLEMENTS

In the Pacific North-West of the United States there are extensive areas called "logged-off" lands upon which forest trees have been felled and which are now covered with stumps varying from 3 to 6 ft. in diameter, intermingled with a successive growth of trees and underwood.

With proper clearing these logged-off lands are very valuable for agricultural purposes. Many methods have been employed for freeing the lands from stumps, such as grubbing, burning, blasting and pulling.

The cost per acre of clearing lends varies considerably with the character of the subsoil, condition of land, etc., but as an average the following may be taken :

Method	Average cost per acre
Powder and horse puller	$ 110
Donkey engine	90
Powder and grubbing	80
Powder and burning	70

A complete land-clearing plant has recently been devised, overcoming some of the disadvantages of the various methods noted and combining most of their advantages It is known as the Blake land-clearing machine and consists of a five-fire Pluto stump burner, a saw, a power grubber and two stump pullers, the whole being operated by a gasoline engine.

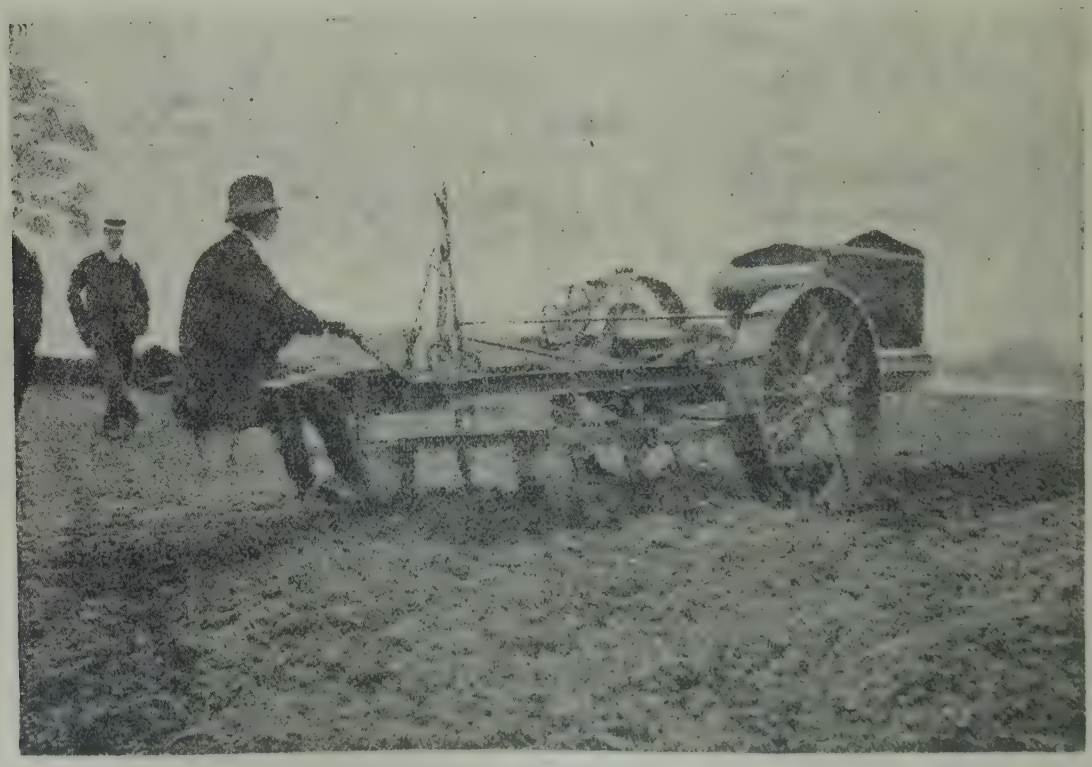
The stump burner is operated by a blower on the machine ; a line of pipe connects the blower to a sheet-iron hood, which is made in four sections and is set over the stump to be destroyed. The use of the burner is simple : a hole is bored down through the centre of the stump and a small explosive cartridge is employed to split it apart. This splitting, while not essential, facilitates the fire started at the top of the stump to gain rapid headway. The hood is then placed over the stump and banked upwith a little earth at the bottom and forms a closed but not air-tight chamber. The fire is started and the pipe connection from the blower is made, after which a constant downblast is turned on the flame. Stumps are consumed in this manner in from 2 to 4 hours or more, according to size. Upon removal of the hood the fire is covered with earth, allowing the roots to charpit to the ends.

Official tests of the burner have been made. During one of them an old water-soaked stump 20 feet in circumference at the base, 13 ft. at the top and 4 ft. high was consumed in 6 hours; the total cost was $ 1.15, divided into 75 cents for gasoline and 40 for explosives.

The method of operating the whole outfit is to set it in a corner of the land to be cleared: five stumps on the immediate vicinity are split, fired and placed under the blower blasts. Meanwhile second-growth trees are pulled out and sawed into cordwood, the roots and snags burned and the undergrowth and small roots are removed with the power grubber. Subsequently the machine is removed to another position and these operations are repeated. By this method a strip of 50 to 100 ft. wide is left ready for plowing and seeding while the outfit is engaged clearing other sections, the whole work being done rapidly at a reduced cost and without waste of the valuable vegetable mold.

938 – **The Garrett-Crawley Agrimotor.** – *The Implement and Machinery Review*, Vol. 40, No. 471, p. 375. London, July 1, 1914.

At the Suffolk Agricultural Association's show, held at Bury St. Edmunds on June 4 and 5, a new tilling machine, the Garrett-Crawley Agrimotor, was shown at work. As can be seen from the accompanying figure



Garrett-Crawley Agrimotor.

it is self-contained and controlled by one man from a seat in the rear. The petrol-driven engine which is situated in front nicely balances the plough shares at the back, so that at the end of the furrow the operator may leave his seat and turn the machine round in its own length on either of the travelling wheels with the utmost ease.

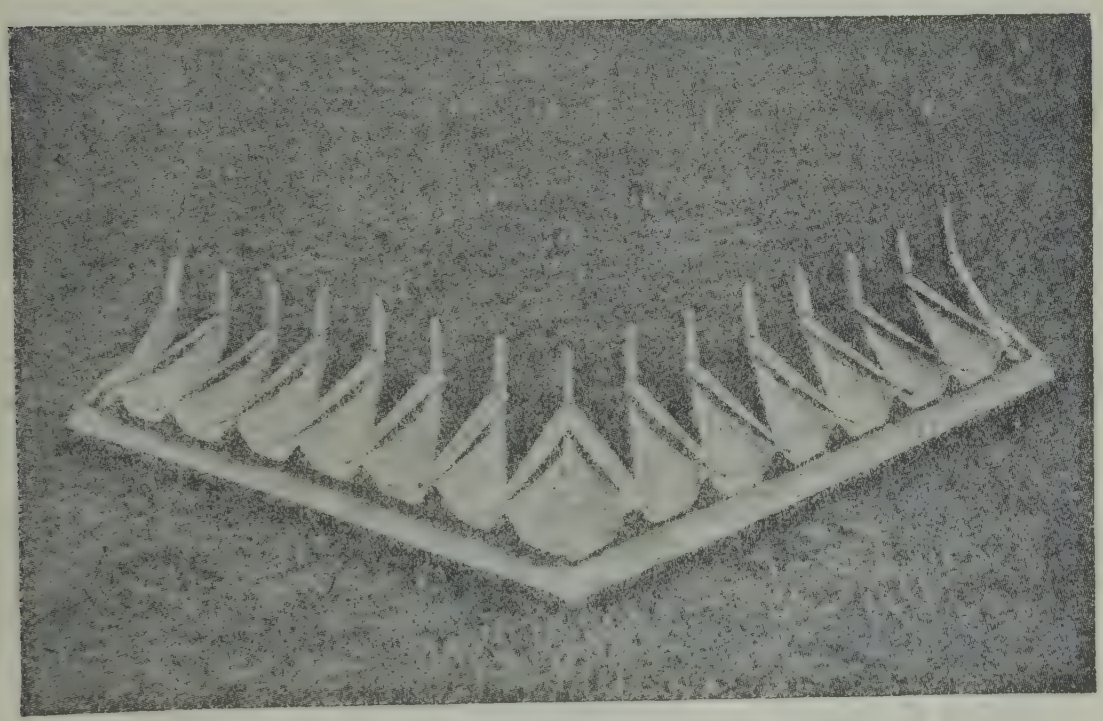
The levers for regulating all the movements of the apparatus are within reach of the operator, one being provided for lifting and lowering the plough and others for declutching either of the wheels, for going forward, stopping or backing, besides a handle for steering. The engine is of 25 H P ; it runs at 1 000 revolutions per minute and can turn over 1 ½ acres per hour to a depth of 5 inches.

When ploughing, one of the road-wheels is raised by means of a hand wheel and worm as high as the depth of ploughing required, while for travelling along a road the plough can be raised by the adjustment of a castor wheel below the driver's seat.

Although primarily a plough, any other farm implement may be attached to and worked by the agrimotor.

939 – **The "Welsh" Bracken Cutter.** — *The Implement and Machinery Review*, Vol. 40. No. 471, p. 390. London, July 1, 1914.

One of the newest implements for the control of bracken is Welsh's bracken cutter. As will be seen from the accompanying figure it consists of a V-shaped frame carrying 15 runners turned up in front, shod with



The « Welsh » Bracken Cutter.

steel and fixed together at the rear by a specially tempered steel plate. The curve given to the front of each runner, together with its individual flexibility, makes easy the "jumping" of any obstruction; the cutting blades and guide plates are so fixed that every bracken stalk which finds its way between the runners is sliced down. The frame, too, is flexible

to enable the machine to keep in close contact with the ground. The implement weighs 1 cwt., is 6 ft. wide and is easily drawn by a horse or pony.

Three or four cuttings may be required the first season and two or three in each of the next three years.

940 – **The Articulated Yoke.** — MANRIN, G., in *Journal d'Agriculture Pratique*, Year 78, Vol. 1, No. 23, pp. 719-722. Paris, June 4, 1914.

M. A. Guérineau's yoke, exhibited at the last Paris Agricultural Show, presents the advantage of maintaining the usual way of fixing the double yoke to the poles of vehicles or to draught chains and at the same time allowing a great freedom of movement to the head of each animal.

The yoke consists of two head-pieces, *A*, *B* (see figs. 1 and 2), of the single-yoke type jointed to the cross-piece *C* which carries the draught gear *T* for the pole or chain.

The head-piece is placed on the neck of the bullock and is attached to the horns with the usual thongs.

In the middle and on the top of each head-piece is fixed a plate, *a* (see section, fig. 3), the top of which bears a pin, *b*, on a turning joint allowing the pin sufficient play to describe an inverted cone; the upper part of *b* is a screw carrying the nut *e*, which causes the counter-plate *c* to press moderately against the plate *a*, allowing a certain amount of play. The plate *c* is strongly fixed by the bolts *d* to the cross-piece *C*. When the nut *e* is in a suitable position, it is fixed there by a hinged piece, *k*, fitting on the square extremity of the pin *b*.

It will be seen in figs. 1 and 2 that the upper surface of the plate *a* is flat, while the under face of plate *c* is a segment of a sphere, thus allowing the pin *b* to move on its turning joint. Fig. 2 shows that plate *a* bears two projections, *n*, *n*, and that the corresponding gaps, *m*, *m*, in plate *c* of the cross-piece *C* are somewhat larger than the projections, so as to allow them play-room and to permit the cross-piece *C* to assume an oblique position in the horizontal plane. The result is that the heads of the oxen enjoy a relative freedom of motion both in the vertical and horizontal directions and independently of each other.

The draught gear, *T*, can be shifted along the cross piece, *C*, so that when animals of different strength are harnessed together the weaker one can be given some relief by the longer lever-arm.

This yoke costs about 31s. It weighs only about 33 lbs., or about 11 lbs. more than the usual yoke.

1 101 543. Windmill.
1 101 856. Seed corn tester.

BUILDING CONSTRUCTION

942 – **Pig Stye with Device for Protecting Sucking Pigs and Keeping them Warm.** — *Deutsche Landwirtschaftliche Presse*, Year XLI, No. 25, p. 315. Berlin, March 28, 1914.

Pig breeders often suffer losses through the sucking pigs being crushed under their mothers. As a means of preventing such accidents a special compartment is sometimes set apart for the sucking pigs; recently Herr Lüdemann has taken out a patent (No. 271 340) in Germany for warming this compartment and thus inducing the young pigs to stay there permanently.

The accompanying figs., 1 and 2, show the new stye in plan and section. It is about 6 ft. 6 in. × 10 ft. and provided as usual with a feeding-trough at one end. At the other end a pit about 10 inches deep and 20 wide runs all along the side of the stye; it is covered by a double sheet-iron cover, with an air-space between the two sheets, laid flush with the floor. This box cover can be heated either by a few petroleum lamps placed under it or by steam or electricity; b^1 and b^2 (fig. 2) are openings for the admission of air and for the escape of the products of combustion. At about 14 inches above the warm surface a plank, *f*, is fixed horizontally to the wall. Besides this a rail of wood about 6 in. square is laid on the floor and fixed at 20 to 28 inches from the pit and parallel to it.

The sucking pigs, as experience has proved, seek the warmest place in the stye, that is the sheet-iron cover (on which soft straw is laid), while

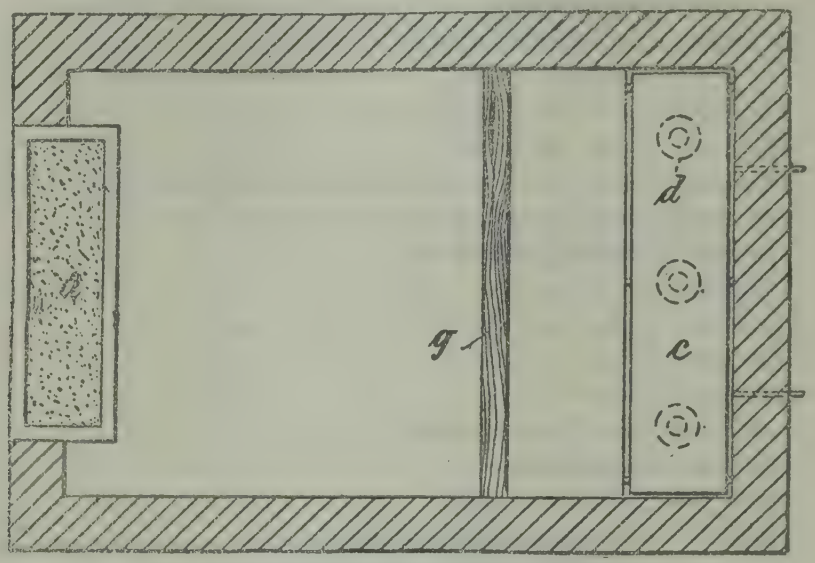

Fig. 1. — Stye for brood sow. — Plan.

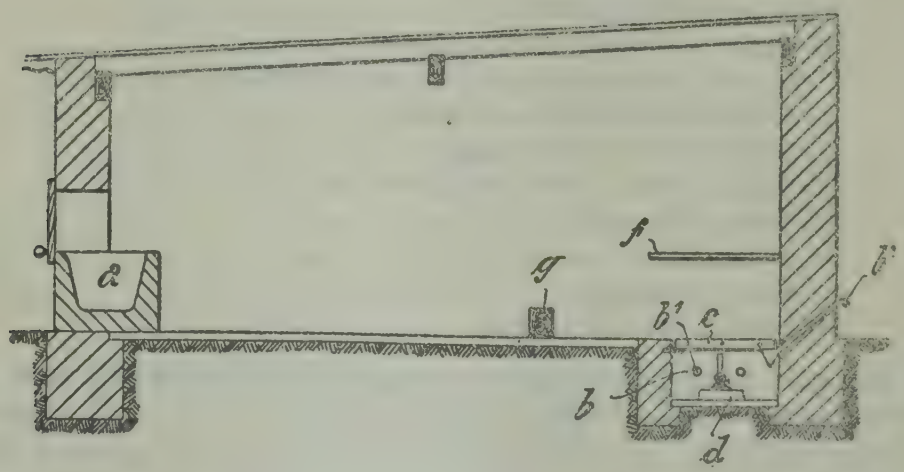

Fig. 2. — Stye for brood sow. — Longitudinal section.

the mother is kept off it by the plank, and lies down with her back against the rail g to suckle her offspring, which are thus absolutely safe from the danger of being crushed.

RURAL ECONOMICS.

943 – **Book-keeping Statistics on the Profitableness of Bee-keeping in Switzerland in 1912-13** (1). — Report of the Swiss Peasants' Secretariat, in *Schweizerische Bienen-Zeitung*, No. 8. Aarau, August 1914.

This Report contains the results obtained by 28 bee-keepers entered on the books of the control section of the Association of Swiss Bee-keepers

(1) For the results of the 1912 enquiry included in the preceding Report of the Swiss Peasants' Secretariat, see No. 170, *B.* Feb. 1914. (*Ed.*).

for the year 1912, and by 25 entered for 1913. These have kept regular accounts of their apiaries according to the uniform method adopted by the above section, and have placed them at the disposal of the Association, which in its turn handed them over to the Swiss Peasants' Secretariat to check and work up statistically.

In order to illustrate the method that has been followed The Table on pp. 1356-1357 gives the principal figures of these statistics.

The economic results of these 25 bee-farms cannot be generalized; nevertheless they confirm the well-known fact that both 1912 and 1913 were bad bee years in Switzerland. From the experience gained by the Swiss Peasants' Secretariat in the matter of statistics of farm book-keeping, it appears that the accounts of 100 bee farms would be sufficient to draw conclusions for the whole country.

Carefully made statistics of the accounts of bee-keepers in Switzerland are useful not only to each bee-keeper who keeps regular accounts, but also to the collectivity of bee-keepers. Consequently the Association of Swiss Bee-keepers solicits the co-operation of a greater number of contributors to this statistical enquiry, with the object of being enabled to draw general conclusions; for this purpose it supplies at a moderate price the forms for bee-keeping accounts

AGRICULTURAL INDUSTRIES.

INDUSTRIES DEPENDING ON PLANT PRODUCTS

944 – **Wine Making without Refrigeration in Warm Countries.** — GAUVRY, E., in *Bulletin de la Direction Generale de l'Agriculture*, Year 18, No. 78, pp. 389-409. Tunis, June 1914.

Refrigeration is generally considered as the final solution of the difficulties of making wine properly in warm countries. Even if not properly applied it produces finer wines, richer in bouquet. But refrigeration, either curative or preventive, requires expensive and extensive plant when, the amount of vintage to be converted into wine daily becomes considerable, and though, notwithstanding its high cost, it is still the best means of ensuring a perfect vinification even during the most violent sirocco, it is frequently difficult or impossible to use on account of the insufficient quantity and sometimes total lack of water at vintage time.

It thus became necessary to discover palliatives in order to obtain sound products with good keeping qualities in spite of the unfavourable conditions obtaining during the time of wine making. In Algeria this has been attained by the systematic use of sulphurous anhydride in heavy doses, either at the moment the vintage is placed in the vats or during the course of fermentation. But in Tunis the conditions of fermentation are still more unfavourable than in Algeria, so that the writer considers it necessary to know exactly how sulphurous anhydride behaves towards the component parts of must and what are its chemical and biological effects, in order to get the maximum benefit from its judicious use.

The ferment of wine presents, according to climate and locality, varieties or strains which impart to the product obtained a special bouquet, but this differentiation is caused also by a natural selection produced by adaptation to environment, to the conditions of wine-making and to the must, the composition of which is not invariable and the elements of which are modified by outside factors.

In warm countries, where the grapes attain full maturity, they are covered by very vigorous and active ferments: these are already adapted to the manner of fermentation of the country and it is they that have to be selected in order to obtain the best results when only wines of current consumption are considered. Commercial selected ferments yield in Tunis too uncertain results to allow of their employment except as a means of increasing the regularity of fermentation. Sulphurous anhydride, even in moderate doses, ensures a sufficient purification. But the ferment of mannitic fermentation and that which causes the turning of wine resist, and they are all the more dangerous inasmuch as their development is favoured by high temperatures. Their evolution may be stopped by increasing the acidity of the medium. Without this circumstance their presence would be permanent in Tunisian wines, the musts of which are always too rich in sugars, with a relatively too low acid content. One must not hesitate to acidify by means of tartaric and citric acid; but while citric acid presents remarkable advantages its use is much restricted by present legislation. With the assistance of acidification the treatment of musts with sulphurous anhydride ensures from the very beginning a practically sufficient bacterial purification to allow fermentation to set in and to develop in the best conditions.

This is the moment in which, in warm countries, the enlightened practical wine maker must interfere to dominate the evolution of the ferments and moderate their activity, as under such conditions they always have a tendency to act too rapidly. The rise in temperature which is so injurious to them is due chiefly to this excess of activity. Ferments, though aerobic, continue to proliferate even when they are deprived of oxygen; further, their activity continues by the emission of a special diastase, zymase, which has the property of instantly transforming grape sugar into alcohol and carbon dioxide, and which does not appear except under anaerobic conditions. The use of large amounts of sulphurous acid is based on these facts, as it obliges the ferment to live from the beginning an anaerobic life in a de-oxygenized medium. On the other hand it is natural that in order to start fermentation in musts treated with sulphurous acid, a ferment in full activity, whose cells have lived in contact with air so as to ensure the maximum of diastatic activity, is necessary. For this purpose an abundant ferment is prepared and the must is leavened with it. This is but a slight complication in the usual methods of wine-making.

The especially prepared ferment seems to be very advantageous, as it is particularly suitable for multiplying and working in a sulphurized liquid; it is used in priming, being placed in the bottom of a vat before filling. The thorough mixing is then performed by a pump. In order to

have a regular action of the ferment in the whole mass, the grapes are freed from the strigs in the case of red wine. This gives finer wines and allows an economy in the capacity of vats, casks, presses, etc., as well as in the labour required for the various manipulations.

In order thus to keep fermentation under the best conditions the above considerations must be borne in mind. In Algeria the *modus operandi* followed by the majority of vine growers varies more or less in details, but is everywhere based on the suppression of refrigeration and on the systematic use of sulphurous acid. For some years past the use of sulphurous acid has been quite scientifically applied by the perfecting of BARBET'S system of wine-making. By this process an absolutely sterile must can be obtained and set to ferment with selected ferments.

Vinification may be retarded at will; in warm countries it may be deferred to the winter months, and this is not the least interesting aspect of the process for Tunis. The possibility of blending musts of different kinds also arises, allowing of the preparation of a single juice of uniform composition for the year.

With the object of obtaining a prolonged state of inactivity in the must, enormous doses of sulphur dioxide have to be employed, and in these conditions even a very active aeration cannot eliminate enough of it to allow fermentation to be set up. BARBET has also solved this difficulty by causing the must to fall through a column of plates in which it is traversed by an ascending column of air. But this method has not received the favour it deserves on account of the price of the apparatus. DEPATY'S desulphurizer, which is based on the principle of aeration by warm air, being cheaper is preferred. Good quality products are thus obtained, but their cost price is still high.

At present experiments are being carried out at the Tunis Laboratory, which promise a much simpler solution of the problem, namely of causing a partial desulphurization of the must, sufficient to allow a regular fermentation by means of ferments accustomed to sulphurous acid.

945 – **Refrigeration in Wine Making.** — LABARDE, J., and DELBAVIE, J., in *L'Industrie frigorifique*, Year 12, No. 135, pp. 179-191. Paris, June 1914.

In a report on the work carried out by the Oenological Commission for the South West of the "Association Française du Froid", the results of experiments made, according to a programme of research, on the effect of cold on wines are given.

The subjects to be studied were: 1) The treatment of wines by short and rapid refrigeration according to the process usually adopted by the "Compagnie générale aérohydraulique"; 2) Slow and prolonged refrigeration in cold chambers at different temperatures: about 0° C. and — 3° C. (32° F. and 26.6° F.). The following wines were experimented upon: *red wines*, Génissac, Château Nodoz, Anglade du Blayais, Bas Médoc; *white wines*, La Brède, Les Salles de Castillon.

The above Company's plant for rapid refrigeration consists essentially of two parts: 1) a refrigerating system; 2) some cooled vats. On leaving the refrigerator the wine is sent into vats of the capacity of 1100 gallons, in

which it usually remains a week ; it is then racked and sent to a filter where it is clarified at a temperature which is still fairly low.

In order to estimate the effect of these treatments, the wines were tasted and submitted to chemical analysis.

Considering only the concordant results of the second and third tasting, undertaken at a time when the wines had in all likelihood assumed their state of equilibrium, refrigeration applied according to the various methods to red Gironde wines proved favourable three times out of four. Among white wines, in the La Brède wine the improvement was more marked at the second tasting than at the first ; the Castillon wine was improved by the complete treatment by rapid refrigeration, while refrigeration alone did not yield the same results.

The analytical data obtained from the wines experimented upon are collected in tables and they show that rapid cooling determines in general a slight thinning of red wines. Rapid cooling and filtering acts particularly on the flavour of the wines, improving it. Prolonged refrigeration in cold chambers has in general a more prononced effect than the former treatment. On tasting wines subjected to it they are generally classed first of all.

The differences observed in tasting were always very slight, and were considered by the tasters, who classified the wines with the greatest care, as in general only shades.

The object aimed at by the Commission was to know if the use of artificial cold on wines could have the same effect as natural cooling. In some localities this cooling may extend over a fairly long period and with sufficient intensity, without however attaining the freezing of the wine, and according to current and very old observations the result is always favourable to the actual and future quality of the wine.

The experiments of the Bordeaux Commission, though limited to a small number of wines, prove that by artificial cooling the principal advantages attributed to natural cooling may be obtained.

The number of white and red wines studied is, no doubt, insufficient to allow of much generalization of results, and if the Commission limited itself to this number, it was because the programme of the experiments contemplated the study of multiple conditions of the application of artificial cold. It has been recognized for the moment that rapid refrigeration has not given very marked results ; on the other hand observations have been clearer as to the prolonged stay of the wine in cold chambers. In the future, investigations must be made with the object of obtaining the maximum effect of low temperature in the shortest time. There is thus a whole series of new experiments to be made and the Commission hopes to be able to continue its researches.

946 — **A New Method of Making Wine and of Utilizing the Pomace.** — Monti, E. in *Giornale Vinicolo Italiano*, Year 40, No. 33, pp. 769-772. Casale Monferrato August 16, 1914.

In view of the fact that within certain limits wine is all the richer in alcohol and perfume the slower the process of fermentation has been, and

ecalling that some years ago he had prepared a partially fermented and ıtensely coloured must (" enocyanine krios ") to be added to light wines ith the object of increasing their alcohol content and colour, Sig. Monti bserves that by retarding the commencement of fermentation, time is iven to the must to dissolve the colouring matter, the acids, the albumi-oids and the other substances contained in the pulp adhering to the pips.

This observation, together with the consideration that the only means f obtaining a harmless sterilization is moderate heat, and that in must ıe disadvantageous separation of albuminoid and phosphatic matter oes not take place under 60° C. (140° F.), suggested to the writer a new ıethod of wine making which the director of the *Giornale vinicolo* (E. Ot-avi) considers a real and important discovery.

The writer proposes to exhaust the fresh pomace systematically by iluted must heated to 55-60° C. (131-140° F.), thus ensuring the complete eparation of the sugar, colouring matter, acids and other useful substances ontained in it. The result of the operation is a liquid possessing a density qual, or only slightly inferior, to that of the must obtained by the first ressure, and of an intense colour. On cooling, all the argol contained in ıe pomace separates completely and on concentrating the liquid by conti-ıous freezing, or *in vacuo* in an apparatus heated by warm water, a juice obtained containing from 60 to 75 per cent. of sugar. It is so intensely ɔloured as to require from 10 to 30 volumes of water, according to the uality of the grapes used, to bring it down to the intensity of colour of ɔmmon wine. This product, which the writer calls " Estratto integrale uva " (whole grape extract) keeps absolutely unchanged for years. It ıay thus be prepared in large quantities in years of plenty and used to ıprove the wines produced in years of bad or insufficient vintage.

This extract may be prepared from common black grapes or from ıe or white varieties, of which it retains the perfume; it is very useful for ıproving wines poor in tannin or solids. The addition of this extract to the ust increases the quantity of wine by 10 or 15 per cent., and to a slight xtent its alcoholicity, besides imparting to it a more delicate flavour and erfume. The preparation of this extract allows a fuller utilization of the ɔmace.

7 – **Determination of the Tartaric Acid in Wines by Physico-Chemical Volumetric Analysis.** — DUBOUX, MARCEL, in *Annales de Chimie Analytique*, Year 19, No. 3, pp. 89-97. Paris, March 15, 1914.

The processes for determining the total tartaric acid in wines under ıe form of potassium bitartrate present the following great drawback: ıe deposition of the crystalline precipitate requires from one to three ıys and the results are not independent of the method followed. The writer ıs thus endeavoured to effect this determination by the method of elec-ic conductivity or physico-chemical volumetric analysis, which allows ıe rapid and precise determination of the following elements of wine: h, potash, lime, magnesia, sulphates, chlorides, phosphates, ammonia, idity, alkalinity, etc. The physico-chemical method presents in all cases marked advantage over volumetric or gravimetric methods, and this has

induced several chemists to adopt it in connection with the usual analytical methods (1).

The study of the determination of tartaric acid in wine by means of conductivity shows that this method is of interest to the chemist who already analyses wines by physico-chemical volumetry. Knowing the acidity of a wine and its exact content in sulphates, he can by a simple titration which takes only 10 to 15 minutes, determine the total tartaric acid in the wine with a precision equal if not superior to that obtained by the usual methods. These results are always rigorously exact in the case of wines of low acidity. They are somewhat less exact when the wines contain an abnormally high quantity of malic acid. If the wine under examination had been treated with citric acid this would would be counted as tartaric acid. It would then be advisable to determine the tartaric acid by the bitartrate method and the citric acid by difference.

The writer describes the technique of the operations and the reagents employed for precipitation (nitrates of lead, silver, lanthanum and uranyl, barium chloride and acetate, caustic baryta). He gives two precipitation curves and the results of the determination of tartaric acid by physico-chemical volumetric analysis in a white wine and in a red one. He then compares in a table the results obtained: 1) by the German official method; 2) by the French official method; 3) by the conductivity method. These figures show that: 1) for wines containing not much acidity, the three methods yield results which agree well with each other; 2) with very acid wines the agreement is not so complete; 3) the official French process yields too low values when the wine contains large quantities of sulphates.

INDUSTRIES DEPENDING ON ANIMAL PRODUCTS

948 – **Ratio between the Specific Gravity of Cow's Milk and its Percentage Content of Fat and Dry Matter.** — FLEISCHMANN, W., in *Journal für Landwirtschaft*, Vol. 62, Part 2, pp. 159-172. Berlin, 1914.

The writer compares the best known formulae for calculating one of the three quantities (specific gravity, fat content and dry matter) from the other two and concludes that all the formulae, even the relatively most precise, are only approximative and can only by chance in some cases yield results which agree with those obtained by analysis.

Considering, however, the uncertainty of determining analytically the weight of the dry matter in milk, it is preferable to determine it by calculation rather than by direct determination, provided formulae which give the nearest possible approximation be used, and the greatest care be taken in determining fat content and specific gravity.

The formula recommended is the following:

$$t = \frac{4.8 \times f \times d}{4} + 0.25$$

in which t = dry matter
f = fat content
d = degrees of lacto-densimeter.

(1) See article by PAUL DUTOIT and MARCEL DUBOUX: "Analysis of Wines by Physico-chemical Volumetric Method." — *B.* Dec. 1912, pp. 2562-2569. (*Ed.*).

The results obtained by this formula agree very nearly with those yielded by Fleischmann's well-known formula.

949 **An Investigation into the Composition of Cheese made from Whole Milk.** — BROWNLEE, G., in *Department of Agriculture and Technical Instruction for Ireland, Journal*, Vol. XIV, No. 3, pp. 499-506. Dublin, April 1914.

Cheese, properly so-called, ought to be made from whole milk, and should contain as nearly as possible all the fat in the milk from which it was made. Hitherto it has not been easy to condemn cheeses made from skimmed or half-skimmed milk, as there is no standard defining what percentage of fat a whole-milk cheese should contain. To obtain comparable figures suitable for the fixing of a minimum fat content, it is necessary to eliminate the factor water, which varies considerably, even sometimes in cheeses of the same type.

In order to determine what would be a reasonable figure for this standard, the Department of Agriculture and Technical Instruction for Ireland arranged for analyses of Caerphilly and Cheddar cheeses, representing semi-hard and hard cheeses respectively, to be carried out from October 1911 to June 1913 by the Albert Agricultural College, Glasnevin, and the Royal College of Science, Dublin. In each case the test was made with : 1) a sample of the whole milk before manufacture ; 2) a sample of the " green " cheese, and 3) a sample of the " cured " cheese.

The results showed that the percentage of fat in the dry matter never fell below 47. In the case of Cheddar cheeses the maximum and minimum were respectively 53.54 and 48.72 in the green, and 52.96 and 48.60 in the cured. In the case of Caerphilly cheeses the corresponding figures were respectively 56.99 and 47.75 for the green and 57.15 and 47.11 for the cured cheese. The average percentage of fat in the dry matter of all the green cheeses is 51.49, and of the cured cheeses 51.19. The general average for all samples (327) is 51.33. Thus 45 per cent. can be fixed as the limit below which the percentage of fat in the dry matter of a genuine cheese should not fall.

Incidentally, the collected results also show that 1 gallon of milk will yield:

1.300 lb. of green Caerphilly cheese.
1.239 lb. of cured Caerphilly cheese.
1.056 lb. of green Cheddar cheese.
1.000 lb. of cured Cheddar cheese.

950 – **On the Characteristic Flavour of Roquefort Cheese.** — CURRIE, J. N. (Chemist, Dairy Division, Bureau of Animal Industry, U. S. Department of Agriculture) in *Journal of Agricultural Research*, Vol. II, No. 1, pp. 1-14. Washington, April 1914.

These researches were initiated to identify the substances which impart the characteristic Roquefort flavour and to account for their presence. After giving a résumé of the preceding work on this subject, the writer describes his experiments as follows :

1) The experimental method adopted was that employed by JENSEN.

2) *Volatile acids.* — The soluble acids present were essentially a mixture of the volatile fatty acids of milk, *viz.* acetic, butyric, capric, caprylic, caproic. The insoluble constituent contained chiefly capric acid. They may be pre-

sent as free acid or in a feeble state of combination without losing their characteristic flavours. A ripe Roquefort cheese gives a distillation number (*i. e.* the number of cc. of decinormal alkaline solution necessary to neutralise 100 cc. of the distillate) between 30 and 60, whilst a slow-ripening cheese of poor flavour gives a distillation index less than 30, and a quick-maturing cheese of highly developed flavour will have an index above 60, in some extreme cases even exceeding 100.

3) *Relation between volatile acids and flavour.* — The writer is of opinion that the cheese owes its piquant flavour to the accumulation of volatile acids (caproic, caprylic and capric) and their easily hydrolysable salts. These generally occur free, or in such feeble combination that their flavour is not masked.

4) *Origin of the volatile acids.* — Since these acids comprise those found in the fatty matter of milk, from lauric to butyric, and in almost the same proportions, the writer believes these acids are derived from the hydrolysis of the fatty matter of the cheese. The small quantities of acetic and possibly formic acid can be accounted for by the fermentation of carbohydrates in the early period of maturation or by the partial oxidation of higher acids or of glycerine during the ripening period.

5) *Culture experiments with Penicillium Roqueforti.* — Cultures were made in Czapek's solution and by inoculation of sterilized coagulum. In the former case about two-thirds and in the latter about one-half of the fatty matter was hydrolysed without an appreciable accumulation of soluble and volatile acids. In the natural cheese, however, these products accumulate, probably on account of the limited supply of oxygen preventing the complete oxidation of the butyric and caproic acids, or more probably because during maturation, especially in the interior part of the cheese where ripening is more complete, soluble enzymes such as lipase are present.

6) *Enzymes.* — A lipase was extracted from the mycelium of *Penicillium Roqueforti*. It was also shown that the ripening process is promoted by an enzyme capable of hydrolysing simple esters as well as glycerides.

The writer concludes that :

1. During the ripening of Roquefort cheese a considerable quantity of fatty matter is hydrolysed.

2. *Penicillium Roqueforti* produces a lipase soluble in water, which is responsible for the hydrolysis.

3. The hydrolysis causes an accumulation of free or combined fatty acids.

4. The piquant flavour of Roquefort cheese is due to caproic, caprylic and capric acids and their easily hydrolysable salts.

A bibliography of 16 works is appended.

PLANT DISEASES

DISEASES NOT DUE TO PARASITES AND OF UNKNOWN ORIGIN.

951 – **Withering of the Panicle in Rice.** — Poli, Polo, in *Il Giornale di Risicoltura*, Year IV, No. 14, pp. 206-209, 2 figs. Vercelli, July 30 1914.

The phenomenon described as " colatura " consists in a special abortion of the flowers of the apical spikelets of the panicle, which become reduced to whitish filaments more or less shrivelled and twisted, forming a small tuft which disappears before the grain is ripe. This results in a diminution of the yield.

Certain varieties of rice, in particular Italian varieties and those grown for a long time in Italy and thus more susceptible, are more frequently attacked by this disease than the hardier and more resitsant Japanese varieties. Thus, for example, the varieties Ostiglia, Ranghini, Nero di Vialone, and Greppi are conspicuously attacked, whilst Originario is less so.

This disease must not be confused with a very similar phenomenon produced by hail at certain times and in certain conditons of the growth of the plant, namely, when the stem is already swollen and the panicle on the point of appearing from its sheath. Then, if a large hailstone strikes the leaf near the base, it bends back and breaks, thus forming an obstacle to the opening of the sheath, and preventing the regular development of the panicle. This forces a lateral opening and remains caught with the apical grains in the sheath, unable to grow up straight and thereby becoming sterile.

As the result of researches carried out in different seasons, the writer considers the disease is generally due to the coexistence of two principal causes, namely, excessive fertility, and a period of intense cold at the time corresponding to the last phase in the formation of the flowers, when the panicle is still enclosed within the sheath.

BACTERIAL AND FUNGOID DISEASES.

BACTERIA

952 – **The Status of Investigational Work on Pear and Apple Blight.** — SWINGLE, DEANE B., in *Montana Agricultural College Experiment Station, Circular* 39, pp. 13-16. Bozeman, Montana, 1914.

Pear and apple blight is a serious disease which has been observed in the United States (Hudson River Valley) since 1792. J. T. Burrill in 1878 discovered the cause of the disease to be a bacterium called *Bacillus amylovorus*. In 1889 M. B. Waite, of the U. S. Department of Agriculture, observed that some insects convey the bacterium from the partially dead bark bordering on that which is still healthy to the flowers when these begin to open in spring, and thus assist greatly in spreading the disease. Of late years the disease has been studied by several American Experiment Stations from all points of view, as well as the different susceptibility to it of the different kinds of pears and apples, the influence of climate and soil on its virulence and the effcts of the most varied fungicides and insecticides. These researches are being actively continued. The Circular invites practical farmers to have faith in the experimental investigations of phytopathologists and not to allow themselves to be taken in by the vendors of specific remedies consisting of chemicals to be spread on the soil or injected into the trunks of the trees, as the efficacy of such remedies has not been borne out by any rigorously conducted scientific experiment.

FUNGI

953 – **Observations on the Life-History of the American Gooseberry-Mildew (*Sphaerotheca Mors-Uvae*).** — SALMON, E. S., in *The Annals of Applied Biology*, Vol. I, No. 2, pp. 177-182. Cambridge, 1914.

Sphaerotheca mors-uvae (Schwein.) Berk et Curt. differs from other introduced Erysiphaceae in producing abundance of perithecia under normal conditions in Europe. Many of these remain in the patches of mycelium on the shoots until the following spring. According to English legislation fruit growers who do not remove these shoots during the winter are liable to prosecution. The writer suggests the possibility that only perithecia formed during the summer attain maturity; such perithecia germinate easily in contact with a drop of water. On reaching maturity they usually fall to the ground; the perithecia formed later do not hibernate, but always perish, as well as the patches of mycelium, and consequently cannot become sources of infection. It may therefore be necessary to modify the Regulations on compulsory control. It remains now to ascertain how the spring infection takes place. It does not appear that it is always due to the ascospores coming from the ground, because in some cases observed by the writer the first berries infected were the highest; probably many mature perithecia in falling, especially during autumn pruning, get caught in the crevices of the bark or between the bud-scales and there germinate in spring.

954 - **Burgundy Mixture.** — FONZES-DIACON, in *Le Progrès agricole et viticole* (*Edition de l'Est-Centre*), Year 35, No. 29, pp. 70-80. Montpellier, 1914.

MEANS OF PREVENTION AND CONTROL

In this communication presented to the International Congress of Viticulture at Lyons in July 1914, the writer gives an account of his laboratory researches on the composition of neutral, acid and alkaline Burgundy mixture. The superiority of acid sprays (*i.e.* all mixtures containing an excess of copper sulphate), as confirmed by the writer, appears to be due not only to the excess of free copper which they contain, but also to the presence, in solution as well as in the precipitate, of the basic sulphate ($Cu SO_4$, 3 CuO, 4 H_2 O) which is insoluble in pure water but very soluble in presence of dissolved carbon dioxide.

It is also to the presence of this basic sulphate that the mixture owes its property of keeping.

Wetting Burgundy mixtures should belong to the acid type, since alkaline mixtures (*i. e.* those containing an excess of free sodium carbonate) enclose only a little or none at all, of this basic sulphate in their precipitate, and have none in solution.

In the preparation of these acid sprays, the dilute solution of sodium carbonate should be slowly added to the concentrated copper sulphate solution which is stirred constantly.

To obtain an acid spray containing about 200 to 500 gms. of free copper sulphate per hectolitre, about 350 to 500 gms. of 90 per cent. sodium carbonate should be added for each kilo of copper sulphate. The copper sulphate is dissolved in 10 to 15 litres of water and the sodium carbonate in the remaining 85 or 90 l.

955 - **A New *Botrytis* on Flowers of Red Clover in Russia.** — BONDARTSEFF, A. S., in *Xurnal Boliesni Rastenii* (*Journal of Plant Diseases*), Year VIII, No. 1, pp. 1-25, figs. 1-3, plates I-IV (abstract in German). Petrograd, 1914.

BACTERIAL AND FUNGOID DISEASES OF VARIOUS CROPS

The writer has found the flowers of red clover (*Trifolium pratense*) in Russia attacked by a new species of *Botrytis*, which he describes as *B. anthophila*.

The mycelium of the parasite penetrates into all parts of the plant, but is most prominent in the intercellular spaces; it develops its conidia on the anthers. The disease is spread by means of the seed and the writer has observed the mycelium below the seed coat of seeds produced from artificially infected flowers, as well as in those of naturally diseased plants. The presence of the fungus appears to have no effect on the cut of clover. The damage only concerns the anthers and consists in a loss of germinative power of the pollen grains, which appear very deformed under the microscope.

The writer points out that the diseased plants produce a smaller quantity of seed than healthy plants, but the germinating capacity of the seeds produced is higher, being about 63 per cent., whilst that of seeds from healthy plants does not exceed 43 per cent.

In every case the seeds harvested from diseased plants are smaller, shrivelled and less heavy than normal seeds.

The writer considers that seed-testing stations should carry their investi-

gations to the testing of the degree of infection of clover seeds with this fungus, as is already done in the case of cereals infected by smut, *Fusarium*, etc.

In 1913, *B. anthophila* was found in the following provinces: Petrograd, Tula, Kursk, Voronezh, Pskov, Novgorod and Ufa. This would lead one to suppose that the fungus is widely spread and that in case of a bad crop of clover seed the damage is often attributable to this disease alone.

The diseased flowers can sometimes be recognized by their dirty pale violet colour, though flowers with this appearance are not necessarily infected. The disease can easily be recognized by opening the flowers and removing the anthers, which when normal are yellow in colour but when attacked by the disease the conidia of the parasite give them a grey dusty appearance.

956 – **Potato Diseases in Great Britain.** — HORNE, A. S., in *The Annals of Applied Biology*, Vol. 1, No. 2, pp. 183-203, figs 1-8. Cambridge, 1914.

This paper is a critical review of the principal potato diseases which are at present of importance in Great Britain and also of the steps that should be taken to know them better and to control them efficiently. Some of these diseases are treated at length: wart disease or tumour (*Synchytrium endobioticum*), potato disease, late blight or murrain (*Phytophthora infestans*) ; " sprain' ', a disease of the tubers, the origin of which is still obscure, and which includes two forms: " blotch" (internal disease) and " streak" (sprain) ; *Fusarium* disease, under which two types of disease are recognized : *Fusarium* wilt caused by *F. oxysporium*, one of the most serious diseases of the potato in the United States, which does not seem to have appeared in Europe, and the dry-rot disease which appears to be caused by one or more species of *Fusarium* including *F. Solani*, of rare occurrence in Great Britain ; leaf-curl (German " Blattrollkrankheit "), according to the writer not due to parasites ; and lastly canker or powdery scab (*Spongospora Solani*).

957 – **Celery Leaf-Spot Disease (*Septoria Petroselini* var. *Apii*) in England** (1). — CHITTENDEN, F. J., in *The Annals of Applied Biology*, Vol. 1, No. 2, pp. 204-206. Cambridge, 1914.

The seed of celery (*Apium graveolens*) is the chief, if not the only, carrier of the disease caused by *Septoria Petroselini* Desm. var. *Apii* Br. et Cav. The seedlings as soon as they emerge from the ground already carry the fruits of the fungus on the cotyledons and on the plumule ; the disease then remains localized on each plant and does not pass from one to another.

Samples of " seed " — the commercial term for the whole or halved fruits (mericarps) of celery, mixed with other parts of the plant — which were examined by the writer were found to contain 90 per cent. of infected seeds ; consequently it will be advisable to see to the disinfection of the seed and to its collection only from healthy plants.

(1) See also No. 3242, *B.* Nov.-Dec. 1911. (*Ed.*).

958 – **Black Rot of Grapes (*Guignardia Bidwellii*) in Spain.** — RAVAZ, L., in *Le Progrès agricole et viticole*, Year 31, No. 30, pp. 114-115. Montpellier, 1914.

France was formerly the only country in Europe in which the black-rot fungus (*Guignardia Bidwellii* Viala et Ravaz) was known; this fungus has now been reported in Spain. It has not of late years caused as much damage as formerly, probably owing to the absence of the sclerotial stage. Vine leaves and grapes showing the distinctive characters of the disease have been received from the province of Valentia. The fruits were almost entirely destroyed by the disease, thus showing the serious importance of the outbreak.

959 – **A Contribution to our Knowledge of Apple Scab.** — MORRIS, H. E., in *Montana Agricultural College Experiment Station, Bulletin*, No. 96, pp. 69-102, 1 plate + 3 figs. Bozeman, Montana, 1914.

In the State of Montana, apple scab (*Venturia inaequalis*, conidial form *Fusicladium dendriticum*), so common a disease in all portions of the civilized world where the apple is grown, appeared first on the east side of Flathead Lake about 1900 and spread slowly all round.

During the summers of the last three years climatic conditions were favourable for the development of apple scab and the occurrence of twig infection was not at all infrequent, especially on the McIntosh variety. On the shoots the spots caused by the disease are similar to those occurring upon the fruits, except that they are minute, being scarcely visible to the naked eye though readily seen under a low magnification. Living cultures were obtained from some of these spots during the month of March, but no data were secured as to the extent to which such twigs are a source of spring infection.

The primary spring infection period in the State of Montana corresponds to that observed by Wallace, according to whom the spring infection occurs about the time the ascospores mature, if weather conditions at that time are favourable; but during the cool damp seasons of 1911 and 1912 late summer or secondary infection occurred. This took place about the middle of August or beginning of September and at harvest time many minute scab spots were visible on the fruit, which might have been prevented by late spraying.

The observations of the writer, covering a period of several years, confirm the opinion of Wallace that *V. inaequalis* is a species entirely distinct from *V. pirina* (pear scab). He has seen scab abundant on apple trees while Flemish pear trees in the same orchard were not attacked; yet Flemish pear is generally conceded to be very susceptible to scab. In older sections, where both diseases have been prevalent for years, this fact could not be observed.

The injury and corresponding loss to the apple crop due to the presence of scab is far greater than is generally believed; nevertheless it is difficult to value in money the total loss due to the disease. A conservative estimate of the loss due to scab in the Bitter Root Valley during 1911 and 1912 would be 15 per cent. of the entire crop. This loss is due to the reduction in price or to total destruction of the fruit by the fungus.

As there are early blooming varieties of apples and late blooming ones, their proper distribution is important in the control of the disease. When the varieties are badly mixed in rows it is commercially impracticable to spray at the proper time; the difference in time between the blooming of the different varieties necessitates extra sprayings. For this reason it is desirable to set the trees in separate blocks. For equally susceptible varieties which blossom about the same time this would not be so important, but it is never advisable to mix susceptible and resistant varieties. It is well known that there are great differences among the varieties of apples grown in Montana with respect to their susceptibility to scab. The selection and improvement of scab-resistant varieties may be one of the effective methods of dealing with the problem. No variety of apple is immune from scab under the most favourable conditions for the development of the fungus, and it is also recognized that varietal susceptibility may vary in different localities. The opinion of several authors that certain varieties may be resistant in one year and susceptible in another year under conditions which for average varieties are as favourable to the disease in one case as in the other, apparently does not apply to Montana. The writer gives a table in which the 44 varieties of apples commonly grown in the western part of the State are divided into 4 classes (practically resistant, moderately resistant, moderately susceptible, susceptible). It is the result of observations covering a period of five years, three of which were favourable for the development of the apple scab fungus.

The practically resistant varieties are: Hubbardston, Oldenburg (Duchess), Wagener, Wealthy, and York Imperial.

The two fungicides which have been used to a considerable extent in the State are lime-sulphur and Bordeaux mixture; lime-sulphur is the more important and is used generally at a strength which approximates that recommended by Scott (4 lbs. of suphur in solution to 50 gallons of diluted spray). Bordeaux mixture, owing to the russeting of the fruit and burning of the foliage, has been almost entirely replaced by lime-sulphur.

For controlling scab on susceptible varieties — classes 3 and 4 — five applications should be given at specified times; for the fairly resistant varieties — classes 1 and 2 — two sprayings should be given, namely one when the flower buds show a pink colour and the other when most of the petals have fallen; according to weather conditions one later spraying may sometimes be advisable.

According to experiments carried out in Montana on 1200 six-year-old trees, the cost of spraying once with lime-sulphur is 2 cents (1*d*) per tree.

The writer has cultivated the conidial form (*Fusicladium dendriticum*) of *V. inaequalis* in several artificial media with varying success.

The paper concludes with a bibliography referring to 505 works on the subject.

960 – **Rotting of Pomegranates in India: *Sterigmatocystis castanea.*** — BUTLER, E. J., in *The Agricultural Journal of India*, Vol. IX, Part II, pp. 205-206. Calcutta-London, 1914.

Specimens of pomegranates were recently received from a garden in Bombay, which, though of excellent external appearance, were blackened and rotting inside. The rot was found to be due to a fungus, *Sterigmatocystis castanea* Patterson, and the disease to be identical with one described in 1912 as a new and serious disease of this fruit in America, where it had been first observed in the United States in 1910.

In the more advanced stages of the disease there are cavities inside the fruit filled with a brown powdery substance, composed of the spores of the fungus.

It is suggested in the United States that the fungus gains an entry while the calyx is open ; subsequently the calyx closes and the parasite develops within the growing fruit. If this be the case it is hard to see how the disease can be checked. But there is another possibility : several cases are known where fruit which is externally sound is mouldy inside, and in these cases the mould is frequently some common species, whose spores are likely to be present in the air in considerable quantity. Walnuts are, perhaps, the most familiar example of this condition. Tea seed is also not infrequently affected in a similar manner, and very probably the mould gains an entry through punctures in the young fruit caused by a large sucking insect. It is possible that the pomegranate rot is due to a similar cause, and if so, the question of its prevention resolves itself into the question of preserving the young fruit from such insect attacks. The writer proposes, with the co-operation of fruit growers, to ascertain whether this hypothesis has any foundation in fact.

961 – **The Bud-Rot (*Pythium palmivorum*) of Coconut Palms in Malabar** (1). — SHAW, F. J. F., and SUNDERARAMAN, S., in *The Agricultural Journal of India*, Vol. IX, Part II, pp. 111-117, plates IX-XI. Calcutta-London, 1914.

In October 1912 the first report of a serious disease of coconuts in Malabar began to attract attention. The first outbreak noticed was at Tamarasseri ; for several miles round this village, cases of the death of single coconut trees in different gardens were common. In February 1913 the neighbouring localities of Kidavur, Pallipuram, Karothur, Vavada, Poonur, and Puthuppadi were inspected and a number of adult plants and in some cases also young seedlings which had been transplanted only a year before, were found to be more or less diseased. Enquiries made in the locality seemed to show that the disease was of about ten years' standing, but it has spread so slowly that it had not alarmed the growers.

The true cause of the disease was not identified when the first inspection was made, the weather at the time being hot and dry, and it was decided to make further investigations during the rainy season.

For this purpose, Tamarasseri was visited about the end of July at the height of the monsoon, when the nature of the disease at once became

(1) See also *B.* Dec. 1910, pp. 368-370. (*Ed.*).

apparent from a study of young trees in an early stage of infection. The first symptom by which a diseased tree may be recognized is that the central leaf turns brown, collapses and dies. As everyone knows, the youngest central leaf of a coconut is folded up like a fan. If now the dead central leaf be removed and unfolded, it will be found that at the point where the leaf has collapsed the folded lamina is covered with a white fluffy growth of fungus. This fungus, starting at one point of the leaf, eats its way straight through the folds of the lamina and produces a softening of the tissues leading to the collapse of the leaf at this point; as a result of this the portion of the leaf above the point of infection turns brown and dies. In cases in which the infection is very recent and the whole leaf has not had time to turn brown, the area infected by the fungus gives rise to very characteristic rows of spots. If, as sometimes happens, the attack does not spread beyond this point, then when the central leaf expands, a row of brown spots in which the leaf tissue has decayed away can be seen stretching across the leaf.

In material from recently infected leaves it was possible to make a very complete examination of the morphology of the fungus, which left no doubt that it was to be identified with *Pythium palmivorum* Butl., the cause of the bud-rot of palmyras (*Borassus flabellifer*).

On leaf spots, the white fluffy mycelium of the fungus bears abundant sporangia, which under appropriate conditions of moisture discharge their spores. In the case, therefore, of a tree in which the central leaf is attacked it is easy to see how the infection spreads. A single day's rain would be sufficient to wash the spores down from the central leaf into the interstices of the bases of the older leaves, where the fungus would find the most favourable conditions for development. In this way, and sometimes doubtless by infection from other trees, the fungus forms rotten spots on the leaf bases, which vary in size; they are of a dark brown colour and present a fibrous appearance.

Once the fungus has become established in spots on the leaf bases, the death of the palm is a mere matter of time. The mycelium eats its way in, passing from one leaf-base to another, and finally reaches the growing point and kills the tree. As this goes on, the outer leaves gradually droop and fall off, while the spread of the rot is accelerated by various saprophytic fungi, bacteria and insects. In the final stage of the disease the tree is left as a bare pole with, possibly, a single discoloured leaf drooping from the crown. In the later stages of the disease when the outer leaves are falling, it is not easy to identify the fungus; the apex of the palm is then a semi-liquid putrescent mass in which saprophytic organisms are extremely abundant. In the early stages of an infection it might be possible to confuse a case of tree bud-rot with an attack by Rhinoceros beetle (*Oryctes rhinoceros*). However, in those cases of bud rot in which the infection is recent and the whole of the central shoot is not involved, the rows of spots on the folded lamina constitute a reliable criterion of distinction.

From a consideration of the habit of *P. palmivorum* it is not difficult o see how such a disease would spread once it was established in any ne locality. On a windy wet day drops of water containing spores may asily be blown from one tree to another, while the practice of climbing rees for leaf cutting and tapping for toddy would also favour the dissemination of the fungus.

The writers obtained the parasite in pure cultures and were successul in carrying out new infections with them.

At the same time at which this disease was diagnosed at Tamarasseri nd neighbouring localities, it was also identified in other parts of Malabar Malappuram, Melmuri, Calicut, Kurmathur, Andoor, Koyyam, etc.).

At present the disease appears to be scattered throughout Malabar, ut fortunately nowhere with the virulence seen in palmyra palms in ertain localities of the Godavari district.

In both the palmyra and coconut palms it is difficult to recognize the ymptoms of disease in an early stage. This fact, coupled with the difficulty in applying any treatment to palm trees, renders the destruction f infected trees the surest method of controlling the disease. As has been one in the Godavari district, the local authorities are taking active steps or the destruction of the affected trees in the various districts of Malabar, here, more fortunately than in Godavari, it has been possible to diagnose he disease in its initial stage. Since the beginning of operations 352 iseased trees have been identified and of these 150 have already been estroyed.

Among the factors influencing the spread of the disease, that most avourable to the growth of the fungus is the degree of moisture.

62 – **Wood-destroying Fungi which Grow on Both Coniferous and Deciduous Trees in the United States of America and in Europe.** — WEIR, JAMES R., in *Phytopathology*, Vol. 4, No. 4, pp. 271-276. Baltimore, Md., 1914.

In the course of investigations on the fungi attacking forest trees n the North-West States, the writer found many new and exceptional osts for certain fungus species heretofore supposed to be strictly confined o coniferous or deciduous trees. In connection with the facts discovered, here is one which must not be overlooked in the correct determination of imilar species growing under a great range of conditions, namely the reat variation induced in some characters of their sporophores.

The following is a first list of fungi and their new or exceptional hosts.

Hydnum coralloides Scop. (?), abundant on the wood of deciduous trees, specially on *Populus*, has been found in the forests of Idaho and Washington on *Abies grandis* and occasionally on *Picea Engelmanni*.

Stereum hirsutum Willd., frequent in the West on various hardwoods, as been found occasionally on conifers, usually on branches of *Abies randis* and *Tsuga heterophylla*.

S. purpureum Pers., which usually grows on *Populus*, *Salix* and *Betula*, has been collected on moist branches of *Larix occidentalis*.

Hymenochaete tabacina Sid. is common on both conifers and broadeaved trees in the North-West.

Trametes Pini (Brot.) Fr., apparently never reported as growing on deciduous wood, has been collected on *Betula occidentalis* in Idaho.

T. picienus Pk. on *Crataegus* sp. in the West.

T. suaveolens L., common throughout the West on *Populus* and *Salix*, has been found on *Abies grandis*.

Polyporus giganteus (Pers.), described by Murrill as growing on deciduous trees, has been found on conifers in Idaho, more often in connection with old decayed roots of Douglas fir, and on *Pinus sylvestris*.

P. frondosus Fr., known on the roots of Italian chestnuts, and *P. umbellatus* (Pers.), have been frequently observed on conifers in Idaho and Washington.

P. Berkeleyi Fr., found in the East at the base of oaks, has been collected on *Larix occidentalis* in Idaho.

P. picipes Fr., common on *Populus* in Idaho and Washington, has been collected on *Picea Engelmanni* and *Abies grandis*.

P. chioneus Fr., usually found on wood of deciduous trees, is quite common on conifers in the North-West, principally on *Thuya plicata*; it has also been found on *Pinus monticola* and *Tsuga heterophylla*.

P. adustus Fr., common on *Betula occidentalis* and on species of *Populus*, is occasionally found on *Larix occidentalis*, *Thuya plicata* and *Pseudotsuga taxifolia*, though very rarely.

P. dichrous Fr., associated in the East with *Quercus alba*, is common on *Juniperus virginiana* in the vicinity of Washington, D. C., and has recently been found to be a serious sapwood fungus on various North-Western conifers (*Thuya plicata*, *Tsuga heterophylla*, *Pinus monticola* and *Larix occidentalis*).

P. sulphureus Fr., common in Europe on both coniferous and broad-leaved trees, attacks practically every native forest tree in America.

P. caesius Fr., which ordinarily occurs in the East on the wood of deciduous trees, is common in Idaho and Washington on *Tsuga heterophylla*, *Larix occidentalis* and *Abies grandis*.

P. benzoinus (Wahlenb.), common in Idaho and Washington on *Tsuga heterophylla*, *Larix occidentalis* and *Abies grandis*, is undoubtedly the same as *P. resinosus* Schrad., on species of *Populus* and *Acer* in the Eastern States.

P. gilvus Fr., thought to be confined to the wood of deciduous trees, is quite common on *Juniperus virginiana* in the vicinity of Washington, D. C.

Polystictus aurantiacus Pk., considered a very rare fungus in the United States, is principally associated with *Pseudotsuga taxifolia* and *Tsuga heterophylla* in Idaho and Washington; the writer has recently collected it from a maple in Idaho.

P. versicolor (L.) Fr., well known on many deciduous trees, has been collected on *Larix occidentalis*, *Pinus monticola* and *Pseudotsuga taxifolia*.

P. cinnabarinus (Jacq.) Fr., occurring abundantly in the North-West

on *Betula occidentalis*, *Acer glabrum*, *Populus*, *Prunus* and *Salix*, has recently been collected on *Thuya plicata*.

P. hirsutus Fr., one of the most common of all polypores on the wood of deciduous trees, has been collected on *Thuya plicata*.

Fomes pinicola, besides occurring on practically every conifer in the North-West, has been found on *Populus trichocarpa*, *P. tremuloides*, *Betula occidentalis*, *Salix lasiandra*, *Alnus tenuifolia*, *Pyrus Malus* and a variety of plum ; the writer has collected it on *Fagus sylvatica* and *Quercus pedunculata* in Baden, Germany, where it also occurs on *Alnus glutinosa ;* Pennington reports it upon *Fagus ferruginea*, *Betula lenta* and *Acer saccharinum* in the Adirondacks, on the balsam poplars of Northern Michigan and on *Prunus serotina*.

F. annosus Fr., which usually attacks conifers, has been collected on various deciduous trees of the North-West.

F. leucophaeus Mont., frequently found on coniferous hosts in the West, is more often associated with deciduous hosts, especially *Populus*.

Lenzites sepiaria Fr., so common on coniferous wood, is frequently found on deciduous trees, among which Spaulding mentions *Alnus* sp., *Populus alba*, *P. deltoides*, *P. tremuloides*, *Salix* sp. and *S. discolor* ; the fungus has been collected in the North-West on *Alnus tenuifolia*, *Prunus demissa*, *Betula occidentalis*, *Populus trichocarpa*, *Salix lasiandra*, *Acer glabrum* and *Crataegus Douglasii* ; all are very rare hosts, especially the last.

Armillaria mellea (Vahl.) Quél., is common on both coniferous and broad-leaved trees.

Pleurotus serotinus Fr., common on *Alnus* and *Populus*, frequently occurs on *Abies grandis*.

Pholiota adiposa Fr., a serious enemy of *Abies grandis*, occurs also, though rarely, on *Populus*.

Paxillus atrotomentosus Fr., common on coniferous wood, is more rarely found on the wood of broad-leaf species.

PARASITIC AND OTHER INJURIOUS FLOWERING PLANTS.

963 – ***Papaver Rhoeas* and *P. hybridum*, Common Weeds in Egypt.** (1) — BOLLAND, B. G. C., in *The Agricultural Journal of Egypt*, Vol. IV, Part I, pp. 53-54, plate II. Cairo, 1914.

After recalling the general characters of the genus *Papaver*, the writer gives a systematic description of the two commonest species occurring as weeds in Egypt : *P. Rhoeas* and *P. hybridum*.

The former, known in Arabic as " Zaghlil " and " Qarun ", flowers in the winter and spring and is found in waste places and barley fields along the Mediterranean coast.

P. hybridum, in Arabic " Abu el Nôm ", flowers in the spring and is found chiefly in the barley fields of the Mariut district.

(1) See also No. 390, *B.* April 1914. (*Ed.*).

This species was noticed by Forkal in his "Flora Aegyptiaco-Arabica" as growing in Egypt in 1775. The word *Papaver* is also mentioned by Prosper Alpinus in his book "De Plantis Aegypti" written in 1640 (1) but no species is given.

INSECT PESTS.

GENERALITIES

964 – **Notes on the Biology of Leather Jackets (*Tipula oleracea*) in the Pastures of the Avesnois (Nord, France).** — DÉSOIL, P. in *Comptes rendus hebdomadaires des séances de la Société de Biologie*, Vol. LXXVII, No. 21, pp. 126-127. Paris, 1914.

During this year (1914) leather jackets have caused serious damage in the pastures about Avesne (Cantons of Bavay and Le Quesnoy). The farmers in this region noticed scattered throughout their fields numerous circular patches of dead yellow grass which did not resume its normal vegetative growth in April. On digging up these dried patches of turf they were found to be swarming with these grubs, especially on a level with the origin of the roots, the majority with their heads almost level with the surface of the soil, others at a depth of from 4 to 5 inches but within the root range of the grasses.

Grasses and clovers are particularly attacked by these larvae whilst plants with larger and tougher roots, such as couch, dock, plantain, Composites, are free from attack. The larvae in the soil bordering on a trench often fall down and being unable to climb out they become heaped several layers deep. They do not migrate from one plant to another but feed almost entirely on the plant near which their eggs were deposited. After the death of the plant they feed on its dead tissues and decaying humus. They are most injurious during their growing period (October to May), especially to plants which live through the winter. This explains why pasture plants are particularly attacked.

Spring-sown crops are therefore less exposed to attack since they do not possess a well-developed root system until May or June when the larvae are entering on the nymph stage.

According to the writer the only practical means of control is to bury the larvae by deep cultivation at the end of winter and to sow a crop in March or April. Spring-sown oats and wheat have grown without damage on infested land treated in this way.

965 – **Observations and Researches on the Life History of the Beet Aphis (*Aphis euonymi*)** (2). — MALAQUIN, A., and MOIT É, A., in *Comptes rendus hebdomadaires des séances de l'Académie des Sciences*, 1914, First Half-year, Vol. 158, No. 19, pp. 1371-1374. Paris, 1914.

In 1913, M. Gaumont recorded deposits of eggs of sexual females of *Aphis euonymi* Fb. on beets, so that according to him this species is able to

(1) According to P. A. SACCARDO: *Cronologia della Flora italiana*, p. XIII, Padova, 1909, the above mentioned work by Alpino (1553-1617) was published at Padova in 1592.

(2) See also No. 296, *B.* March 1914. (*Ed.*).

complete its life cycle on herbaceous plants. In October 1913 a large number of colonies of this aphis were found on beans and comprised winged males and wingless females ; the latter deposited large numbers of eggs on the stems and leaf-stalks. The observations, accompanied by experiments, were carried on to the spring of 1914.

It was found that eggs deposited by sexual females on beans (intermediate host) in the autumn did not hatch, whilst eggs deposited on the principal host, *Euonymus europaeus*, hatched out normally. Further, when the larvae from these eggs were placed on beet leaves, they refused to attack them.

It appears therefore that in the case of a migratory species such as *A. euonymi*, the generation produced from the fertilised eggs is adapted only to the conditions of its principal host, and the adaptation to different food (intermediate hosts) appears in later generations.

966 – **The Emergence from the Soil of the First Larvae of *Phylloxera vastatrix* in Italy.** — GRASSI, B., in *Rendiconti delle sedute della Reale Accademia dei Lincei, Classe di Scienze fisiche, matematiche e naturali*, 2nd Half-year, Vol. XXIII, Part 2, pp. 19-30. Rome, 1914.

Researches carried out in North, Central and South Italy show that the emergence of the first larvae from the soil before they commence to feed is a normal phenomenon of more general occurrence than was believed by Faucon, who first observed it (1868), and the other authorities who have recorded it. A close examination with the naked eye or a hand lens of loose soil close to diseased stocks is sufficient to reveal their presence.

The emergence of the larvae is more or less abundant throughout the year, except during the hibernation and the period preceding the birth of the first daughter generation of the hibernating females. In Southern Italy they do not appear so frequently from the second half of July to the end of August, the period corresponding with the partial aestivation of the insect.

Considering such a powerful means of distribution of the insect as these first larvae, it is reasonable to suspect that the passing of workmen to and fro in the vineyards is a source of danger. This fact should be taken into account before adopting measures for controlling the disease, when an old centre of infection has been discovered and especially when there is reason to believe that the whole vineyard has become infected.

Researches are being conducted to determine the influence of tillage, the presence or absence of superficial roots, of root development, etc., on the numbers of these first larvae which emerge from the soil. It has already been determined that winter digging is a most effective means of propagating phylloxera over both small and large distances.

It is also affirmed that it is dangerous to examine for phylloxera during windy weather, since a slight wind suffices to carry the larvae from the exposed roots. The necessary precautions to prevent these dangers are too often neglected by the workmen.

967 – **Notes on *Aspidiotus bromeliae*.** — LINDINGER, LEONHARD, and GREEN, E. ERNEST, in *The Journal of Economic Biology*, Vol. 9, No. 2, pp. 73-75. London, 1914.

Contrary to the opinion of Green (1), Lindinger affirms that *Aspidiotus bromeliae* is indigenous to the Azores and not the Canaries. He also adds that as this scale attacks only Bromeliaceae, its original country should be sought in America where these plants (including the pineapple) are indigenous. He also disagrees with Green that this insect may become a serious pest of the pineapple, as its development is too slow.

Green replies that our knowledge of this species is too incomplete to make definite conclusions, since it is not yet known if it is confined to the Bromeliaceae. Further, the Bromeliaceae are indigenous not only to America but also to India, Ceylon, Java and other eastern countries. As to the danger of these scales, Green mentions that the pineapple material from the Seychelles was so badly infested that the health of the plants must have been seriously affected. The rapidity of development of these insects depends so much on the presence or absence of their natural enemies (Coccinellids and Hymenopterous insects) that conclusions based on conditions prevailing in one region may be completely upset by conditions in another region.

968 – **On the Reproduction and Fertility of the Elm Leaf-Beetle (*Galerucella luteola*).** — LÉCAILLON, in *Comptes rendus hebdomadaires des séances de l'Académie des Sciences*, 1914, 2nd Half-year, Vol. 159, No. 1, pp. 116-119. Paris, 1914.

The elm leaf-beetle (*Galerucella luteola*) belongs to the Chrysomelidae and occurs in Europe, Algeria and in the United States. Both larvae and adults feed on the leaves of the elm (*Ulmus campestris*), often causing considerable damage to trees in parks and public places. Sometimes the insect is so numerous that only the veins and petioles of the leaves remain, and when this happens several years in succession the life of the trees is endangered.

The extraordinary abundance of this insect cannot yet be attributed to the occurrence of two generations in one year, but the writer has observed this year on trees near Toulouse and on laboratory specimens that the period of reproduction extends from the beginning of May until early July. The number of eggs in each cluster on the lower surface of the leaf is very variable ; the number laid by one female is much greater than was formerly believed, some females reared in captivity having deposited more than 500 eggs. During the period of reproduction the males and females feed abundantly. In the open the females do not lay all their eggs on the same leaf, or even on the same tree. Further, the larvae from one egg-cluster move to different leaves on reaching a certain size.

(1) See No. 798, *B.* Aug. 1914. (*Ed.*).

69 – **Winter Precautions against the Pupae of Vine Moths (*Conchylis ambiguella* and *Polychrosis botrana*) in Piedmont** (1). — TOPI, M., in *Rendiconti delle sedute della Reale Accademia dei Lincei, Classe di Scienze fisiche, matematiche e naturali*, 1914, 1st Half-year, Vol. XXIII, Part 12, pp. 981-984. Rome, 1914.

The writer gives an account of his observations and researches on he control of the hibernating pupae of *Conchylis ambiguella* and *Polychrosis botrana*, carried out on several occasions in the Upper Monferrato territory of Alice Bel Colle), Piedmont, partly in collaboration with F. Monticelli.

The canes generally used for supporting the vines often have the op internode open, thus providing suitable shelters for the larvae seeking places for pupation. For this reason the tipping of the canes and destruction of the tips is recommended, in addition to the stripping of the stocks, which is a laborious operation not without danger.

To determine the value of this tipping, it was necessary to know to what extent the larvae use the tips of the canes for pupation. In a badly attacked vineyard, 25 vines were stripped during the winter and the tips of the canes were examined: the result was 19 pupae in the canes and 8 under the bark. If this is a general proportion, tipping would prevent he emergence of about half the moths, which is not a sufficiently large proportion for a good control; further, the method is laborious.

Better results can be obtained by using artificial shelters, among which the most successful are those described and used by G. Cantoni, in the Trentino. The method consists in placing cloth bands at the base of the shoots on the two-year-old wood; the larvae pupate in these and can be easily destroyed. Where canes are used as supports, they should be tipped, and the bands may be placed on them as well as on the stocks. In a comparative experiment it was found that in this case the stocks were as much used by the hibernating larvae as the canes, or even more so.

These measures can be made more effective if the bands containing he pupae are placed in special cages to allow the escape of any Hymenopterous parasites that may be present, but not the moths. Out of 100 cocoons, 57 moths and 22 Hymenopterous parasites were obtained; the rest of the pupae were attacked by fungi and a few cocoons were empty. If they had been in the open, a certain number of pupae would no doubt have been destroyed by animals, fungi and other causes. Frequently a species of *Helops* and the larvae of *Malachius bipustulatus* are found in the ends of the canes, and though they are believed to prey on the pupae, their usefulness and voracity must be considered highly doubtful.

The writer remarks on the preponderance of *Polychrosis*, since out of the 57 moths mentioned above, 54 were *Polychrosis* and only 3 *Conchylis*. In the catch of molasses traps the number of *Conchylis* was appreciably larger, namely 10 to 73 *Polychrosis*; possibly *Conchylis* was abundant locally in the district in which these researches were made.

(1) See also No. 590, *B.* June 1914. (*Ed.*).

970 – **The Fumigation of Citrus Trees in Egypt.** — GOUGH, LEWIS, in *The Agricultural Journal of Egypt*, Vol. IV, Part I, pp. 17-19. Cairo, 1914.

After having mentioned that citrus trees in Egypt are subject to the attacks of several species of scale insects (1) among which the most important are *Aspidiotus aonidum* (?), *A. aurantii* and *Icerya purchasi*, Dr. Gough describes the system of control which has been adopted and which is carried out only by the Government and which consists in the well known process of fumigation with hydrocyanic acid.

INSECTS INJURIOUS TO VARIOUS CROPS

971 – **The Principal Pests of Rice in Indo-China.** — DUPONT, L., in *Journal d'Agriculture tropicale* Year 14, No. 157, pp. 204-207. Paris, 1914.

I. INSECTS. — The writer gives some information on the following insects injurious to the rice crop.

a) Lepidoptera. — 1) *Sesamia inferens* Wlk., the young larvae of which enter the upper portion of the stem and bore their way to the base, where they frequently pupate; the pupae are easily destroyed in great numbers by raising the level of the irrigation water so that they become submerged. A certain number of larvae, however, always ascend the stem to pupate. As many as ten pupae have been found in one stem. This species, already recorded in India, Java, Tonking, etc., caused great damage to the rice crop in the state of Pahang (Federated Malay States) in 1906.

2) *Schoenobius bipunctiferus* Wlk., the larva of which, on leaving the stem, protects itself with a fragment of the leaf until it returns to pupate at the base of the stem; the moth emerges after 10 or 15 days. It has caused great damage in the Philippines and occurs in Java, Tonking, etc.

3) *Cnaphalocrocis medinalis* Gn., is the commonest padi borer; after boring the upper portion of the stem, it gradually works its way to the base. Its presence is indicated by an empty panicle of a blanched appearance, later turning ashy grey or dark grey on the development of saprophytic fungi. The damage due to this insect may vary from 5 to 25 per cent. It is kept in check by cutting the diseased stems as low as possible, soon after the appearance of the panicles, and destroying them without delay, or by ploughing in the stubble immediately after harvest. This species has been recorded in India, Java, and Tonking.

4) *Artona walkeri* Moore; this seems to be the first record of this species as parasitic on rice; in 1911 it caused considerable damage in the province of Thaï-Nguyen, and it was recorded in the neighbourhood of Hanoi in 1913.

5) *Sitotroga cerealella* Oliv.

b) Hemiptera. — 1) *Leptocorisa varicornis* Fabr. is widely distributed at all seasons of the year. It sucks the milky contents of the young grains. When they occur in large numbers they may be kept in check by sweeping with nets of fairly large mesh. It is also useful to destroy the grasses

(1) See No. 1485, *B.* Oct. 1912. (*Ed.*)

which grow in the neighbourhood of rice fields. *Cicindela sexpunctata* is a very effective and abundant natural enemy of this pest in Tonking.

2) *L. acuta* Thumb., which causes similar damage, is widely spread in the Philippines ; in 1909 it caused serious damage to the rice fields in Ceylon.

II. Fungi. — Finally the writer mentions two fungi : *Ustiliginoidea virens* Tak. and *Tilletia horrida* Tak. (1).

The former, restricted to rice, is common in Tonking, the ten-months' rice being most particularly attacked. Near Hanoi as many as 15 diseased grains have been found on one panicle by the writer. It is most abundant in rice fields which are badly cultivated. The infested grain swells and assumes a yellowish-green colour more or less intense according to the development of the disease ; it soon becomes a dull green velvety mass covered with spores, from 6 to 10 mm. in size and darkening in colour until almost black, whilst its surface disintegrates and falls to dust : beneath the greenish-black dusty layer of spores there remains a small very hard, orange-yellow mass with a hard white centre. The fungus is common in Japan, China, etc.

Tilletia horrida also attacks the grains in the panicle, converting them into a black powdery mass of spores. The writer has observed it on ten-months' rice near Hanoi and in the province of Phu-Yen. It is much rarer than *U. virens*.

972 – **The Mole Cricket (*Gryllotalpa vulgaris*) damaging Rice Fields in Italy.** — Novelli, N., in *Il Giornale di Risicoltura*, Year IV, No 13, pp. 189-193. Vercelli, July 15, 1914.

The writer records that the mole cricket occurs in increasing numbers in certain irrigated rice-growing districts in Italy, where the conditions are undoubtedly very favourable to its development.

It causes considerable damage and the writer has seen entire fields almost devastated by the insect. Wheat, oats and barley have been badly thinned and maize reduced so as to require re-seeding. Where the crops were drilled the damage was worse, since the crickets follow along the lines more easily. Close to the banks dividing the rice plots in the previous year, the damage is always complete; wheat or maize following grass is always greatly thinned and market garden crops are very seriously damaged. Dry land rice is attacked similarly to wheat ; and in ordinary cultivation they come down from the banks to devour the rice when the water is run off, especially at the first drying. The banks often become so infested by these insects that their resistance to water becomes seriously impaired, the escaping water giving rise to so-called cold spots below, where the rice remains stunted.

The writer points out the importance of adopting measures against this pest without delay and recommends the following : *a*) summer cultivation in the irrigated regions, so as to interfere with the development of the insect, and destruction of the nests by children or labourers following

(*Ed.*).

(1) See No. 992, *B.* March 1911.

the plough: stamping on them is sufficient to destroy the eggs or young larvae; *b*) early ploughing of the leys intended for wheat, maize, etc., followed by a second ploughing before sowing; *c*) searching for the insects during the irrigation of the fields: as the water rises they leave their burrows and collect on the higher grouud, many swimming to the banks, where they can easily be destroyed; *d*) searching for the insects and their nests in the banks, or injection of carbon di-sulphide in holes 8 inches or more deep and 30 inches apart, or watering the banks with 20 per cent. petroleum emulsion: any insects which come out on the surface as a result of these treatments can easily be destroyed under the feet.

973 – **Sweet Potato Sphinx (*Herse convolvuli ?*) in Natal.** — FAURE, J. C., in *The Agricultural Journal of the Union of South Africa*, Vol. VII, No. 4, pp. 515-519, fig. 1. Pretoria, 1914.

The sweet-potato industry in the New Hanover-Dalton District in Natal has increased rapidly in recent years. There are probably about 2000 acres under sweet potatoes every year, and the gross value of the crop is about £20 000.

In November 1913 reports from the district came in about severe injury to the crop caused by a larva which the writer refers doubtfully to *Herse convolvuli* L. It devours the leaves of the sweet potatoes, causing a loss which is estimated at from 25 to 50 per cent. and even more. One 17-acre field was severely infested and the whole of it was practically defoliated in the course of a week.

Growers are of opinion that there are three occurrences of the larvae every season, one towards the end of November, one in January and another in March. The January infestation seems to be that most feared. At Schroeders in Natal the insect has been known for the past twentyyears.

The writer gives the following information on the life-history of the sphinx: the eggs are laid singly on the under sides of the leaves: the larvae show a great variation in colour and markings, the majority, however, being dark brown; pupation takes place in the soil.

From dead larvae Tachinid flies have been reared, as well as a small Chalcid which might be a hyperparasite.

The experiments carried on at Schroeders on a small scale indicate that the sphinx can be readily controlled by the use of arsenical sprays. Paris green gave the best results, but arsenate of lead will probably also answer the same purpose. The former was used at the rate of 1 lb. to 2 lbs. of lime and 75 gallons of water, and arsenate of lead at the rate of 3 lbs. to 50 gallons. The mixtures were sweetened in both cases. From 30 to 80 per cent. of the larvae were thus killed and besides this the sprayed areas were markedly avoided by migrating larvae. Hand-picking will probably be very successful on a small scale, and since the insect hibernates in all probability as a pupa in the soil, thorough winter ploughing and harrowing may destroy many of the pupae and thus aid in the control of the pest. During their migrations the caterpillars might be killed by digging ditches for them to collect in or by the use of poison bait spread across their line of march.

974 – **Large Narcissus Fly (*Merodon equestris*) and Small Narcissus Fly (*Eumerus strigatus*) Injurious to Bulbs in Great Britain and Ireland.** — *Board of Agriculture and Fisheries, Leaflet*, No. 286, pp. 1-7, 1 plate. London, 1914.

Of the various animal pests attacking the bulbs of Narcissi and related plants, none are more injurious than the two Narcissus flies, *Merodon equestris* F. and *Eumerus strigatus* Flu. The former, often known as the Large Narcissus Fly has been known in England since 1869, and is now widely distributed in England and Wales, while it also occurs in many parts of Scotland and in Ireland. It is generally supposed to have been brought to England, probably from Holland, but in the opinion of others it is considered to be native.

The systematic description of the insect is given in the leaflet together with its life history.

The bulbs attacked include the Narcissus, Hyacinth, Tulips (rarely), Amaryllis, Habranthus, Vallota, Galtonia, Scylla and Leucojum. As regards Narcissus, it has been observed that the hard bulbs of the *N. maximus* and *N. spurius* type are least attacked, while the most susceptible are the *N. poeticus* and *N. Lecdsii* varieties, and, further, that varieties with coloured cups are more susceptible than those without.

The interior of the bulbs is hollowed out, a wet mass of frass and decayed matter only remaining. The decay due to *Merodon*, however, does not cause such a complete breakdown of the bulb as in the case of an attack by *Eumerus*.

When the larvae are large the infested bulbs can be detected by gently pressing near the neck with the fingers : sound bulbs being hard, and infested ones less resistant. When the larvae are young, it is much more difficult to be sure of their presence, but it is said that any bulb in which the basal ring is incomplete or damaged should be regarded with suspicion.

When a number of bulbs in a row fail to appear in the spring, those which have missed should be searched for and destroyed. Bulbs should be lifted in summer and all found to be infected should be destroyed. Bulbs may be steeped in water for from 24 to 48 hours. The water should be just warm, and if possible should not be allowed to become very cold in order not to injure the bulbs. The steeping seems to make the bulbs swell, so that the larvae are forced out or drowned, though they can live for many days when immersed. This treatment has been found very effective. Netting the flies with a butterfly net has been found quite successful in gardens.

The Small Narcissus Fly (*Eumerus strigatus*) has been only recently recognized as seriously injurious to Narcissi ; it attacks also Hyacinths, Onions and Shallots (the two latter only on the Continent).

The systematic description of this insect, as well as its life-history, which has not yet been completely traced, are given in the leaflet.

In an advanced stage of the attack the interior of the bulb is entirely destroyed and is full of a semi-liquid decaying mass. The attack seems to begin at the neck, and in mild cases the larvae are found in the neck or under the scales at one side. The presence of many larvae and the complete

decay produced distinguish the damage done by *Eumerus* from that done by *Merodon*.

The destruction of affected bulbs when lifting is obviously indicated, and since the decay produced is rapid there is little difficulty in recognizing them. Early lifting also seems desirable to destroy the larvae before the emergence of the second brood.

The larvae of several other flies are frequently found in bulbs decaying from other causes, but they do not appear ever to start an attack on a healthy bulb. The commonest species are *Lonchaea chorea* and species of *Scatopse* and *Sciara*.

The Grass and Clover Seed Industry in New Zealand

by

A. H. COCKAYNE

Biologist, Department of Agriculture, Industry and Commerce, New Zealand.

New Zealand Agriculture is not conspicuous for harvested crops. The area devoted to them is insignificant when compared with that utilized for grazing or feeding-off by stock. During the season 1913-14 less than eight hundred thousand acres out of a total of forty odd million acres that are under occupation were utilized for the production of all kinds of harveted produce, including hay. Less than one per cent of the sown grasslands are annually cut for hay, and this gives a very clear indication of the small provision that need be made in New Zealand for the production of stored winter feed. As, compartively speaking, no exportation of cereals takes place, the reason for the minor position of annually harvested crops is readily explained. Of the 800 000 acres employed in their production, over 100 000, or more than 12 per cent., were devoted to grass and clover seed. Thus the growing of "pasture seeds" occupies quite an important position amongst the minor agricultural industries; in point of view of both acreage and value of production, pasture seed raising ranks third in importance (after oats and wheat) and far exceeds in value the hay crop.

Although New Zealand is eminently adapted for the successful production of all kinds of pasture seeds a large quantity is annually imported. This is due to the fact that the utilization of land purely for growing pasture seeds is rarely attempted, and unless the growing of a comparatively pure crop of any grass or clover will fulfil other functions besides that of producing a seed crop its cultivation is not entertained. The only grasses that are grown on any extended scale purely for seed production are

Crested Dogstail and Western Wolths Ryegrass; in nearly overy other case the primary object in the laying down of grassland is the securing of either temporary or permanent pasturage. Whether or not the grassland will be shut up for seed depends on the market prospects and whether the farmer intends to stock the whole of his grazing area fully during the summer. The profit to be made by temporary fattening is in most cases the deciding factor. Thus grass and clover seed raising can in New Zealand be looked upon as really a bye-product of pasture land made use of when it appears to be more profitable to let the seed mature than to feed off the growing herbage with grazing animals for the elaboration of mutton, beef or butter fat. It would thus be surmised that the main pasture seeds produced in the Dominion would be those that comprise the dominant elements of the ordinary pastures. This surmise would be quite correct: the two main grass seeds produced are those of Ryegrass and Cocksfoot, which represent the two main grasses used in pasture formation and which form the dominating elements in the majority of the sown grasslands of New Zealand.

The demand for "pasture seeds" in New Zealand is large and probably no other country in the world uses a larger variety in the laying down of permanent pastures. The formation of permanent pasture is one of the most important features of New Zealand agriculture. There is no natural grassland that in any way corresponds with true pasture and the grasslands of New Zealand can be sharply divided into two classes: the natural grasslands and the sown grasslands. The former are characterized by the dominance of tall, densely tufted tussock grasses, belonging to the genera *Poa* and *Festuca*, growing at more or less regular intervals from one another and never making a compact sward capable of being mown. The sown grasslands are characterized by consisting almost entirely of European pasture grasses belonging mainly to the genera *Dactylis*, *Lolium*, *Festuca*, *Agrostis* and *Holcus*, and forming in most cases a uniform sward kept closely cropped by grazing animals. The sown grasslands comprise some 17 million acres, of which about four million consist of leys with a duration of from 2 to 7 years, the remainder being permanent pasture. Each year about one million acres are sown down in temporary and permanent pasture, the area in the latter being steadily increased through the conversion of native vegetation, mainly forest, into grassland. As roughly over 25 pounds of seed is used per acre, the annual consumption of pasture seeds is roughly about 12 000 tons.

Although a very large variety of grasses and clovers are sown in New Zealand, only a few are grown for seed purposes in sufficient quantities to satisfy the local demand. These are the following:

1. Perennial Ryegrass (*Lolium perenne*).
2. Italian Ryegrass (*Lolium italicum*).
3. Cocksfoot (*Dactylis glomerata*).
4. Chewing's Fescue (*Festuca saburicola*).
5. Danthonia (*D. pilosa* and *D. semiannularis*).
6. Ratstail (*Sporobolus indicus*).

7. Prairie grass (*Bromus unioloides*).
8. Reed Fescue (*Festuca arundinacea*).
9. Yorkshire Fog (*Holcus lanatus*).
10. Suckling Clover (*Trifolium minus*).
11. Boyd's Clover (*Lotus angustissimus*).
12. Lucerne (*Medicago sativa*).

The following are regularly produced, but in insufficient quantity to cater fully for the local demand :

1. Crested Dogstail (*Cynosurus cristatus*).
2. Meadow Foxtail (*Alopecurus pratensis*).
3. Red Clover (*Trifolium pratense*).
4. White Clover (*Trifolium repens*).
5. Birdsfoot Trefoil (*Lotus uliginosus*).
6. Western Wolths Ryegrass (*Lolium italicum* var.).

Grasses and clovers that are regularly used in the laying down of pasture but which are rarely harvested in any appreciable amounts are the following :

1. Kentucky blue grass (*Poa pratensis*).
2. *Poa trivialis*.
3. Timothy (*Phleum pratense*).
4. Sheeps Fescue (*Festuca ovina*).
5. Red Fescue (*Festuca rubra*).
6. Hard Fescue (*Festuca duriuscula*).
7. Meadow Fescue (*Festuca pratensis*).
8. Fiorin (*Agrostis alba*).
9. Red Top (*Agrostis vulgaris*).
10. Brown Top (*Agrostis canina*).
11. Paspalum (*Paspalum dilatatum*).
12. Alsyke (*Trifolium hybridum*).
13. Trefoil (*Medicago lupulina*).

It will be noted that nearly all the recognised pasture grasses of Europe are made use of, with the notable exception of Tall Oat Grass (*Arrhenatherum elatius*) ; although fairly widely naturalized, it is not used in New Zealand agriculture.

The main Pasture Seeds harvested.

Perennial Ryegrass. — About 50 000 acres are annually cut for seed. The majority is harvested from pastures of short duration, although a proportion is procured from permanent pastures. In many parts, notably on the east coast of the South Island, it is a regular practice to crop land for a season or two with annual crops and then lay it down in Ryegrass, White and Red Clover ; it then remains in pasture until such time as the land is again required for cropping and during this period several crops of seed may be taken off. The permanent pastures of Ryegrass are mostly found in the North Island and if not required for fattening purposes a seed crop is harvested in certain cases annually. In most cases stock are exclu-

ded for about three months of the year, but in certain instances the land may be lightly stocked even after it has been decided to harvest a seed crop. The crop is generally cut with a reaper and binder, but a stripper may be occasionally employed. The yield varies from 400 to 600 pounds per acre. The land from which the seed is harvested is ordinary pasture in which Ryegrass, although dominant, is only one of the elements of the association; as no cultural methods are adopted the harvested product contains a large proportion of seeds other than Ryegrass. Thus the cleaning of the harvested seed is a very important matter and in some instances a loss of over 50 per cent. by wieght is experienced in the dressing, although as a rule 25 per cent. may be looked upon as the average. The cleaning is done by power machines; in most cases rotary riddles of varying mesh are employed for removal of the extraneous seeds, and winnowing is also utilized for the extraction of light seed. The bushel weight varies from 26 to 36 lbs. and 30 lbs. is looked upon as the minimum bushel weight of first-class machine-dressed seed. The germination of high grade seed is over 90 per cent., and 75 per cent. is the average of all lines. The total crop sometimes exceeds 8 000 tons of dressed seed, and nearly the whole of this is used locally, only a cemparatively small quantity being exported and that mainly to Australia.

It is difficult to determine the amount of *Italian Ryegras* produced, as there are no separate figures for this crop, but 1 000 tons would be a moderate estimate. The yield of Italian is on the whole higher than that of Perennial Ryegrass, and the bushel weight is rarely more than 23 pounds. In most cases the purity of machine-dressed seed is low, owing to the large amount of Perennial Ryegrass that is generally present in the pastures from which the seed is harvested.

Cocksfoot. — An average of 30 000 acres is annually harvested. The main quantity of seed is produced on steep hillsides on Banks Peninsula in the South Island and is termed "Akaroa" Cocksfoot. Cocksfoot is also harvested by machines from level pastures of Cocksfoot and Ryegrass, when it is termed "Plains Cocksfoot", and even after machine dressing may contain as much as 30 per cent. of Ryegrass. All the hillside Cocksfoot is cut and threshed by hand labour and each man is paid from 1*s* 3*d* to 1*s* 6*d* per hour. The bushel weight of machine-dressed seed varies from 14 to 20 pounds, 16 lbs. being looked upon as the standard. The average yield is about 160 lbs. per acre and the loss in cleaning averages 20 per cent. Machine-dressed seed of 16 pounds bushel weight generally contains less than 3 per cent. of extraneous seeds (consisting mainly of *Holcus lanatus* and *Hypochaeris radicata*) and about 10 per cent. of empty and semi-empty husks. The germination of the *pure* seed averages about 84 per cent. The annual crop occasionally exceeds 2 000 tons of dressed seed. A considerable amount of Cocksfoot is exported to Europe, and for years New Zealand seed was looked upon as superior to that from any other country at the present time, however, Danish seed is looked upon with more favour than formerly, and threatens to supersede New Zealand on the European markets unless our local seed is cleaned to a higher standard than is a

present adopted. The price of labour is now so high in New Zealand that the margin between the cost of the undressed seed and the average price for dressed seed in Europe is too small to allow of any more loss in cleaning than is now experienced.

Chewing's Fescue (*Festuca saburicola*). — About 6 000 acres are annually harvested in the southern portion of the South Island. The yield averages about 400 lbs. per acre. As Chewing's Fescue forms one of the purest of the New Zealand pasture associations, the amount of extraneous seeds is not great even in undressed samples, but seed of this fescue, like many other species of the genus, contains a large percentage of empty husks, and thus the loss in cleaning is often very great. A large proportion of the seed is exported to Europe where it is sold under the name of New Zealand Red Fescue. The germination is generally high and when harvested under good conditions averages over 85 per cent.

Pasture Seeds Harvested in Small Quantities.

Besides the four grasses mentioned, a number of others are harvested in limited quantities. The most important of these is *Crested Dogstail*, which is occasionally produced in sufficient amount to more than satisfy the annual local demand of about 150 tons.

Clovers are not extensively harvested and roughly about 3 000 acres are cut for seed. The most important is *Red Clover*, nearly always sold under the name of Cowgrass, but the quantity produced is never sufficient for local requirements. The large number of species that are regularly sown but not grown for seed is peculiar, but is explained by the fact that none of them normally occupy a dominant position in any type of pasture, although the majority are generally distributed throughout the majority of our sown grazing land. Wherever a pasture consists mainly of a single species it may be shut up and harvested for seed ; thus in certain instances such grasses as Meadow Foxtail, Danthonia, Prairie grass and Reed Fescue may be harvested in quite large amounts. In very few instances, however, is the pasture laid down with the express inteution of utilizing it for seed production, but the conditions being favourable for the final development of a comparatively pure association of a single species the production of a seed crop of that particular species becomes profitable and this practice is then adopted.

Seed Cleaning.

There are two systems in vogue with regard to the cleaning of grass and clover seed. In the first one the merchant pays so much per pound to the farmer for his seed in the rough, *i. e.* uncleaned. In the other the merchant pays a certain price for the seed after it has been dressed and brought up to a specified purity and bushel weight. When seed is bought in the rough the merchant puts it through the cleaner, of which he is generally the owner, and utilizes any bye-products that may result. When the merchant buys machine-dressed seed the farmer has to pay for the

cleaning and is credited with the value of any bye-products that are of any commercial value. The price paid for cleaning varies with the kind of seed that is being dealt with. Ryegrass generally costs 3*d* for every 20 pounds put through the machine, and Cocksfoot and Chewing's Fescue about ¼*d* per pound, while Crested Dogstail generally averages about ½ *d* per pound. The price charged for clover cleaning varies according to the purity to which it has to be dressed, but ½ *d* per pound is about the average price in vogue.

The large amount of impurities that are general in New Zealand harvested grasses and clovers, due to the utilization of ordinary mixed pasture for their production, has necessitated the invention of many mechanical devices in order to produce a clean line. The majority of the seed-cleaning machines in use are manufactured locally and have been specially designed to suit local requirements.

Bye-products of Seed Cleaning.

The main object of seed cleaning in New Zealand is the more or less total removal of all extraneous seeds. It is not unusual for many lines to contain large quantities of extraneous seeds that have a commercial value and many of the cleanings are re-cleaned and sold. In many instances the value of the bye-products of the machine cleaning are sufficient to cover the cost of dressing the original seed, and in certain instances the bye-product may be more valuable than the seed that is being dealt with. The main grass and clover seeds of commercial value found in cleanings are as follows:

1) Yorkshire Fog (*Holcus lanatus*). — A bye-product of most grass seeds in New Zealand. Although Yorshire Fog is only intentionally sown in certain situations, it is a regular constituent of nearly all pastures. The covering glumes are always removed in the cleaning process and the re-cleaned article is quoted as " shelled Fog ". The majority of the seed is exported to Europe and Australia.

2) Suckling Clover (*Trifolium minus*). — Like Yorkshire Fog, Suckling Clover is a regular constituent in all pastures although it is rarely intentionally sown. The seed is all exported to Europe and is most probably used as an adulterant in White Clover. It is significant in this respect that the brighter the sample the more readily will it sell, while dark coloured lines, even though the germination and purity may be excellent, are comparatively unsaleable.

3) White Clover (*Trifolium repens*). — White Clover is frequent in undressed Ryegrass seed and whenever it occurs in appreciable quantities is re-cleaned. It is generally of excellent quality and is often used to mix with imported lines to improve the colour. In certain instances undressed Ryegrass may contain as much as 25 per cent. of White Clover.

The major portion of the cleanings from New Zealand seed consist of Sorrel (*Rumex Acetosella*), Goosegrass (*Bromus hordeaceus*), Catsear (*Hypochoeris radicata*) and Sweet Vernal (*Anthoxanthum odoratum*), while

during certain seasons large amounts of Ergot sclerotia are removed from Ryegrass. None of these have any commercial value, although at times certain of the cleanings are ground up and incorporated into stock feeds. In general, however, the majority of the cleanings are burnt.

Adulteration of Seed.

Comparatively no adulteration of pasture seeds occurs in New Zealand. In certain instances Chewing's Fescue (*Festuca saburicola*) may be sold under the name of Sheep's Fescue (*Festuca ovina*) and occasionally Suckling Clover (*Trifolium minus*) is added to lines of White Clover. Formerly Cocksfoot was sometimes adulterated with either Ryegrass or Chewing's Fescue, but this practice is now rare. The mixing of different grades of the same species is, however, not uncommon. This refers more particularly to Ryegrass, where a low and a high germinating line may be mixed together in about equal amounts. There are many lines of New Zealand grown grasses on the market that contain a very large percentage of extraneous seeds, but these are in no case examples of adulteration. They simply represent seed that has not been properly dressed and has been harvested from mixed pasture in which a single species, although the dominant element of the association, may not occupy more than 70 per cent. of the ground. Ordinary machine-dressed seed, with the exception of Italian Ryegrass, however, is nearly always of high purity so far as freedom from extraneous seeds is concerned. Seed cleaning has in New Zealand been raised to a fine art and the standard set by seed cleaners is so high that so far as purity is concerned, machine-dressed local seed compares more than favourably with that imported.

The Present Condition of Forestry in Hungary

by

Károly Schmidt,

Royal Counsellor for Forests and Waters.

Forest Legislation. — The forest law XXXI, of 1879, marks an important point in the history of Hungarian forest economy. This law, made necessary by the devastation and progressive diminution of the forests between 1850 and 1870, gave wide powers to the State, though at the same time respecting the rights of private property. After the abolition of servitudes and the development of small freeholds, large extents of forest fell into the hands of peasants who knew little about their management, and either cleared them for cultivation or ruined them by excessive grazing. At the same time the economic development which started in 1870 and the improvement in means of transport due to railway construction, both increased the demand for wood and facilitated heavy exploita-

tion of the forests. It was thus essential for the State to take energetic action to check the constantly increasing deforestation.

The clauses of the forest law, or *forest code*, as it may well be called, provide for the maintenance of forests in the interests of public economy and take full consideration of the question of situation and soil, dealing with protection forests, forests on shifting sands and those on soils which could not be profitably used for other types of cultivation (arable or grass land, gardens or vineyards). In the forests of the first type, clearing and clear felling are prohibited : in those of the other two types only clearing. Further, removal of litter is prohibited in protection forests and forests on shifting sands ; and in these types grazing is not allowed when it might result in damage to the trees, the young growth or the soil.

The clauses relating to rational exploitation of the forests refer to forests owned by the State, by "jurisdictions" (1), by communes, by religious bodies and by the clergy ; as well as to forests under the control of special foundations and held in trust ; also to "compossessoral" (2) forests, which include those which, under the "urbarial rule" (3), have become the property of the former vassals. Lastly, these clauses are also applicable to forests belonging to limited companies founded for working mines or for other industrial undertakings. The forest law imposes the exploitation of the forests mentioned according to the plans for systematic management (Art. 17), and prohibits the employment for the purpose of persons other than forest agents who have been through a special technical training (Art. 21).

The forests of the Kingdom of Hungary occupy an area of 22 113 950 acres, which is 27 per cent. of the total area of the country. Of this area Hungary proper with Fiume possesses 18 332 010 acres (26 per cent. of its total area), while Croatia-Slavonia contains 3 781 940 acres (35 per cent of the total area). Under the forest law, the various forests are submitted to plans of management according to their nature as shown in Table I.

As the owners of communal and other forests could not themselves bear the expenses entailed by the plans of management without burdening their estates with a mortgage out of proportion to their incomes, it was necessary to make the provisions of the forest law capable of practical application. For this purpose, law XXXI of 1879 was supplemented by law XIX of 1898, by virtue of which small and large communes possessing forest property of an area of at least 5 000 arpents (7 110 acres) only have the right of maintaining forests at their own expense if they can include in their budgets the sums necessary for the management of the woods, and if the exploitation proves profitable. If this is not the case, all these forests

(1) This is the title given to bodies, counties and free or royal boroughs which formerly had the right of holding courts of justice.

(2) A "Compossesorate" is a meeting of nobility who hold in common certain land which remain in the family without division.

(3) This rule was established to allot to the peasants of every territory certain land which they received either in exchange for rights of usage or by purchase from the owne

(*) The forests of Croatia-Slavonia are submitted to the system of management established by the special law of 1894 and 1895; the regulations concerning fruition and exploitation agree in essentials with those of the law XXXI of 1879.

as well as those to which art. 17 of the law of 1879 refers, shall be under the State Forestry Department.

For the administration of the forests, the owners are required to pay an annual tax. In 1912, the State administered 16 710 forest estates with an area of 5 058 432 acres. The taxes paid by the owners amounted to 792 503 crowns (£33 021), as against 2 664 142 crowns (£111 006) for the expenses of the State.

The provisions of the above-mentioned laws, as well as the data given above, show on the one hand that these laws ensure the preservation and maintenance of forests situated on land unsuitable for other cultivation, and on the other hand that they guarantee systematic exploitation controlled by the authorities to such an extent that the forests under uncontrolled exploitation represent only a very small portion of the total area of forest in Hungary. Considering the unsystematic exploitation of the preceding period, this restriction was very necessary to the forestry of Hungary; moreover, it should continue to be so, for although as regards forest area our country occupies a very good position, many of the Hungarian forests contain a relatively small bulk of standing timber, and consequently do not afford the permanent and uniform production of normal forests.

Distribution of forests and species of trees in the different parts of Hungary. — As most of the forest regions of Hungary extend along the Carpathians and their spurs, they bear the characteristics of the medium and high mountain types. In the northern forest region are found pine, silver fir, spruce and beech. The regions of the east (Eastern Hungary and

Transylvania) and the south-east, are for the most part covered with beech, silver fir and oak being of less importance. The forest region of the west is situated on the right bank of the Danube upon the slopes of the mountains of intermediate altitude; here, the principal trees are beech and oak, together with Scots pine. The region between the Danube and the Tisza, *i. e.* the Alföld, which extends to the southern frontier of the country, is the least rich in woods; here, oak and beech play only an unimportant part, and pine is almost absent; on the other hand, false acacia is found and in some places willows and poplars. In general, the forests of Hungary consist of trees belonging to the Central European flora. The respective percentages are given in Table II.

TABLE II. — *Percentage areas occupied by the different trees in Hungary.*

Beech	36.11
Oaks (*Q. Robur* [*pedunculata*] and *Q. sessiliflora*)	21.04
Turkey oak (*Q. Cerris*)	5.64
Spruce	14.34
Silver fir	4.34
Hornbeam	9.03
Birch	2.34
Poplars and willows	2.16
Ashes, elms, maples	1.42
False acacia	1.00
Scots pine	1.99
Larch	0.06
Alder	0.45
Limes	0.08

There are also found, although rarely, Austrian pine (*Pinus austriaca*) and stone pine (*P. Cembra*).

The area of 22 113 950 acres under forests in the Kingdom of Hungary is distributed as follows:

	Hungary proper with Fiume	Croatia-Slavonia
	acres	acres
Beech and other bread-leaved trees	9 084 023	2 520 175
Oaks	4 872 504	831 377
Conifers	4 375 483	430 389

Hungary possesses more beech than can be profitably used. Although beech is finding increasingly wide uses, the practice has been adopted, as a principles of forest economy for special cases, of substituting oak, pine or silver fir for it.

Forest Management. — More than 65 per cent. of the forests of Hungary are high forest; the rest are coppices, of which a very small portion are with standards. In some places, in consideration of the grazing rights, the system of grazing-forests has been maintained. The spruce and oak forests are mostly exploited by clear felling with artificial regeneration of the cleared

round, while in forests of silver fir and mixed forests the system of gradual elling obtains. In beechwoods either system is practised, according to the equirements of natural regeneration. In protection forests, and in some ther places, in order to ensure regeneration and to guarantee the productiity of the soil, selection felling obtains. Coppice growing is practised specially in the smaller forests, sometimes also for the production of tan ark; further, in the poplar and willow plantations and in *Robinia* forests hich cover the Alföld. In the high forests, the rotation varies between 0 and 120 years ; in the coppices, between 10 and 60 years.

The work of reafforestation. — In the system of the reafforestation of orests which have been cleared, artificial regeneration plays an increasngly important part. The Government shows great activity in all that concerns the replanting of the communal and other forests submitted to its management. Further, to assist regeneration, it encourages and favours the work of private individuals by means of grants, State premiums and the annual distribution of large quantities of young trees; these are supplied either gratuitously or at a low price. The forest law of 1879 havng established a National Forest Bank, maintained by fines for the infraction of regulations, its funds are destined, for the most part, to provide premiums and subsidies, and for carrying out useful forestry work. A considerable sum from the budget of the forests exploited by the State goes also to the creation of nurseries and to reafforestation. Further, a large sum is devoted from year to year to the regeneration of bare and eroded areas. Finally, the forest directions and the Treasury forest offices, as well as the foresters' schools, distribute a large number of trees for reafforestation purposes.

The following data afford an illustration of what I have just said : In 1912, the State gave 30 different premiums of the value of 15 000 crowns (£ 625) for the reafforestation of bare land effected independently of the State ; further, 1039 poor proprietors received grants of £ 6 390 for reafforesting 6 754 acres of bare land; four nurseries (116.4 acres) of the special foresters' schools furnished 6 986 000 young trees; 186 nurseries (1360 acres) administered by the forest offices provided 64 586 000 trees. Of these trees 37 265 000 were distributed free to 2101 proprietors. From nurseries with an area of 845 acres managed by the owners at their own expense, 46 million trees were used for reafforestation. Finally, 1 609 000 young trees were handed over to private individuals by the forest authorities of the Treasury. In 1912 the areas planted were :

	acres
Land to which art. 17 of the law refers	138 218
Private land	13 522
Land not prescribed for reafforestation	6 766
Total . . .	158 506

A further 74 908 acres remained unplanted on account of unfavourable climatic conditions, deficiency of seeds and want of labour.

In 1913, the National Forest Bank gave £ 2 651 8s for reafforestation. According to the budget of the communal forests, etc., a sum of £20 400

was devoted to the same object. Further, a sum of £54 000 was granted for the reafforestation of bare and eroded land.

We should also note that for a number of years the labours of the State in the domain of forestry, especially in that of afforestation, have been crowned with success : thus the replanting of the moving sands on the borders of the towns of Szabadka and Szeged amongst others, and the fixing of the moving sands of the Puszta Déliblát, constitute remarkable performances of Hungarian forestry and are also well known abroad.

Exploitation of forests and utilization of timber. — The timber felled on moderate sized forest estates is, for the most part, used by the proprietor for his domestic and agricultural requirements, so that only the larger estates are in a position to market timber ; this not only serves to satisfy the demands of the country, but also gives rise to an export trade.

The most valuable tree is oak, furnished by the forests of Eastern Hungary, Transylvania and Slavonia ; these oak woods enjoy a world-wide reputation. Then comes the fir of the Carpathians and Transylvania, which can hold its own on the European market. As for beech wood for carpentry, its exportation, especially to Italy and Spain, is progressively increasing. The chief external trade is with Austria, whence we import large quantities of deal. In 1912 the total amount imported by Hungary was 660 800 tons, worth £ 1 334 000, while 1 060 700 tons, worth £ 3 463 000, were exported.

Cattle breeding being practised on a large scale in Hungary, the question of pasturage has often caused difficulties, especially on account of the preventive measures adopted in favour of forestry. The question has been solved, thanks to the elaboration and application of the system of grazing forests, according to which the requirements of stock-breeding can be satisfied as far as the state of the forest and its soil permit. At present, most of the forests are already free from servitude and the work of dividing the properties is, to a great extent, completed.

The State forests. — In Hungary, the largest owner of forests is the Treasury. Its forest enterprise, which has long been carried out in a systematic manner, is one of the largest of the State undertakings, and is a considerable factor in its financial resources. Also from the points of view of public and economic interest, the State forests play an important part in the forestry of the country.

Table III gives the area of the State properties in the forest regions according to the branches of cultivation.

The total value of the properties amounted to £ 9 024 in 1912. The distribution of the various trees in the State forests is given for 1912 in Table IV.

With the exception of some forests of oak and of softwood broad-leaved trees in the south of the country and in Slavonia which are in the plains, the State forests clothe the mountain districts, especially in the highest zones. Above these occur alpine pastures in many districts, and the greater part of the sterile ground is also found here in the rocky regions above the limits of vegetation. The alpine pastures and the meadows are let t

TABLE III. — *Areas of the Hungarian State properties in the forest regions (acres).*

the inhabitants of the respective districts. Of the alpine pastures belonging to the Treasury, about one-half are found in Maramaros county, where are established model dairies and cheese factories, which are being imitated in other districts of Hungary. In the mountainous regions, fish-breeding is also practised, trout being the most important fish. Pasturage, letting of meadows, fisheries, shooting, the temporary agricultural exploitation of clearings, brick-making and lime burning yield at present, as secondary resources of the forests, an annual revenue which may be estimated at £ 75 000, while the primary resources, which include charcoal and the production of wood for firing, carpentry and building, as well as of sawn wood (beams, props and staves) bring in an annual revenue of £ 1 000 000.

According to the budget of 1912, the expenditure on the State forests was £ 752 000 and the receipts were £ 1 033 000, which gives a balance to the good of £ 258 000, or a profit of 1s 5*d* per acre. In previous years, when circumstances were more favourable, the budget showed profits of from £ 290 000 to £ 375 000.

Before giving an opinion upon the results obtained in our time, it is necessary to take into consideration the fact, that it is not yet possible to practise in Hungary the intensive exploitation of forests which obtains in

Western countries ; on the other hand, we must not forget that wages, the great cost of transport, patronage charges and loans given free or at a low interest, are also a heavy burden upon the State enterprise.

The timber is sold by public auction, either as it stands or in depôts as sawn timber. As wood for carpentry and builder's timber is also sold retail, not only the large merchants, but also small traders, are able to purchase it. The retail sale is effected according to prices fixed in the tariff for forest products.

For transport, more than 6000 miles of large and small forest roads, 1 250 miles of waterway and 168 miles of railway are available. Much importance is now attached to the last means of transport, on account of the great distances and the large quantity of timber of enormous dimensions to be transported. The expense of the organization of means of transport, building and the purchase of real property must be estimated at £ 62 500 per annum.

The cost of the reafforestation effected in 1912 on the State properties is set forth in Table V.

TABLE V. — *Reafforestation effected in* 1912 *on the State Properties.*

In Hungary, the Treasury nurseries (857 acres) have furnished for:

reafforestation of the State forests. . . 38 243 000 trees
private persons . . . . . 1 609 000 »
the promotion of silkworm breeding . 4 892 000 young mulberry trees.

Of the trees supplied, $^5/_6$ were pines and $^1/_6$ oaks and other broad-leaved trees.

In Croatia-Slavonia, the State nurseries (11 ½ acres) yielded 701 000 young trees for the use of the State forests.

The Staff of the State forests consists of : 501 foresters, 87 accountants, 8 clerks, 9 doctors, 22 assistant foresters, 1391 forest rangers, 266 foremen. The number of permanent woodsmen is 2300, while other workmen number about 22 000.

Organisation of the Forest Administration. — The direction of all forestry matters devolves upon the Hungarian Ministry of Agriculture, which for the accomplishment of this task has created and incorporated

two large forestry sections, of which one carries out the work relating to Hungary proper : *viz.* 1) forest inspection and administration ; 2) arrangements regarding forest exploitation ; 3) administration of the forest register ; 4) experimental service ; 5) forest statistics ; 6) control of the Staff; 7) technical instruction ; 8) the reafforestation of denuded land. The other section superintends all the economic and administrative business relating to the State forests situated in Hungary and Croatia-Slavonia, as well as all matters regarding the workmen, the proprietors and patronage.

In order to ensure the general supervision of all the forests, the country is divided into 20 districts, at the head of each of which is placed a royal forest inspector with the necessary assistants under him. In each county has been instituted a commission of forest police, to which the forest inspector is attached in the capacity of consulting member. Matters regarding infractions of forest regulations are dealt with by the administrative organs.

Compossessoral, communal and some other forests are administered by a forest direction with 43 forest offices, to which are subordinate 167 forestry agencies which extend their services to 91 counties and municipal boroughs. The forests of the city of Fiume are directly under the Ministry. In the Government administration are employed 294 superior and 100 subordinate functionaries, who supervise the reafforestation work. The proprietors are responsible for the maintenance of the foresters. The State forests in Hungary are administered by four forest directions, four chief forest offices and seven other forest offices ; in Croatia-Slavonia, they are administered by a forest direction, one chief forest office and one other forest office.

In conclusion we will give some information respecting instruction in forestry, the Service of forestry experiments and the part played by the National Forestry Society.

Forestry Instruction. — In 1770, the Empress Maria-Theresa founded at Selmeczbánya the Royal Academy of Mines, to which was annexed in 1807 a chair of forestry and from which there afterwards developed the Royal College of Mines and Forests. It trains foresters, for whom the course extends over 4 years ; only students possessing matriculation diplomas are admitted. After passing the leaving-examination, students must also pass a State examination in forestry preceded by two consecutive years of practical work.

During the scholastic year 1911-1912, the number of lecturers was 14, while the students numbered 405.

Lower grade forestry instruction is given in the four Royal Forest Rangers' Schools, founded by the State between 1883 and 1893 at Királyhalom, Vadászerdö, Liptóujvar and Görgényszentimre. The course lasts two years and the students are boarded. These schools give both theoretical and practical instruction. One of them has a normal supplementary course extending to the third year. The syllabus of the latter is so arranged as to allow of the students being employed in the administra-

tion of small private forest estates. The teaching Staff of these four schools was in 1912 : 4 directors, 4 masters, 4 assistant masters and 18 forest rangers. During the scholastic year 1911-1912, the number of students was 157. These four schools have administered : 9881 acres of forests, 116 acres of nurseries and 119 acres of botanical gardens.

Those persons who have received practical forestry instruction for three years, and have passed the examination for forest rangers may be regarded as fully competent from the technical point of view.

In Croatia-Slavonia, in 1898, a College of Forestry with a four years' course was attached to the University of Zagreb. The teaching Staff consisted of 6 special forestry lecturers, and 23 University professors and Government functionaries. The number of students in 1912 was 64. In Croatia, there is in addition a private school for forest rangers.

Service of Forestry Experiments. — In 1898, there was added to the College of Forestry a Central Station for Forestry Experiments, while four other such stations affiliated to the central one were attached to each of the Schools for Forest Rangers. These stations show great activity in all matters relating to planting, growth, conditions of cultivation, systems of management, etc. The results obtained from these experiments are published in the periodical entitled *Erdészeti Kisérletek* (Forestry Experiments) .

The *National Forestry Society*, which has its seat in Budapest, was founded in 1863. It possesses 2087 members (of whom 867 are original members and 1220 ordinary members). It has a library and has published for the last 53 years a bi-monthly periodical - *Erdészeti Lapok* (Forestry leaflets). Further, it makes a grant to the professional journal *Erdõ* (The Forest) intended for subordinate forest officials. At the end of 1913, it had a capital of £.42 072. Its aim is to increase the spread of useful information concerning forestry, and to guarantee the interests of forest agents and assist their widows and orphans.

There are in addition : three *Provincial Forestry Societies*, the *Forestry and Hunting Society*, and the *Society of Subordinate Forest Officials*.

In 1877, the *Forestry Society of Croatia-Slavonia* was founded at Zagreb ; it now has 1405 members. This society publishes the forestry journal *Sumarski List* (Journal of Forestry) and as a supplement to the latter, *Lugarski Vijestnik* (Foresters' Communications). At the end of 1913, its capital amounted to £ 7856.

Report on the Poultry Industry in South Australia

by

D. F. LAURIE,

Poultry Expert & Lecturer.

From the earliest days of the founding of this State, poultry keeping has formed a by no means inconsiderable branch of rural industries. It was soon found that the equable climate and general conditions were most

favourable to all breeds and varieties of domestic poultry. Various importations of different breeds were made from time to time until in due course the newest breeds and varieties evolved in other countries were soon represented here. The fancier was primarily responsible for the introduction of the various breeds, and very soon poultry societies and shows were organised. At the present time there is one Metropolitan Society, in addition to which the Royal Agricultural and Horticultural Society does much to encourage the poultry fanciers, and provides numerous classes at its Shows. In the country districts are numerous poultry societies, and also Agricultural Societies which provide classes for poultry at their annual shows. Specialist clubs attend more particularly to the welfare of several of the prominent breeds.

The poultry fanciers as a rule are not large breeders, and few breed more than two hundred chickens in a year. Farmers thoughout the State keep flocks varying in numbers from one to five hundred. The utility breeders, collectively, are becoming an important factor in this State, and many of them breed from one to five thousand or more chickens in a season. At the present time there is a general move in the direction of larger plants, and several are in operation which will shortly provide for several thousand layers and the production annually of many thousands of chickens. Egg production is receiving more attention than flesh production, as the general opinion is that the former is the more certain, and also the more profitable branch.

Among the utility breeders for egg production the White Leghorn (Australian type) is the most popular. There are a few who breed Minorcas, Brown Leghorns, and laying strains of Orpingtons, Langshans and Wyandottes. The all round breeds such as Orpingtons and Wyandottes, Langshans, and Plymouth Rocks are bred in fair numbers and there is every evidence that there will shortly be a great revival in these, or at amy rate some of them.

Imports. — No poultry or eggs for human consumption are imported into this State. Poultry breeders import on the average about a thousand head of various breeds from the other States, and oversea, for breeding purposes. They also obtain from the other States annually a few hundred dozens of eggs for hatching.

Exports. — Shipments of eggs in cold storage have been successfully sent to England. Each year some thousands of chickens and ducklings have also been shipped to England where they realised excellent prices. At the present time the great prosperity and rapidly increasing population of the Australian States result in excellent markets for all our available surplus. Increased prosperity and large demand have resulted in very materially improved prices, so that the prospects of the oversea trade, as at present, are not so enticing as they were. The annual value of eggs and poultry sent to the other Australian States is over £ 150,000, and the annual value of the poultry products of this State is £ 750 000. While the growth of the industry has been satisfactory as regards quantity, the increased value is largely due to the higher prices obtained for the products.

TABLE I. — *R*

Large numbers of high class stock are sent to the adjoining States, New Zealand, South Africa, America, India, and other parts.

Prospects of the industry. — There is no branch of rural activity which can offer to the producers of this State a more satisfactory prospect, as regards markets. Not only are the interstate markets satisfactory and likely to continue, but in addition the general shortage in the World's supplies of eggs and table poultry affords markets in England and on the Continent, which will be available for profitable exploitation in the near future.

Government Assistance. — Seventeen years ago the Government of the day was struck by the possibilities of the industry. An experienced breeder and expert was appointed to lecture in the country districts and to write pamphlets and articles and to take steps to promote the breeding of poultry on commercial lines. Grants of money were made to various poultry and agricultural societies to provide prizes to encourage the breeding of certain specified breeds of poultry.

Exhibits of an instructive nature were organised, and staged at the metropolitan and the chief country agricultural shows. These exhibits demonstrated the best methods of packing eggs and poultry for market. Principal foods, with their uses and feeding values, were shown, together with a mass of valuable information in statistical form easily understood. In connection with the export trade to England the State made cash advances on both eggs and poultry shipped, in addition to undertaking the grading, packing and shipping of eggs, and the killing, preparation, grading and packing of table poultry, also the sale in England.

The Poultry Section of the Department of Agriculture is organised as follows:

The Poultry Expert & Lecturer is officer-in-charge, assisted by two Inspectors. Correspondence, which includes a large amount of instruction, the designing of poultry plants for breeders, investigation of

e series of Tests.

Eggs Laid by Winning Pen.	Market Value	Cost of Food per Hen.	Return per Hen.	Profit per Hen.	Average Price of Eggs per Doz.

1 413	663 11 2	5 7.8	16 6	10 10.2	13.06

diseases, the inspection of poultry yards under the Stock Diseases Act, are carried out from the Adelaide Office.

The Expert lectures at various country centres in connection with local Agricultural Bureaux and Agricultural and other societies. He also lectures at the Agricultural College, Roseworthy, and gives annual courses at the School of Mines & Industries. Personal visits of inspection and to impart advice on the spot are paid by the Expert and Inspectors. Beginners are supplied with plans of buildings, the erection of which is supervised; and, if required, all operations are overloooked.

Publications. — Through the Departmental Journal of Agriculture breeders are supplied each month with information contained in seasonable notes, general and special articles. Much time is given to original research on diseases and parasites and the results are published in the Journal and in Bulletin form. A "Poultry Manual" (now in the third edition) is on sale at a nominal price. All other publications, including an extensive Annual Report and Bulletin on the Egg Laying Competitions, are distributed gratis.

Poultry Experiment Station. — Until recently there were three Poultry Stations, one at Roseworthy, on the Agricultural College grounds, one at Murray Bridge, and one at Kybybolite, in the south east part of the State.

It was deemed desirable, for many reasons, to concentrate all work at one centre and a new site was chosen at Parafield, near Salisbury. Parafield was formerly a wheat-breeding station and consists of 100 acres of first-class wheat land, but rather heavy for poultry. The distance from Adelaide is only 11 miles by rail and about 10 miles by road. Here will be assembled, with many additions, the dismantled poultry stations removed from the old sites. The accommodation now in course of provision will include a block of 160 pens for the Laying Competition, yards and

houses to accommodate 5000 laying hens, and 150 pens of breeding stock with chicken-rearing yards to accommodate 10 000 to 12 000 chickens. There are two incubator rooms fitted with Cypher's hot-air machines of 400 egg capacity. Two brooder houses each 100 ft. long are provided, and the brooders and incubators are heated by an air gas (gasoline) plant, which will save labour and obviate many disabilities. Food stores, and distributing houses, workshops, stables, etc., are also in course of erection. Water is laid on to all buildings and pens. The whole of the land will be under cultivation, and considerable areas of lucerne and other fodder crops will be grown under irrigation.

In addition to the Laying Competition it is intended to organise Single Testing Competitions. Each competitor will enter 6 pullets, each of which will be confined in a small house and run : this is a more accurate and scientific method than trap nesting. Food tests will be carried out, and many problems connected with incubation, breeding, etc. will be dealt with. It is intended to accommodate sufficient laying hens to provide sufficient revenue to make the Station self supporting.

The education value of this easily accessible Poultry Station will be very great.

Later on provision will be made for students and also for the delivery of short lectures to the public on visiting days. The present staff consists of seven assistants, Assistant Superintendent, Superintendent and two farm hands. In addition to the 930 competition birds there are 50 pens of breeding stock and about 2000 layers. The breeds are White Leghorns and American Barred Plymouth Rocks. Later on some other breeds will be stocked.

The Laying Competition. — The results of the South Australian State controlled Laying Competitions have attracted attention throughout the world. The object of these tests is to demonstrate that it pays to breed good strains of layers and also to house and feed them properly. These three important considerations are not always understood, nor is their true value recognised.

Table I (pp. 1402-1403) shows the results of the Competitions hitherto held.

The current test 1913-14 consists of 154 pens, the largest number ever gathered in one test.

There are three sections: Sec. 1. Light Breeds; Sec. 2. Heavy Breeds; Sec. 3. Pens entered by Farmers, Pastoralists, Fruit and Vegetable growers.

The egg production in the first three months is satisfactory and there is every prospect that the final result will uphold the great reputation of the fowls of this State.

Experimental and Research Work.

Feeding poultry for egg production. — During recent years continuous feeding tests have been carried out at the Poultry Stations in connection with the Egg Laying Competitions, which are organised by the Department of Agriculture.

TABLE II. — *Feeding Test from June 1st, 1910, to May 31st, 1911 (12 Months).*
10 *White Leghorn Pullets in each Test.*

Pen.	How Fed.	June.	July.	August.	September.	October.	November.	December.	January.	February.	March.	April.	May.	Total.

1	6	Andalusian	961	961	160.1
1	6	Plymouth Rock	1 069	1 069	178.1

Throughout the series the feeding has been only slightly varied and is as follows:

7 a. m. — Mash, a mixture made as follows: bran 1 part by weight is scalded over night generally with soup made from meat meal; this i mixed with pollard two parts, and worked to a crumbly mass. Sometime lucerne hay chaff, in the proportion of about one third of the bulk, is used At noon a supply of cut green food is fed, and in the evening a meal o grain, which is generally wheat. In cold weather maize, oats, and pea are fed occasionally.

It may be added that the birds are confined in yards 10 feet wide, b

40 feet long, with a house at one end. The yard is floored with scratching litter.

Testing various foods. — To test various foods and methods of feeding, 80 carefully selected White Leghorn pullets were divided into flocks of 10 each, housed and yarded under similar conditions.

Table II (p. 1405) shows the results.

Breed tests. — A further test extending over 12 months was made. In this test 30 carefully selected pullets of each of three breeds were taken. The results are shown in Table III.

In the various detailed reports of the Egg Laying Competitions the results of the egg production of each breed represented have been tabulated.

TABLE VI. — *Weights and Measurements of Eggs and Shells.*

No	Breed	Weight	Length, Long Diameter	Breadth, Short Diameter	Thickness of Shell					Weight of Shell	Weight of Shell as percentage of egg	Color and Appearance of Shell

	Average	61.95	5.82	4.39	0.443	0.450	0.450	0.448	—	7.34	11.87	

Table IV (p. 1406) is representative of this and concerns a number of different breeds and varieties.

Fertity test. — At the close of the breeding season a test was carried out to ascertain how long after the removal of the male bird from the breeding pens the eggs laid would be fertile. The result is shown in Table V (p. 1407).

These Tests were confirmed on other occasions.

Weights and measurements of eggs of various Breeds of Fowls. — A dozen average eggs of fifteen different breeds and varieties of fowls were selected and carefully measured and weighed. Table VI shows the results.

Loss of weight in eggs during incubation. — Numerous experiments have been made. Careful records have been tabulated of the temperatures and moisture content of the air of the incubator rooms and of the incubators. Hot-water heated and hot-air heated machines were used. The average loss of weight per egg was found to be: hot-air machines, 16.24 per cent; hot-water machines, 15.78 per cent.

Flesh production. — Among other tests certain pure breeds and crosses were selected and fed with a cramming machine. The results are as follows:

Breed	Average increase per bird.
Indian Game crossed S. Wyandotte	2 lbs. 1 oz.
Buff Orpington	1 » 5 ½ »
White Wyandotte crossed O. E. Game	1 » 5 »
Indian Game crossed Dorking	1 » 2 »
Black Orpington	1 » 2 »
White Leghorn	14 ½ »
Faverolles	15 ½ »

Investigating diseases of poultry. — Most diseases of poultry are due to the presence of ecto and endo parasites. The following are met with and have at various times been the subject of investigation.

Parasite.	Disease caused
Argas persicus	Spirochaetosis
Goniodes sp.	Phthiriasis.
Goniocotes	Are probably carriers of spirochaete and other endo-parasites.
Menopon	
Lipeurus.	
Dermanissus gallinae	Coccidiosis in fowls and turkeys. Little Chick Cholera.
Coccidium avium (gallinae)	
Nematoda (Heterakis sp.)	Malnutrition, arrested metabolism and septicaemia.
Taeniae	Taeniasis.
Demodex	Itch, etc.
Sarcoptes	Scaly leg.
Lophophyton	Lophophytosis (Favus).

Various diseases, such as roup (generally due to invasions of *Bacillus diphtheriae gallinae*) and chicken pox (due to a fungoid parasite), are commonly met with and have been carefully studied. Preventive measures in all cases are advised as the only scientific method as regards successful poultry culture. Bulletins on some of the above parasites have been published and others will appear in due course.

Work of the Entomological Section of the Swedish Central Agricultural Experiment Station, during the Years 1907-14.

by

Prof. ALBERT TULLGREN,

Director of the Section.

The Entomological Section has had from the beginning a twofold aim. On the one hand it gives the public advice and information on all questions connected with agriculture and kindred industries, and on the other hand it works at the theoretical and practical solution of certain problems of economic importance, such as the life history of animal pests and the means of controlling them.

This latter field of activity should naturally be the most important for the Section, as the scientific and practical solution of the problem connected with animal pests forms the necessary basis for really useful advisory work; nevertheless the actual state of things is quite different, owing to several obstacles which have hitherto been unsurmountable. During the period 1907-14 the Section has, in the first place, accomplished a vast amount of informatory work. The public has availed itself of this privilege in a large measure; the Section endeavours at the same time to keep in close touch with farmers by means of correspondence and the diffusion of articles drawn up in a popular form. There is no doubt that these efforts have been attended by much success, as is proved by the fact, among others, that the control of the commonest animal pests — at least in the domain of horticulture — has become, of late years, more general and more intense.

One of the factors of the informatory work of the Section — a factor which also favours to a great extent practical and scientific research, — is the service started in 1911 which has taken the name of Intelligence Service. Its chief object is to supply a certain, and if possible, complete knowledge of the distribution, frequency and life-history of injurious animals in Sweden, as well as the value of the means of control, etc.

There are in different parts of the country about 500 persons ready, according to their culture and available time, to transmit at certain periods reports on the animal pests of their districts. These reports include not

only the animals which injure field crops, but also those which cause damage to gardens, orchards, and forests. All these reporters have the advantage of being entitled to send their correspondence and samples post free.

The Intelligence Service has, as has been said above, two advantages. On the one hand it facilitates the relations between the Section and the public, and on the other it supplies the Section with considerable material for study. By means of the correspondence and research work on the samples sent in, the Section endeavours to determine, as far as possible, the exactness of the communications received. The reporter who has taken part in this work for some years and has become interested in it acquires a relatively good knowledge concerning the commonest animal pests and may in his turn supply information. The Section has already learned a good deal from the reports that it has received. Thus, for instance, the knowledge on the distribution and life-history of *Argyresthia conjugella* Zell. and of *Aphis padi* L. has been enriched by precious contributions.

As regards the scientific activity of the Section, it may be stated that it has illustrated, in its principal publications, the life-history of many injurious animals of importance to Sweden. One of the insects most injurious to fruit trees in the country, the above-mentioned *A. conjugella*, has especially been the object of diligent study. The results of these investigations have been published in the " Communications " of the Central Institute. For several years past the aphides of Sweden have been studied with the greatest care. The first part of a monograph on them was published in 1909. Of late years the life-history of several Tenthredinids has been likewise studied. To these works must be added researches on Acari, wood-boring Lepidoptera, and Coleoptera (such as the larvae of Elateridae and of Halticinae) of importance from an economic point of view. Some of the results obtained have also been published in our " Communications ".

As for the practical and experimental work, the following deserves special mention. A vast series of investigations has been carried out in the matter of the utility of carbolineum in horticulture. The result of these investigations has been that spring spraying with 8 to 10 per cent emulsions has been proved to be extraordinarily efficient against several animal pests, such as apple sucker (*Psylla mali* L.), pear-leaf blister mite (*Eriophyes piri* Pagst.) and numerous scale-insects. On the other hand it has been ascertained that against fungi the utility of carbolineum is very limited, and that in certain cases it may prove fatal to plants.

Numerous experiments have also been made with lime-sulphur washes, partly to check results obtained abroad and partly to increase our knowledge regarding this important means of control.

Among arsenical compounds used in sprays, only Paris green and arsenate of lead were experimented on a large scale. Good results against the animal pests of Cruciferae have been obtained by adding to the wash substances capable of increasing its adhesiveness, such as gelatine.

Besides the above-mentioned sprays, the Section submitted to critical examination a great number of other products, including two English preparations for the disinfection of the soil : " Vaporite " and " Apterite ". But all these investigations yielded almost exclusively negative results.

Among the injurious animals — which of late years have attracted special attention — the following deserve to be mentioned : winter moth (*Cheimatobia brumata* L.), codling moth (*Carpocapsa pomonella* L.), *Argyresthia conjugella* Zell., apple sucker (*Psylla mali* L.), pear-leaf blister mite (*Eriophyes piri* Pagst.), *Agriotes* sp., *Phyllotreta* sp., *Haltica* sp., *Phaedon cochleariae* Fabr., *Hyponomeuta* sp., *Coleophora laricella* Hbn., *Tetranychus* sp., *Bryobia praetiosa* C. L. Koch.

The efforts of the Section to improve its material position also form a part of its work. Its desires have been to a great extent realized of late years. In 1913 a new building for the Institute was erected ; it is spacious and arranged in the most modern manner to meet the requirements of practical and scientific experiments. A remarkable collection of preparations illustrating the cycle of development and the habits of our animal enemies, an important collection of photographs, and a rich library may also be considered as, to a great extent, the result of our activity during recent years.

SECOND PART.

ABSTRACTS

AGRICULTURAL INTELLIGENCE

GENERAL INFORMATION.

LEGISLATIVE AND ADMINISTRATIVE MEASURES

5 – **Encouragement of Olive Growing and Fruit Growing in Tripolitania.** — *Decreto del Governatore.* Tripoli, Augnst 6, 1914.

On the suggestion of the Director of the " Ufficio Agrario " of Tripoli, l growers shall be entitled to a grant of 4 *d* for each properly grown young ive plant obtained from seed or from cuttings and 2 ½ *d* for every almond other fruit tree grafted. The " Ufficio Agrario " is authorised to distri- ute a suitable number of olive plants (" ovoli " or cuttings) and grafted uit trees to growers who apply for them and give the assurance that ey will undertake to cultivate them according to the recognized agri- ltural practice.

DEVELOPMENT OF AGRICULTURE IN DIFFERENT COUNTRIES

6 – **Agriculture in Réunion.** — *Ministère des Colonies Bulletin de l'Office colonial,* Year 7, No. 78, pp. 300-309. Melun, June 1914.

The island of Réunion has an area of 970 sq. miles. It is essentially olcanic and is divided into two groups of mountains joined on the south- est by the Plaine des Cafres and on the north-east by the Plaine des almistes.

Réunion is an essentially agricultural country ; plants from all parts the tropics flourish in the littoral zone and those from temperate regions the mountainous interior. All the land is available to cultivation cept the forest reserves established in 1874, which comprise nearly o sq. miles. The remaining portion is distributed as follows :

	sq. miles
Coast zone suitable for cultivation	390
Cultivable area in the cirques and islets	75
Area unsuitable for cultivation	115

Soils. — The soils consist of volcanic matter in different degrees disintegration, the process being most advanced in those of the north-w mountain group, where also the deepest sediments occur. They are ch racterised by a low percentage of lime and potash, probably due leaching.

Climate. — Two types of climate prevail : one in the east, exten ing from St. Joseph to St. André with a rainfall of 2300 mm. (90 inche and the other with a rainfall of scarcely 900 mm. (36 inches). There a two distinct seasons : the cool season from May to October with a mi imum mean monthly temperature of 21.15° C. (July) ; the warm seas from October to April with a maximum mean monthly temperature 27.5° C. (February). The only danger to crops is from cyclones whi often lower the yield by 20 to 40 per cent.

Agricultural Position in 1892 *and* 1912.

Area cultivated		In 1892	In 1912
		acres	acres
Sugarcane		72 000	47 000
Vanilla		1 680	1 380
Coffee		3 830	2 970
Cacao		62	86
Cloves (isolated trees)		area undetermined	
Tobacco		865	1 240
Manioc		3 880	8 650
Aromatic plants		740	4 000
Maize		37 000	50 000
Fallow, bare or cropped		50 000	37 000
Various crops, potatoes, orchards, vegetables, gardens		15 000	12 500
Exports.			
Sugar	tons	37 800	37 960
Vanilla	lbs.	212 235	148 051
Coffee	»	426 191	30 515
Cacao	»	1 883	1 378
Cloves	»	2 930	309
Tobacco	»	83 319	247 846
Essential oils	»	23 732	103 593
Rum	gallons	370 026	774 772
Tapioca and starch	tons	654	2 037
Dried manioc	»	—	242
Choco (*Sechium edule*)	lbs.	—	108 097
Spirits from sugar cane	gallons	—	51 328
Fourcroya gigantea fibre	tons	—	202
Preserved fruits	lbs.	—	21 475

The total value of the exports of the chief agricultural products ma be estimated at £578 000 in 1892 and £645 000 in 1912 ; it should b noted that in the latter year the price of sugar was very low : 9*s* 8*d* t 10*s* 6*d* per cwt.

Price of land. — The average value per acre varies from £16 to £64 cording to the locality, and it has not appreciably varied during the st 20 years.

Sugarcane. — This crop covers about a quarter of the cultivated ea. From 1870 to 1912 the annual production varied between 20 000 d 38 000 tons, reaching a maximum of 46 000 tons in 1895. Some richer rieties have recently been introduced and propagated, *viz.*: Bigtanna, , Boabilla, Cristalline, No. 100, etc. Under good cultivation they yield to 19 per cent. of sugar. Chemical manures are in common use, sulting in bigger yields being obtained. The factories provided with cylinder mills and defibrators obtain from 1500 to 1550 lbs. of juice per n of cane.

Vanilla. — The average yield from 1892 to 1912 was about 70 tons, aching a maximum of 200 tons in 1898. The crop gives excellent re-lts in the island, but has suffered considerably from recent cyclones.

Coffee. — The yield of coffee has fluctuated considerably between 892 and 1912. The exports have fallen from 426 190 lbs. in 1892 to 3 755 lbs. in 1900 and 30 515 lbs. in 1912. This is coincident with a fresh utbreak of *Hemileia* in 1900, which was successfully treated with copper prays, but in 1902 occurred an outbreak of *Lecanium viride*, introduced om Mauritius and Ceylon. New species have been introduced, but the lanters prefer the old types, *arabica* or round coffee and *roy* or pointed offee.

Aromatic plants. — The cultivation of these plants has increased nsiderably during the last 20 years. In 1892, 23 732 lbs. of essence of eranium and ylang-ylang, valued at £20 000, were exported. The xports in 1912 were as follows:

	lbs.
Essence of geranium	95 105
» » vetiver.	3 132
» » ylang-ylang	4 718
» » patchouli	110
» » citronella	489
» » longose	40

epresenting a total value of £90 730. Geranium is extensively cultivated. lang-ylang has taken a more important place with the rise in price of is essence, which reached nearly £10 per lb.; important plantations ere established in the littoral zone and continue to exist to-day in spite f the fall in price. Other plant essences, such as patchouli, citronella, emon-grass, gardenia and "longose", are distilled with success.

Manioc. — This crop has increased greatly since 1892, when there ere only three mills dealing with about 12 million lbs. of manioc. At ne present time there are seven mills producing about 4 ½ million lbs.of our and tapioca from about 40 million lbs. of tubers. During recent years ried manioc has been exported in small cakes containing 85 to 90 per ent. of flour. This product is used in France in the preparation of alcohol r liqueurs.

Textile plants. — The crop from these is not very profitable. *Fo croya gigantea*, or Mauritius hemp, yields only 35 to 40 per cent. of fib Sisal hemp (*Agave Sisalana*) yields a greater percentage of fibre fetchi a higher price. An experiment in jute cultivation at the Botanic Gard was successful and the cultivation of this crop should be very importa in the island, since more than half a million sacks are used annually in t sugar and manioc industries.

New crops. — Several new crops have been introduced during the pa 20 years, the most important being the following : varieties of manioc ri in starch ; sugarcane from Mauritius, Hawaii, Barbados, Australi disease-resistant coffees, including *C. robusta*, *C. stenophylla*, *C. congens C. canephora*, and the varieties Maragogipe and Golden Drop, as well some Javanese hybrids ; new varieties of exotic tobacco, of which Mar land, White Burley, Connecticut and Szamoshati have given excelle results as cigar leaf ; new selected varieties of aromatic plants, andr pogon, citronella, lemon-grass, patchouli, longose, gardenia, ylang-ylan peppermint. New varieties of sisal hemp have been planted on a lar scale. Since 1911 *Canna edulis* has been cultivated on the high plateau it yields a flour highly prized by biscuit makers. Of new forest plan the following have been introduced : the carob, Java kapok, various ta nin-yielding acacias, *Styrax benzoin*, etc.

New industries. — Preparation of perfumes by volatile solvent new factories for the distillation of flowers with modern fractional distill tion apparatus ; a ground-nut-oil factory. The apparatus in the sug factories has been greatly improved. A hydro-electric motor has be installed for supplying electric power to the port from the Galets strea

The *Agricultural Service* was founded in 1854 with the institution a Botanic Garden for the multiplication and preservation of useful plan in the colony. In 1907 a School of Agriculture was founded at Providen and in 1911 an experiment station followed. A scheme of reform for th experiment station and reorganization of the Agricultural Service h been presented to the General Assembly.

AGRICULTURAL INSTITUTIONS

977 – **The Royal Colonial Garden at Palermo.** — *Communication from the Directo Professor* A. Borzi.

The Colonial Section of the Botanic Garden of Palermo, which h existed since 1907, has now acquired autonomous administration with th functions of State Colonial Garden. In its new form, this institute w study and experiment with exotic plants useful in industry and commerc with a view to the agricultural and economic development of the colonie and to the increase of agricultural production at home by means of ne crops.

CROPS AND CULTIVATION.

978 – **The Effect of Climatic Conditions on the Rate of Growth of Date Palms.** – VINSON, A. E., in *The Botanical Gazette*, Vol. LVII, No. 4, pp. 324-327 + 2 diagr. Chicago, April 1914. AGRICULTURAL METEOROLOGY

The observations on which this study of the effect of climate on the rate of growth of date palms is based were made at the Cooperative Date Orchard, Tempe, Arizona. The length of every leaf on four palms — two Deglet Noors and two Rhars — was carefully measured every week during 1906 and 1907. By the system adopted the maximum error did not exceed one-quarter inch. Daily records were also kept of maximum and minimum atmospheric temperatures, and of soil temperatures at 1, 3 and 5 ft. below the surface. It was observed that after a new leaf has emerged well from the central bud, it makes the greater part of its growth in five or six weeks. In order to obtain a series of comparable figures representing weekly growth it was found that the sum of the elongation of the inner five leaves gave the most satisfactory series.

Both years the rate of growth was maintained late into the autumn, considerably in excess of the amount of heat available.

The rate of growth is most active not at the period of highest maximum, but rather at that of the highest minimum temperatures, which means warm nights. This period coincides with the summer period of highest relative humidity, that is, in Arizona, in July, August and sometimes September, and it is at this time that weakly palms recover their vitality. By far the greater part of the total yearly growth falls in the second half of the year. The rate of growth throughout the entire year is, in most cases, in proportion to the heat-time units over 50° F. (10° C.). Humidity is undoubtedly an important factor, but probably less so to date palms than to other plants.

The rate of maturation of the fruit is probably influenced by the same factors as the rate of growth of the foliage. The effect of high minimum temperature in promoting the ripening of the Deglet Noor date has recently been observed at Gafsa, in Southern Tunis.

979 – **The Influence of Sulphur on Soil Acidity.** — LINT, H. CLAY (New Jersey Agricultural Experiment Station, New Brunswick) in *The Journal of Industrial and Engineering Chemistry*, Vol. 6, No. 9, pp. 747-748. Easton, Pa., September 1914. SOIL PHYSICS, CHEMISTRY AND MICROBIOLOGY

Considering the favourable results obtained by the application of flowers of sulphur to the soil for the control of some parasitic fungi which are capable of persisting in the soil (for instance *Oospora scabies*, which causes potato scab), the question of its effect on the acidity of the soil acquires a certain importance.

The researches of DEMOLON (1), BRIOUX and GUERBET have not only proved that the sulphur in the soil is converted into sulphates by bac-

(1) See No. 478, *B.* May 1913. (*Ed.*).

terial action, but they have furnishd data on the influence of various substances such as calcium carbonate, saccharose, peptone, etc., when added to the soil in which the sulphur was introduced.

In the writer's recent work under field conditions, as much as 600 lbs. of sulphur was applied per acre; it was noticed that a large amount of the sulphur was still present at digging time apparently in an unchanged condition. In order to ascertain facts on the rate of oxidation of the sulphur in the soil a series of tumblers containing 100-gram portions of soil were arranged, one-half containing sulphur, the other half without it; 33 mgms. of sulphur, equivalent to 1000 lbs. per acre-foot (3 000 000 lbs.) were added. The soils were made up to 20 per cent. moisture content and covered with Petri dishes. The moisture content was kept practically constant throughout the experiment, which lasted 11 weeks. One tumbler containing soil mixed with sulphur and one without were removed each week and tested for acidity.

It appeared that the sulphur had almost all been oxidized within the first eight or nine weeks. There is very little change in the acidity after the seventh week.

The fact that sulphur causes this increase in acidity under field conditions is shown by the following table, in which are the analyses of soils from four old potato rows to which sulphur had been applied the preceding year; the fifth row had not received any sulphur.

In valuing the results it must be borne in mind that rows 1 and 2 had received ammonium sulphate, while rows 3 and 4 had had sodium nitrate.

Row	Rate of sulphur application, lbs. per acre	Lime requirement, in lbs. CaO per acre
1	600	3 187
2	300	2 590
3	600	3 025
4	300	2 247
5	none (check)	883

Laboratory experiments show that sulphur oxidizes more rapidly in sandy than in clay loams, and in those kept constantly at 20 per cent. of moisture than in those allowed to dry from time to time.

980 – **Acid Mineral Soils.** — DAIKUHARA, S., in *The Bulletin of the Imperial Central Agricultural Experiment Station, Japan* (article in German), Vol. II, No. 1, pp. 1-40 + 1 table. Nishigara, Tokio, March 1914 (1).

The acid reaction of certain soils is generally due to the presence of humic acids: other causes are the oxidation of pyrites particles, repeated application of certain fertilisers, such as sulphates of ammonia and potash on soils poor in lime, volcanic emanations or the initial fermentation of organic manures, such as green crops, cakes, straw, fresh dung. There is another instance of acidity in purely mineral soils which has not yet been

(1) See also preliminary note, abstract No. 600, *B.* July 1914. (*Ed.*).

escribed. It is produced by the adsorption of compounds of iron and lumina by colloids of the soil, which then give an acid reaction to litmus. n soils of this type free from humic acids, the acidity persists after leaching, ince it is insoluble ; but treatment with a solution of neutral salts, such as otassium chloride, potassium sulphate, potassium nitrate, sodium chloride, esults in the appearance in solution of free acid with the compounds of iron nd alumina. Since the salts of iron and alumina are adsorbed by the umic acids and other colloids of the soil and are set free again on treatment ith neutral salt solutions, these compounds must exercise considerable nfluence not only on the acidity of purely mineral soils, but also on that f soils containing humus.

The injurious action on vegetation of compounds of alumina and iron dsorbed by the soil colloids is due chiefly to the liberation of soluble acid alts of iron and alumina on the application of saline manures.

In Japan and Korea a large number of soils, making about three-quarers of the samples examined, show an acid reaction, due in more than alf the cases to compounds of alumina and iron. Soils of Mesozoic origin ave most often an acid reaction ; they are followed by the Tertiary, alaeozoic and Pleistocene, whilst alluvial soils show acidity only half as ften as the Mesozoic. Further, soils formed from so-called acid crystalline ocks show acidity in a larger number of cases than those from basic rocks, hile those formed from volcanic ashes still less frequently show acidity.

Litmus paper is the simplest means of determining qualitatively the cidity of a soil. More exact methods are those of Baumann and Gully nd of Loew. The writer proposes an equally exact and simpler method sing potassium nitrite. It consists of treating 5 gms. of soil in a test-tube ith a 10 per cent. solution of pure potassium nitrite, adding it drop by rop until the soil becomes thoroughly moist ; the test-tube is then closed ith a plug of cotton-wool, from which hangs a strip of starch-iodide aper ; after a certain time the degree of acidity of the soil can be deterined by the intensity of the blue coloration of the paper.

The property of liberating free acid from neutral salts possessed by the olloidal compounds of iron and alumina has suggested to the writer a ethod of determining quantitatively the acidity of soils by means of potasium chloride. For this 100 gms. of air-dried soil are treated with 250 cc. f normal potassium chloride solution in a retort of 600 cc. capacity during days, shaking it at intervals, or better placing it in a shaking machine for ne hour ; 125 cc. of the supernatant liquid are then taken and boiled ntil free from carbon dioxide, when it is titrated with a decinormal soluon of caustic soda, using phenolphthalein as indicator. A further 125 cc. f the potassium chloride solution is added and the titration repeated. This rocess is repeated until all the acidity has been determined. By determing the relation of the first titration to the total quantity of acid the method an be reduced to one operation ; the writer is preparing a formula for is. Tables are also given showing the quantity of limestone or quicklime ecessary to neutralize a given quantity of soil.

The above-mentioned acid soils are generally deficient in lime, th ratio of lime to magnesia being unfavourable to growth. These observation are summarized in the accompanying table.

Reaction of the soil and the ratio $\frac{lime}{magnesia}$

Reaction of Soil	Mineral acidity of Soil — cc. of $\frac{N}{10}$ NaOH	Cultivated Soils		Uncultivated Soils	
		No. of samples	Mean ratio $\frac{lime}{magnesia}$	No. of Samples	Mean rati $\frac{lime}{magnesia}$
Extremely acid	> 20	8	0.81	15	0.54
Very acid	20 — 5			20	0.65
Acid	5 — 1	13	0.88	11	0.96
Feeb'y acid	< 1	12	1.33	29	1.04

PERMANENT IMPROVEMENTS. DRAINAGE AND IRRIGATION

981 – **Irrigation in Spain.** — De La Rosa, Fernandez, in *Boletin de Agricultura tecni y economica, Direcion general de Agricultura, Minas y Montes*, Year VI, No 67, pp. 62 622. Madrid, July 31, 1914.

Except for the north-west of the Iberian peninsula where the rainfa is abundant and regular, almost the whole of Spain suffers from frequer drought or irregular rainfall. The problem of irrigation therefore pr sents itself and has been dealt with since the remotest times. Proof of th is found in the remains of hydraulic works of aboriginal tribes and of th Roman period, also in the irrigation canals constructed by the Arabs f watering the orchards of Valencia and Murcia and the rich plains whic extend from the mountain slopes in the districts of Malaga and Grenad and the regions bordering the Ebro. Later constructions are the gran canals of Urgel in Catalonia and Imperiale in Aragon, but it was onl at the end of last century that they were utilized to the full.

Three systems of irrigation are practised in Spain : 1) by means of *wel* from which the water is raised by wheels or more rarely mechanical pumps 2) *canals* fed by the large rivers by means of hydraulic wheels or dykes 3) *artificial lakes* (" pantanos ") which feed the irrigation canals. Preferen has been given to the collection of water in reservoirs, in place of the dire deviation of rivers, owing to the fact that during the winter rains th become devastating torrents, whilst during the summer the water is co siderably reduced and many rivers dry up. The total irrigated area is esti ated at 3 233 108 acres, of which about 200 000 acres are irrigated wi subsoil water. This area is distributed in the four great districts of Spa as follows :

Aragon and Navarre: The canals Imperiale, Tauste, Jalón, Galleg Huerva, and artificial lakes of San Bartolomé, and of Mezalocha in t province of Saragossa ; canal of Jaca, reservoirs of Huesca and Hijar,

gation canals from the Guadalaviar, the Jiloca and the Martin in the provinces of Teruel and Huesca ; artificial lakes of Grágera, Calahorra, and Cervera in the province of Logroño, and canals of the Rio Llano and Bayuriga in the province of Pamplona. The total irrigated area is 580 091 acres.

Catalonia: The canal of Urgel in the province of Lerida ; canals of Manresa, the Infanta and others fed by the Llobregat in the province of Barcelona ; numerous branches from the Ebro in the province of Taragon and the small reservoirs of Puigcerdá, Figueras, La Bisbal and Santa Coloma de Farmés in the province of Gerona ; in all about 472 920 acres irrigated.

Levante : Irrigation canal Real del Júcar de la Mayor and numerous others from the Turia and Palancia in the province of Valencia ; canals of Mijares, which fertilise the " Plana " in the province of Castellon ; artificial lakes of Tibi, Elche and Elda in the province of Alicante ; irrigation canals by filtration from the Segura, Guadalentin and Moratella, and artificial lakes of Puentes and the Val de Infierno in the province of Murcia: total 629 259 acres.

Boetic-Mediterranean region: The rivers Genil, Guadix, Dauro, Illora and Guadalfeo in the province of Grenada ; canals of Guadiaro and Genal, artificial lakes of San Pedro Alcantara and San Luis de Sabinillas, and the wells of Marbella in the province of Malaga ; numerous streams or small canals (" caceras ") from different watercourses in the province of Almeria ; in all 364 690 acres under irrigation.

The above sixteen provinces comprise about two-thirds of the irrigated area in Spain ; the other thirty-three provinces make up the remaining third.

Since 1900, the Government has initiated hydraulic works on a large scale and organised a special Department consisting of 10 divisions, for carrying out the numerous projects. The following works have been completed: artificial lakes at Mesalva (Teruel), Gragera (Logroño), Peña (Huesca), Gasset (Ciudad Real), Talava and Alphonso XIII (Albacete) and the Aragon and Catalonia canal.

The following are in course of construction: the artificial lakes of Cueva Foradada and Pena (Teruel), Toíx (Barcelona), Riudecañas (Tarragon), Guadalmellato (Cordova) and Guadalcacin (Cadiz). Amongst the numerous projects in course of discussion, the most important concern the artificial lake of the Ebro, the artificial lake of Cuerda del Pozo in Duero, and the irrigation of the lower valley of the Guadalquivir, in the provinces of Cordova and Seville. On the completion of these works during the next ten years, unless unexpected developments arise, over a million acres of land will be brought under irrigation. Nevertheless, the total area suitable for irrigation is at least 10 million acres, and it will require many generations before the irrigation requirements in this country are completed.

Artesian wells have been tried in some provinces for several years, but with only meagre results. Though satisfactory in certain parts of Levante, they were a complete failure in other parts of the southern region. The boring of these wells in the province of Leon was successful, especially on the Royal estate of El Pardo.

MANURES AND MANURING

982 – **Experiments with Bacterized Peat.** — *The Agricultural News*, Vol. XIII, No. 321, p. 263. Barbados, August 15, 1914.

Experiments have been made with a view to determining under English conditions the practical value of Professor BOTTOMLEY'S (1) bacterized peat.

One series was conducted in the open ground and the other on plants in pots and boxes. During the former a drought occurred which rendered it difficult to draw any conclusion as to the beneficial effect produced by bacterized peat.

But when artificial watering was adopted in order to compensate for the lack of rain, the favourable results were always evident. In one experiment with lettuces and radishes grown in ordinary garden soil and manured with different substances which included guano and bacterized peat, the results showed these two substances to be of about equal value.

But the most interesting series of trials and the one which seemed to show conclusively that bacterized peat is of value, was that in which radishes (96 per box) were grown in ordinary soil in boxes 1 yard square and treated as indicated in the following table:

	Roots		Tops		Total Weight	
	lb.	oz.	lb.	oz.	lb.	oz.
Control, two boxes, average	0	11	0	8 ½	1	3 ½
Farmyard manure, small dressing	0	12	0	12	1	8
Guano (½ oz. before sowing, and ½ oz. top dressing)	0	14	0	8 ½	1	6 ½
A well proved fertilizer, ½ oz. before sowing and ½ oz. top dressing	1	0	0	11	1	11
Nitrolin (3 oz. per box before sowing)	1	3	0	12	1	15
Bacterized peat (4 oz.)	1	8 ½	0	13 ½	2	6
Bacterized peat (8 oz.)	1	5	0	11	2	0

The result shows: 1) that bacterized peat is of high manurial value; 2) that it favours the development of both roots and tops (leaves) but especially the former; 3) that, as has been observed in other experiments, a lighter dressing of bacterized peat is somewhat more effective than a heavier one. Incidentally the experiment goes to show that nitrolin is a fertilizer which deserves a good trial on garden crops.

Bacterized peat used in the relatively small quantities in which it can be used effectively does not appear to exercise a beneficent action on the water-holding capacity of the soil; it has valuable manurial properties and these do not seem to be limited to the provision of nitrogen.

These experiments confirm the results reached by the earlier experiments at Kew and elsewhere.

(1) See No. 410, *B.* May 1914. (*Ed.*)

983 – **The New Potash Deposits in Spain.** — 1. Documentos parlamentarios, Criaderos de sales potásicas y otro minerales empleados como abonos ó que sirven para su fabricación. — *Boletin de Agricultura Técnica y Economica*, Year VI, No 68, pp. 739-743. Madrid, August 31, 1914. — 2. Editorials, Potash Supply. — *The Engineering and Mining Journal*, Vol. 98, No. 11, p. 497. New York, September 12, 1914. — 3. SCHMIDT, K. Die Kalilager in Katalonien. — *Zentralblatt für die Kunstdünger- Industrie*, Year XIX, No. 16, pp. 338-339. Mannheim, August 15, 1914.

1. — Following the announcement of the discovery of deposits of potash salts in Spain, the Minister of " Fomento" has presented a scheme for the regulation of their exploitation.

According to this report, the deposits in the neighbourhood of Suria and Cardona (prov. of Barcelona) give hope of considerable future development, as much by the area, depth and strength of the beds as by the quality of the minerals. Various companies have explored these deposits and have applied for concessions several thousands of acres in area, not only in the province of Barcelona but also in those of Gerona, Lérida and Huesca.

The Spanish Government, realizing the importance of the question, nominated a commission of the Geological Institute of Spain to undertake the necessary researches. This commission has issued a memoir confirming the favourable prospects of the discovery. Considering that the consumption of potash salts in Spain has reached the value of £149 270 (3 731 750 pesetas) and that it will increase considerably when the price is reduced, the Spanish Government considered it advisable to submit to Parliament measures concerning the exploitation of these discoveries, for the benefit of agriculture and national prosperity.

The first article of the law reads as follows :

" From the date of publication of this law all mining concessions for potash salts and other minerals employed as manures or for the fabrication of manures, including all minerals containing or capable of producing such substances, even though the concessions may have been granted under another denomination, are placed under state control with regard to the production and sale of the products obtained. The concessionaries must undertake to continue the prospecting and working of the concessions without interruption.

" The State reserves the right to regulate and change the manner of working in the interests of the public and to impose special conditions in the interests of the national consumption, such as the imposition of a tariff on exported products ".

2. — In confirmation of the above it is useful to note that amongst the most important of the concessionaries is an American firm, the " American Agricultural Chemical Co.", which has undertaken the working of some of these deposits. The last report of this company gave promise for the future and stated that the deposits resembled those in Germany.

3. — In this connection may be considered the communication of Professor Schmidt before the last meeting of the German Geological Society at Berlin and the discussion which followed.

The deposits of potash salts are found in the Tertiary strata of the Ebro basin, *i. e.* in the same region as the large mass of rock salt at Cardona

known since antiquity. The discovery was made by a small contractor who came across layers of carnallite and sylvine whilst boring in the neighbourhood of Cardona. Prospecting made up to the present shows that there is a deposit 260 ft. in thickness, containing 70 ft. of beds of carnallite with 20 per cent. potassium chloride, and 33 ft. of sylvine with 95 per cent. potassium chloride. Later explorations will establish the extent of these deposits. In origin they are analogous to those of Alsace, *i. e.* they are not primary formations resulting from the evaporation of seawater, but secondary formations derived from more ancient saline deposits, probably from Triassic saline deposits of the Pyrenees and the coast ranges of Catalonia.

984 – **Manuring Experiments with Manganese Carbonate in Italy.** (1) — D'Ippolito, G., in *L'Agricoltura moderna*, Year XX, No. 17, pp. 259-260. Milan, September 1-15, 1914.

Experiments with manganese carbonate were conducted on wheat and three-year-old lucerne. The latter crop, which had received a dressing of superphosphate and sulphate of potash at the end of the winter, was divided into two plots: one of 1370 sq. yds., manured on the 18th of March with 50.7 lbs. of natural manganese carbonate of 35 per cent. purity; and the other of 1292 sq. yds. with 48.5 lbs. of phospho-manganose (a natural rock containing 35 per cent. carbonate and 11 per cent. phosphoric acid). These amounts are equivalent to 180 lbs. per acre for each plot. A third plot of 1091 sq. yds. was used as a control.

The quantities of hay obtained in the first cut are as follows:

Plots	Yield of hay per acre
	cwt.
1 with phospho-manganose	61.9
2 » manganose alone	61.5
3 control	40.6

The succeeding cuts were damaged by rain and are omitted. The net profits of the manured plots over the unmanured were £1 8*s* 10*d* and £1 7*s* 11*d* per acre respectively.

The wheat was grown on broken-up lucerne ley manured with 535 lbs. per acre of basic slag. Two plots, each of 594 sq. yds., were chosen; 33 lbs. of natural manganese carbonate was applied to one and 35 lbs. of phospho-manganose to the other, making 267 lbs. per acre. A third plot of 566 sq. yds. was used as control. The variety Hybrid Unlodgeable was sown at the rate of 107 lbs. per acre.

The results at harvest were as follows:

Plots	Yield of grain
	bu. p. acre
1 with phospho-manganose	48.3
2 » manganose alone	41.1
3 control	31.3

(1) See also Nos. 226 and 266, *B.* March 1913. (*Ed.*)

The net profit of the manured over the unmanured plots was 11*s* 5*d* with phospho-manganose and £1 12*s* 9*d* with manganose.

These results show the importance of manganese to crops. The writer so remarks that no other of his 11 experimental plots, not even that with nitrate of soda, reached the yield of these manganese plots.

5 - **Comparative Morphology of Some Leguminosae.** — MARTIN, JOHN N., in *The Botanical Gazette*, Vol. LVIII, No. 2, pp. 156-167 + IV plates. Chicago, August 1914.

The writer carried out at the University of Chicago and at the Iowa State College microscopical investigations which enabled him to determine the process of development of the embryo-sac, embryo and endosperm of *Trifolium pratense, T. hybridum, T. repens, Medicago sativa* and *Vicia americana.*

In the course of his investigations the writers observed that the sterility of ovules is a prominent feature in *Trifolium pratense,* and this seems to be due to moisture conditions. Undoubtedly this tendency always lowers the percentage of seed production and in some cases reduces it almost to zero. The fact that this tendency varies among plants under similar conditions suggests that it may be partly eliminated by selection. The tendency toward sterility is not so pronounced in *T. hybridum* and is not much marked in *T. repens.* No sterility was observed in *Medicago sativa,* but all material used, so far, was collected during rather dry periods, and further investigation is necessary to determine the effect of moisture upon its fertility. In *Vicia americana* some sterile ovules were found, but the tendency toward sterility is not so pronounced as in the clovers. The literature cited includes fourteen works.

5 – **The Exchanges between the Plant and its Nutritive Solution.** — MAZÉ, P., in *Comptes rendus hebdomadaires des Séances de l'Académie des Sciences*, Vol. 159, No. 3, pp. 271-274. Paris, July 20, 1914.

In experiments on maize the writer has shown that the production of a given weight of vegetable tissue requires a constant volume of mineral solution of definite composition and concentration. He has further shown that the roots excrete mineral and organic matter (1). The present researches provide an experimental basis for studies on the function of osmosis in the absorption of nutritive substances by roots.

Maize plants were grown in aseptic mineral solutions containing 2 to 3 per cent. of saccharose. At the moment when the plants lost their turgescence in the sunshine owing to the increased concentration of sugar, the percentage of sugar was determined in the nutritive solution and in the sap of roots, stem and leaves. The results obtained showed that the nutritive solutions contained more sugar at the end of the experiment than at the beginning and that there is no relation between the sugar composition of the nutritive solution and that of the saps of the various parts of the plant. The exchanges between the plant and its nutritive solution are therefore in this case not subject solely to the laws of osmosis, but are rather sub-

(1) See No. 19, *B.* Jan. 1914. (*Ed.*).

ject to the chemical work of the plant. In order to reduce the respirator functions to a minimum, the plants were placed for 11 days in a positio facing north with diffused light of low intensity. In this case also analy sis showed that the nutritive solution contained more sugar at the end o the experiment than at the beginning and that the plant had consume some of its reserve sugar. The exchange between the root and the nutritiv solution is not therefore in accordance with the laws of osmosis.

In a medium containing excess of one or several ingredients, the root become impervious even to water. Considering that in the case of physio logical nutritive solutions colloidal organic bodies are absorbed, it follow that the function of absorption of the roots is one of filtration, the spee of which is determined by the chemical activity of the plant at any give moment.

987 – **The Influence of the Osmotic Pressure of the Soil Solution on the Growth o Spring Wheat.** — TOULAÏKOFF, N. (Director of the Experiment Station of Bésai tchouk, Russia), in *La Pédologie*, Year XV, No. 4, pp. 71-103. Petrograd, 1913.

Analyses of the nitrogen content of wheat grains in south-easter Russia show a slight increase in the nitrogen content of wheat from slightl saline soils. This fact had already been noticed by V. S. BOGDAN in hi work on the wheats of the district of Novoouzensk.

The higher protein content of wheat from south-east Russia wa formerly attributed to the low rainfall. This explanation is plausibl if the low rainfall accounts for the increased concentration of the soil solu tion. The writer was therefore led to study the physical, as distinct fro the physioolgical, effects of salts on the wheat plant , as in the earlies stage of development the germinating grain is subject more to the physica than to the chemical changes of its environment. As the swelling and germ ination of the grain depend chiefly upon the rapidity of absorption of th surrounding solution, it seemed advisable to begin by studying the in fluence of the osmotic pressure of salts on growth.

Experiments were made with the salts occurring in the region of Bé saintchouk, *viz.* NaCl, Na_2SO_4, etc. They were carried out durin 1910-13 in zinc vases containing about 11 lbs. of black soil (chernoziom) seed ed with the spring wheat Biélotourka. The necessary nutritive solutio was supplied in order to obtain the maximum yield of vegetable matte In the calculation of the osmotic pressure in the soil solution, the nutritiv matter already present in the soil and that added is omitted, as it woul not be possible to determine it by ordinary methods. However, since th same quantity of soil and manure was added to each pot, the osmot pressure of the soil solution may be considered the same in each case (abou 4 atmospheres) and left out of account. Therefore in speaking of 3, 5, 7 10 atmospheres of osmotic pressure, the figures refer to the increases osmotic pressure due to the non-nutritive salts added. The control po containing no non-nutritive salts were maintained at a constant osmot pressure of about 4 atmospheres by maintaining a constant humidity 60 per cent. of the maximum by means of daily spraying with distill water. Both nutritive and non-nutritive salts were added to the po

t the time of filling. The osmotic pressure of the solutions of non-nutrive salts was determined for the pure salts, and not their mixtures.

Experiments in 1910 *and* 1911. — These were only of a preliminary nature, to determine the suitable limits of osmotic pressure.

Experiments in 1912. — The following salts were used: sodium chloride, sodium sulphate, magnesium sulphate, sodium carbonate and ammonium nitrate. The first three were also used in mixtures of two and three. Ammonium nitrate was not used as a nutritive salt, but only to increase the osmotic pressure. The osmotic pressures compared were 0, 5, 7, 12 and 15 atmospheres.

Twelve sprouted grains of wheat were planted in each pot on the 13th of April. On the 18th, the control pots and those with a pressure of 5 atmospheres showed seedlings 5cm. high. The seedlings in pots of higher pressures were much shorter, but not so much in the case of ammonium nitrate. The plants in the control pot commenced tillering on the 24th of April, whilst the others did not begin before the 28th and 29th. They were thinned out on the 2nd of May, leaving only seven plants in each pot. The height of the plants was measured on the 15th and 29th of May and the 7th of June. It was found that during the first period of vegetation small quantities of salts stimulate the vegetative growth of wheat, but that later they retard it: towards the 3rd of June the control plants were higher than all the others.

Increase of osmotic pressure causes an appreciable diminution in the mean growth of the variety Biélotourka, though it hastens the appearance of the ear, the flowering and the ripening, thus shortening the vegetative period. Exception to this occurred in the ammonium nitrate pots, in which the phases were retarded and the vegetative period was longer even than in the controls.

As the plants reached maturity they were submitted to the following tests: length of ear, yield of total vegetable matter and of grain, weight of 1000 grains, percentage of nitrogen in grain, coefficient of transpiration (calculated). The data obtained showed that increase of osmotic pressure diminishes the yield of total vegetable matter and grain, the length of ear and the weight of 1000 grains, whilst it increases the percentage of nitrogen in the grain even in soils rich in nitrogenous matter.

Experiments in 1913. — The maximum osmotic pressure was reduced from 15 to 12 atmospheres and for every salt experimented with two additional pots with an osmotic pressure of 3 atmospheres were added. Since the experiments of 1912 had shown that the salts of the soil solution cannot be considered as merely increasing the osmotic pressure, but as exercising also other influences, physical, physiological, etc., it was considered advisable to increase the number of salts under experiment. The following salts were therefore used: sodium chloride, ammonium chloride, calcium chloride, magnesium chloride, sodium sulphate, ammonium sulphate, magnesium sulphate, sodium nitrate, ammonium nitrate.

The results obtained are summarised in the Table below, which shows clearly the existence of a stimulating action of all salts when the osmotic

pressure reaches 3 atmospheres. At this pressure, under 1913 conditions the coefficient of transpiration of Biélotourka was lowered, while the total yield and the yield of grain were increased, although the weight of 1000 grains was decreased by 1.1 gm. from that of the controls.

Mean results of 1913 *experiments.*

Osmotic pressure of soil solution	Water evaporated, gms.	Coeff. of transpiration	Total yields, gms.	Yield of grain, gms.	Weight of 1000 grains, gms.	Nitrogen content of grain, %
Normal	15 622 (maximum)	314.2 (minimum)	48.2 (maximum)	18.71 (maximum)	38.27	2.068
» + 3 atmospheres	16 156	291.5	55.44	22.43	37.14	2.283

An increase of osmotic pressure above 3 atmospheres caused a decrease in the yield of grain and in the 1000-grain weight, as well as a less efficient utilisation of the soil moisture, assuming that the coefficient of evaporation increases proportionally to the increase in osmotic pressure. On the other hand an increase of osmotic pressure caused an increase in the percentage of nitrogen in the grain and in the flintiness, but a decrease in the percentage of starch.

Action of different salts and their elements.

A. *Acids.* — 1) At an osmotic pressure of 3 atmospheres the maxima of total yield and yield of grain are obtained from nitrates, which are followed by sulphates and then by chlorides.

2) At 5 atmospheres the highest yields are given by the sulphates, followed by chlorides with respect to grain and nitrates for still less grain.

3) At 7 atmospheres, the yield is better with sulphates than with nitrates.

B. *Bases.* — At 3 and 5 atmospheres ammonium salts give the largest increase of total yield and of grain yield, as well as the largest percentage of nitrogen in the grain. In respect to yield the salts of magnesium come second and those of sodium third. In respect to percentage of nitrogen, sodium salts come second and magnesium salts third.

Conclusions. — 1) The character of the soil solution, especially its concentration and osmotic pressure, have a distinct influence on the vital functions of spring wheat. Increase of osmotic pressure at first stimulates growth, then beyond an optimum limit of 3 atmospheres, whatever the salt, it has a depressing influence on growth, but at the same time increases the percentage of nitrogenous matter in the grain.

2) Under certain meteorological conditions, a very pronounced stimulating action on the wheat plant can be obtained by bringing the osmotic pres-

sure up to the optimum, irrespective of the salt used. This results in a greater yield of straw and grain, a better quality of grain, a higher nitrogen content and a more efficient utilisation of the soil moisture by the plant.

3) The presence of nitrogen in solution, either as base or acid, appreciably increases the yield of straw and grain as well as the percentage of nitrogen in the grain, compared with non-nitrogenous salts. Of the latter, sulphates have a greater influence on yield than chlorides.

988 – **The Action of Various Electrolytes on the Grains of *Avena sativa*.** — PLATE, F., in *Annali di Botanica*, Vol. XII, Part 3, pp. 261-343. Rome, May 1914.

These researches concern the stimulating effect of chemical agents on the imbibition of grains of *Avena sativa*.

It is well known that seeds are able to resist injury from solutions of salts up to a certain concentration and that such solutions exert an influence on the subsequent development of the embryo and seedling. In these experiments the effect of the different ions of acids, bases and salts was investigated. The strengths of the solutions used were N, $\frac{N}{2}$, $\frac{N}{5}$, $\frac{N}{10}$, and the period allowed for absorption was 2 hours. The increase in weight of the seed was determined at intervals of half an hour. Observations were made of substances which accelerate or retard germination and on the effect of imbibition on the external morphological characters of the seedlings with special reference to the size of the shoot and root, and the fresh and dry weight of the seedling. The quantities of salt absorbed were determined by weighing and also in parallel series of experiments by analysis of the liquid remaining after each period.

From these results the writer concludes that immersion for only two hours exerts an influence in many cases not only on the physico-chemical phenomena of imbibition, but also on the subsequent development of the seedlings. The absorption of distilled water or tapwater varies within near limits according to the individuality of each grain, but generally it increases rapidly during the first stage of immersion, continues more steadily during the second stage and decreases slowly during the third stage until it ceases completely. The beginning of imbibition and the quantity of water absorbed vary with different grains, with different solutions and according to the concentration. These experiments confirm the conclusion that during imbibition, seeds absorb more proportionally of the solvent than of the electrolyte, so that the solution becomes more concentrated after immersion.

Classified according to their effect on imbibition the substances are grouped as follows :

1) Substances not absorbed and having no influence on imbibition : the chlorides of sodium, potassium, calcium, barium and zinc ; bromides of sodium and potassium; nitrates of potassium, barium, cadmium and silver ; sulphates of potassium, cadmium and copper; formate, acetate, and oxalate of potassium.

2) Substances absorbed without influencing the total amount of liquid absorbed under normal conditions : the chlorides of cobalt and iron.

3) Substances which, though not absorbed, diminish considerably the imbibition : acid phosphates of sodium and potassium, sulphates of aluminium, chromium and iron.

4) Substances which, though not absorbed by the seeds, not only diminish the imbibition but also influence the germination : ferrocyanide, permanganate and bichromate of potassium ; the alums of potassium, chromium and iron; the nitrites of sodium and cobalt; the chlorides of cerium, tin, cadmium and mercury ; bromide of mercury.

5) Substances which are absorbed and diminish the imbibition, as well as affecting germination : iodides of cadmium, sodium, potassium, and the nitrates of mercury and cobalt.

6) Substances absorbed, increasing the imbibition and also favouring the germination : formic, acetic, oxalic, nitric, sulphuric and phosphoric acids.

7) Substances not absorbed, but accelerating imbibition and to a considerable extent promoting germination : malic, citric, tartaric and hydrochloric acids.

Excluded from this list are the hydrates of the alkalis and alkaline-earths, which in the concentrations used were fatal to the grains.

It follows from these results that substances which are absorbed for a period of two hours, do not penetrate throughout the seed, but are arrested at the testa. It remains to be determined if they will penetrate further if imbibition is prolonged.

Malic, citric and tartaric acids are most favourable to growth, though they are not absorbed by seeds. This is explained by supposing that some indeterminable trace of acid acts on the seeds catalytically and causes a greater acceleration of the physico-chemical processes.

These researches support the conclusion that the laws of absorption are not constant for all solutions and concentrations, but that specific coefficients of absorption should be attributed to each cation or anion.

The specific actions of hydrogen ions and hydroxyl ions have considerable biological importance, and it is probable that the carboxyl group is not less important.

989 – **Effect of High Frequency Currents on Plants.** — HOMBERGER, ERNST, in *Die Umschau*, Year XVIII, No. 36, pp. 733-735 + 2 figs. Frankfurt-on-the-Main, September 5, 1914.

The writer recalls the observations of Lemström, who attributed the greater rapidity of growth in polar regions to the higher potential of atmospheric electricity, and the experiments in electroculture carried out by Lemström, Lodge and others. While the use of high tension continuous and alternating currents led directly to the soil and to the plants was always connected with injury to the latter as soon as the intensity of the current exceeded certain limits, this injury was no longer observed when alternating high frequency and high tension currents were employed.

Experiments of this kind were recently conducted in the Moräne farm near Dayton in the United States. Several experimental plots were sown with radishes and salad. After they had sprouted the electric current was started.

One plot was subjected to the action of high frequency currents which passed through a wire stretched at about 16 inches above the soil. The difference of potential between the soil and the conductors was about 10 000 volts; the frequency was of 200 000 periods per second generated by Tesla currents. The passage of the current lasted one hour in the morning and one hour in the afternoon. The growth of the salad compared to that of the check plot was increased by about 75 per cent.

Alternating high frequency currents are biologically harmless to plants, animals and man. Arsonval introduced them into therapeutics. On transforming high tension into high frequency, diathermic currents are obtained with which heat can be produced in the deep strata of animal tissues. With the diathermic apparatus the human body can be traversed without danger by currents of an intensity somewhat over 1 ampère; only if the intensity be too much increased does combustion take place.

The writer experimented upon plants with such an apparatus; he placed the two electrodes in flower-pots with plants between them. Most of the experiments were carried out with beans, and they regularly showed that the stem grew thicker and the leaves larger than in the check plants. During the experiments three treatments per day were made; as soon as the temperature reached 35° C. the current was interrupted. The length of time that the soil retained the heat was remarkable and still more so the fact that the stem and the leaves formed a greater quantity of chlorophyll than those of the check plants.

In order to determine whether the greater intensity of growth was due to the heat or to the high tension of the electromagnetic field, the writer treated other plants of beans with Tesla's currents (that is high tension and high frequency). The effect of one such treatment lasting 5 minutes was very evident and proved that the stimulus to growth is due to the oscillating field and not to heat. The greater formation of chlorophyll in the treated plants is perhaps due to the fact that under the influence of the oscillating electro-magnetic field chemical decompositions take place in which large molecules take part; these decompositions are similar to those caused by the catalytic action of the still more rapid luminous vibrations.

990 – **Influence of X-Rays on Vegetation.** — MIÈGE, EM., and COUPÉ, H., in *Comptes Rendus hebdomadaires des Séances de l'Académie des Sciences*, Vol. 159, No. 4, pp. 338-340. Paris, July 27, 1914.

Experiments were made on *Raphanus sativus* and *Lepidium sativum*. Ten seeds were sown in each of a number of pots of garden soil and covered with half an inch of leaf-mould. The pots were then subjected to the action of the rays; the frequency and the intensity of the radiations varied in the nine groups that were made. Differences began to appear on the 22nd day; the experiment terminated on the 38th day.

From the results of these preliminary experiments the writers conclude:

1. That X-rays exert a clearly favourable action on the vegetation of both *Raphanus* and *Lepidium*, as shown by the increase of weight, which attains in *Raphanus* 45 per cent. for the leaves, 59 per cent. for the whole plant and 193 per cent. for the bulb.

2. — That this benefit is all the more marked the more frequent and intense the radiations, also when they attain an intensity (75 H. per month) which would render them decidedly injurious to animal tissues.

3. That X-rays have a slight reaction on the morphology and anatomical structure of the plants under consideration (in general the vascular and supporting tissues are more developed and better differentiated).

991 – **A Study on the Germinating Power of Seeds.** — DARSIE, MARVIN L., ELLIOTT, CHARLOTTE, and PEIRCE, GEORGE J., in *The Botanical Gazette*, Vol. LVIII, No. 2, pp. 101-136 + 18 figs. and diagrams. Chicago, August 1914.

Until recently the tests of the longevity or viability of seeds have depended upon the percentages of actual germination in prepared beds. Such tests are simple enough in the case of seeds which germinate quickly and in these cannot be improved upon. When, however, two weeks or more must elapse even under most favourable conditions before one may know the quality, that is the germinating power, of the seeds, a quicker method is desirable, also because in briefer exposure there is less danger of injury or loss from fungus or other enemies. Mr. G. J. Peirce has shown that by using silvered Dewar flasks as calorimeters one may quickly determine that heat is evolved in the germination of seeds and has suggested that there may be such differences in the heats liberated by seeds of different ages that they may be used as indicators of age and germinating power or viability.

Some experiments were undertaken in order to test this idea.

The germination experiments were made in silvered Dewar flasks and in seed beds with seeds of barley, clover, maize (Cory sweet corn), hemp, oats and wheat of different and well known ages. The results show that, other conditions being equal, a high temperature within a reasonable time is indicative of high germinating power, and also of the ability to make a rapid growth of root and shoot after germination, in other words of vigour. With the increase of the age of the seeds the quantity of heat produced diminishes, but of course such decrease is not always perfectly regular, owing to the different climatic conditions under which the seed was grown and harvested, to its degree of maturity and to the conditions of storage. Each species of plant that was studied appears to have, like the higher animals, a " normal " or characteristic temperature, departures from which indicate deviations from the best conditions of the organism. Other conditions being equal the " normal " temperature is evolved by the freshest and most vigorous seed : a higher temperature generally indicates an infection (fungoid) ; a subnormal temperature on the other hand denotes lessened vigour, generally due to increased age.

The " normal " temperature, or average daily heat yield in terms of 10 grams of seed, is 1.82° C. for hemp, 0.75° C. for clover, 0.73° C. for wheat, 0.55° C. for oats and 0.49° C. for maize.

PLANT BREEDING

992 **Selection of Cocksfoot *(Dactylis glomerata)* in New Zealand.** — HILL, W. S., in *The Journal of Agriculture*, Vol. VIII, No. 3 pp. 262-265 + 2 figs. Wellington, 1914

Cocksfoot is one of the most widely distributed and most useful grasses of New Zealand. Its seeds, especially those from the Banks peninsula,

upply a lucrative export trade to Europe. This plant, however, being so videly distributed and growing in the most different environments, pre- ents a number of types and variations. It has been found that the varia- ions in cocksfoot apply not only to the form of the panicle, but also to the quantity, quality, shape and colour of the leafage, to the height, to the degree of rust resistance, to the earliness of maturity, to the yield of seed, etc.

Consequently at the Moumahaki Experiment Farm a work of selection has been started with the aim of producing plants with abundant and good foliage and with a high resistance to rust. Plants exhibiting these desired points to a greater or less extent have been isolated, and the reproduction of selected types is being effected by vegetative or clonal reproduction, by inbred seed and by open fertilized seed.

993 – **Mutation in Egyptian Cotton.** — KEARNEY, THOMAS H. (Physiologist in Charge, Alkali and Drought Resistant Plant Investigations, Bureau of Plant Industries) in *Journal of Agricultural Research*, Vol. II, No. 4, pp. 287-302 + IX plates. Washington, July 1914.

The writer summarises as follows the facts that he has ascertained from the literature on the subject and from the observations made by him during his work of selecting cotton in Arizona.

The origin of the Egyptian type of cotton is obscure. According to one theory, it is a product of hybridization between a brown-linted tree cotton and American Sea Island, both of these types having been cultivated in Egypt nearly a century ago. Whether this be true or not, there can be no question that the varieties now grown are of mixed ancestry, a condition which some investigators regard as favourable to mutation.

Numerous varieties have appeared from time to time in Egypt. The Ashmuni variety, now grown only in Upper Egypt, originated about 1850. This variety gave rise in 1887 to the Mit Afifi, and from the latter the Abassi, Yannovitch, Nubari, Sakellaridis and Assil varieties have successively been developed.

As grown in Arizona from imported seed, most of the Egyptian varieties are readily distinguishable by the habit of the plants and by the characters of the leaves, involucres and bolls, as well as by the fibre.

So far as the scanty evidence goes, each of these varieties originated with a mutant, *i. e.* an individual plant which showed an abrupt and definite change in the characters expressed. This conclusion is supported by the more complete data at hand regarding the history of the varieties which have been developed in Arizona.

Plant breeding work in Arizona was begun 12 years ago with imported seed of the Mit Afifi variety. Persistent selection of the best plants caused some improvemet in earliness and productiveness and in the quality of the fibre, but the progress was not very substantial prior to 1908, in which year two types very different from the Mit Afifi were recognized and isolated. One of these was the Yuma variety, now commercially grown in Arizona. This form has continued to express its distinctive characters with a high degree of uniformity, notwithstanding the fact that the parent individual and its immediate progeny were not protected against cross pollination.

Two additional varieties described in this paper under the names "Pima" and "Gila" have lately been developed in Arizona. The Pima variety appeared as a single plant of marked individuality in a field of Yuma cotton at Sacaton, Arizona, in 1910. Its characters have been expressed in its progeny with great uniformity during the three subsequent generations. This variety is easily distinguished from the parent Yuma variety by its relative limblessness and by the correlated retention of the lowest fruiting branches and bolls; by the more uniformly deeply 5-lobed leaves; by the shorter, relatively wider, and nearly separate involucral bracts; by the plumper and more abruptly and sharply pointed bolls and by the longer fibre (average length of fibre: Yuma 1 ½ inch; Pima 1 $^{5}/_{8}$ to 1 $^{3}/_{4}$ in.; Gila 1 $^{7}/_{16}$ in.).

The Gila variety is derived from a single plant discovered by Mr. E. W. Hudson in a field of the Mit Afifi stock grown at Sacaton, Arizona, in 1908. In its external characters this type resembles the parent Mit Afifi variety much more than the Yuma, but differs in its earlier ripening, smaller vegetative branches, greater productiveness and longer fibre.

The individuality of the parent plant, together with the uniformity shown by its progeny during the subsequent generations, indicates that the Gila variety, like the Yuma and the Pima, is of mutational origin.

Egyptian cotton exhibits, although in a minor degree, the tendency to develop new varieties by mutation which characterizes *Oenothera Lamarckiana*. There is a further parallel in the fact that in both cases very similar, if not identical, new characters come into expression at different times and in different places. An example of this phenomenon in Egyptian cotton is afforded by the Nubari and the Yuma varieties.

If the tendency to produce mutants is a result of remote or complex hybridization, the mutability of Egyptian cotton might be accounted for upon either of the following grounds: 1) the supposed hybrid origin of the type as a whole, or 2) later crossing with other types of cotton.

Ever since mutation became recognized as a factor in the breeding of Egyptian cotton the following methods have been followed in Arizona: 1) recognition and isolation of desirable mutants; 2) selection and comparison on the progeny-row basis of those individuals among their progeny which express most fully the desirable characters of the new type; 3) elimination from the seed increase fields, preferably before blossoming begins, of the aberrant and otherwise undesirable individuals.

The bibliography of the literature cited comprises 21 works.

CEREAL AND PULSE CROPS

994 - **New Varieties of Wheat and Oats in New South Wales.** — PRIDHAM, J. T., in *The Agricultural Gazette of New South Wales*, Vol. XXV, Part 3, pp. 230-233 + 3 figs., p. 236 + 2 plates. Sydney, March 1914.

Varieties of wheat. — The new varieties of wheat obtained or imported by the Department of Agriculture are grown in the stud plots and compared with the standard varieties to determine their yielding qualities and their defects and good points. A sample of any variety found promising in the field is sent to the Departmental Chemist to be milled, and is recommended

o farmers if it yields a satisfactory flour; if it fails in this respect it is not ncluded among the list of varieties recommended.

In 1913 two varieties, "Bomen" and "Sunset", were recommended or further trial and they have fully justified that recommendation. Other wo varieties, "Canberra" and "Nardoo", are suggested for further trials at the Experiment Farms. The writer describes these four varieties. "Bomen" is awnless and bunt-resistant; in its pedigree it includes an Indian variety "Zaff", one from Manitoba, "Power's Fife" and two Australian wheats. "Sunset" is also awnless; it is intermediate between the medium strong and weak flour classes, and is very early. "Canberra" is slightly awned at the tip; it is a cross between Federation (the dam), and Volga barley, a two-rowed sort; it has yielded well and gives a high percentage of flour which is of excellent colour and belongs to the medium strong class. "Nardoo" is awnless, medium horny; it is decidedly smut-resistant and an excellent hay wheat; it is a hybrid of several varieties, including "White Naples".

Varieties of oats. — Among the oats recommended for further trials at the Experiment Farms by the recent Departmental Conference are "Sunrise" and "Guyra". "Sunrise" is a natural cross bred from Algerian oats, which it surpasses in length of straw by about a foot, and in earliness by a week; it is recommended for the warmer districts. "Guyra" is a cross between "Algerian" and "White Ligovo"; it stools very fairly and its grain is plump; it is suited to typical oat districts.

995 – **The Effect of Ammonium Salts on the Tillering of Wheat.** — WILD, L. J., in *The Journal of Agriculture*, Vol. IX, No. 1, pp. 31-32. Wellington, N. Z., July 1914.

This experiment was suggested by a statement in Dr. Griffith's "Treatise on Manures", to the effect that treating the seed wheat with a solution of sulphate of ammonia gives an increase in the number of stems produced by the individual plant. Five varieties of wheat were treated with nitrate of ammonia and three with sulphate of ammonia in 3 per cent. solution, and sown in plots of from 10 to 15 square yards in area. Check plots were also sown with untreated seed. No difference was noticed between the treated and untreated plots as regards rate of germination or rate of subsequent growth. When the grain was in ear twenty plants were taken at random from each plot and the average of stalks per plant was determined. The results were as shown in the accompanying table.

These results show that nitrate of ammonia is more effective than the sulphate in increasing the tillering power of wheat and point to the desirability of investigation on a more extensive scale.

Variety	Average tillering power		Increase	Percentage increase
	Treated	Untreated		
Varieties treated with sulphate of ammonia				
Hunter's White	7.5	6.4	1.1	16.7
King's White	6.5	5.6	0.9	16.0
Bordier	12.4	11.4	1.0	8.8
Totals	26.4	23.4	3.0	Average 12.8
Varieties treated with nitrate of ammonia.				
Red Tuscan	10.5	10.0	0.5	5.0
Solid Straw Tuscan.	10.1	7.6	2.5	33.0
White Tuscan	8.3	6.7	1.6	23.9
Glynus	7.0	6.3	0.7	11.1
Pearl	8.0	5.8	2.2	37.9
Totals	43.9	36.4	7.5	Average 20.6

ROOT CROPS

996 – **New Blight-proof Variety of Potatoes.** — *Queensland Agricultural Journal*, Vol. II, Part 2, pp. 103-106. Brisbane, August 1914.

A new variety of potatoes called the "New Era" has been obtained by a farmer who is also a keen student and observer, Mr J. G. Harris, of Raetihi, New Zealand. In the locality in which the potato was produced it has proved blight and frost proof; it is suitable to grow for the early potato trade and, it is stated, has produced up to 20 tons per acre.

The origin of this potato is as follows: six years ago Mr. Harris had an acre and a half in potatoes, Eldorados and Northern Stars. The potato blight swept the whole crop with the exception of one plant. Its tubers were multiplied during the next five years, and proved resistant to blight, while the above-mentioned varieties, as well as Irish Rock, Up-to-date and Gamekeeper (1), were all attacked.

FORAGE CROPS. MEADOWS AND PASTURES

997 – **Grasses at Hawkesbury Agricultural College, New South Wales.** — BREAKWELL, E. (Agrostologist) in *The Agricultural Gazette of New South Wales*, Vol. XXV, Part 8, pp. 653-656 + 11 figs. Sydney, August 1914.

Although the soil at Hawkesbury Agricultural College is not of a good character there are many grasses which stand the adverse conditions remarkably well.

The principal of these are: *Eragrostis leptostachya* Steud. (Paddock Love-grass), a native grass, particularly adapted to soils of a light or sandy nature; it is a heavy seeder and the seeds appear capable of

(1) See also No. 791, *B.* August 1914. (*Ed.*)

y germination. *Eragrostis curvula* and *E. curvula* var. *valida* have n recently introduced from America and are particularly adapted growing under adverse conditions, such as light soils and low rainfall; y produce, however, a coarse fodder. The latter of the two has a thick wth about 3 feet high and seeds heavily.

Andropogon intermedius (Blue grass). This is a native grass; its habitat n alluvial formations or on moist black soils in general; nevertheless ppears particularly adapted to the poor soil of the College. The grass heavy seeder, but so far the seed has not germinated very well; on other hand root planting has been very successful. It yields a heavy culent flag, which remains green from September well into May. It ery sensitive to frosts. At the College it is often attacked by a fungus *rebella* sp.).

Poa arachnifera (Texas Blue grass), is the most vigorous of the as and appears well adapted to the light soils. Propagation by seed ncertain, but it readily spreads if root planting is resorted to.

Poa pratensis (Kentucky Blue grass). — It quickly covers the ground. the College it suffers very much in the summer.

Poa sempervirens (Evergreen-Meadow grass). — This grass is really ariety of *Poa nemoralis*; it remains perfectly green during the heaviest frosts, and it grows fairly vigorously during the colder months of the r. Its texture is also finer than that of most of the other Poas.

Poa compressa. — Although this grass produces only a small quantity foliage, it is very nutritive and remains green during the greatest part the year. Its vigour at the College shows its adaptability to poor s, and its capability of enduring a limited rainfall is shown by its per-nent character at the Cowra Experiment Farm.

Pollinia fulva (Sugar grass). — A native grass; its flag is very succu-t and it is particularly drought resistant; it will also stand a large amount feeding off. At Hawkesbury, however, the production of seed has been newhat disappointing.

Bromus inermis (Awnless Brome grass). — This is a native of Europe, d a grass which has met with great success in the United States of Ame-a. It remains green the greater part of the year and stands the summer ter than *Bromus unioloides*. It is very nutritive and stands grazing well.

Bromus unioloides (Prairie grass) . — A very succulent grass, which duces a large quantity of feed during the cooler months of the year. der cultivation it yields heavily, and when cut for hay the new plants ing from the old root, becoming perennial in habit; but when stocked lisappears rather suddenly, behaving as an annual.

Bromus pumpellianus. — This is one of the newer bromes. It has far made a promising growth, while *B. sterilis*, *B. maximus* and *B. mollis* ve proved useless.

Chloris gayana (Rhodes grass). — Having already proved successful, cultivation of this grass has spread rapidly; for producing the quickest wth on the lighter soils, it appears to have no equal. It seeds heavily.

Chloris barbata (Australian Rhodes grass), *Paspalum dilatatum* a *Setaria nigrirostris*, which has given good results in the Transval; at t College it has grown vigorously, while at the same time its flag does become coarse.

Phalaris bulbosa is one of the best winter grasses introduced at t College.

Festuca elatior does well on the poor soils of the College and star the dry summers fairly well.

F. arundinacea is largely cultivated in New Zealand.

F. ovina, *F. rubra*, and *F. duriuscula*. — All these grasses will gr in light soils, but they have finer leaves and smaller growth than the t previously named.

998 – **Senegal Perennial Rice** (1) **as Forage.** — WOOD, C. E. (Manager, Kamerunga St Nursery) in *Queensland Agricultural Journal*, Vol. II, Part 2, pp. 154-157 + 5 f Brisbane, August 1914.

Mention having been made of the existence of a perennial rice in S negal, French West Africa, the Queensland Department of Agricultu procured a small parcel of seed which was tried at the Kamerunga Sta Nursery. The germination of a parcel of seed received in 1913 w fairly good; planted out in the open in January it was in flower by t end of May.

Perennial rice is a good forage, relished when green by cattle and hors and it also yields a good hay. It has, however, the drawback of produci only a very limited quantity of seed. The panicles are few and bear fr two to ten grains, the other glumes being empty. Owing to the scarci and leanness of the grain it is not likely to be of any use for human consum tion in its present form in Queensland.

999 – **Drought-resistant Grasses and Fodder Plants.** — BREAKWELL, B. A., in *Agricultural Gazette of New South Wales*, Vol. XXV, Part 5, pp. 385-386. Sydney, 19

The exceptionally dry summer through which the interior of New Sou Wales has just passed provided a good opportunity of investigating th plants which best endured the drought.

It was observed that of the plants growing in the Experiment Farm the following, tabulated in order of drought resistance, were the most p minent grasses : *Panicum bulbosum* (Experiment Farms at Wagga, Bathu and Cowra), introduced from America.

Panicum prolutum — Coolah grass (Wagga, Bathurst, Nyngan), nati
Andropogon bombycinus — Silky heads (Wagga).
A. intermedius — Rare blue grass (Cowra and Nyngan).
A. erianthoides — Satin top grass (Cowra).
Panicum floridum — (Cowra, Bathurst and Wagga).
Chloris gayana (Wagga, Nyngan and Cowra).
Poa arachnifera — Texas blue grass (Cowra and Bathurst).

(1) See No. 802, *B.* March 1911. (*Ed.*)

Other fodder plants:

Medicago media — Sand lucerne (Wagga and Nyngan). This lucerne ginated as a cross between the yellow-flowered lucerne (*Medicago falcata*) l the common lucerne (*M. sativa*), and in power of drought resistance ibits the characteristics of the former. It also differs from the ordinary erne in having a procumbent growth; this renders it more suitable for ture than for hay, but makes it a poorer seeder than Tamworth lucerne.

Poterium Sanguisorba — Sheeps' burnet (Wagga).

Vicia dasycarpa — (Bathurst).

o - **Cowpeas (*Vigna catjang* Endl.; *Vigna unguiculata* Walp.) in New South Wales.** — HADFIELD, J. W. (Instructor in Agriculture, Hawkesbury Agricultural College) in *The Agricultural Gazette of New South Wales*, Vol. XXV, Part 8, pp. 657-661+2 plates. Sydney, August 1914.

The cultivation of cowpeas is spreading from year to year in New uth Wales, where it began to become general between 1890 and 1892. its early development the Department of Agriculture cooperated by tributing large quantities of seed in small lots. It is now distributed nearly all the warmer parts of the State, though the production of seed still largely confined to the North Coast District.

As a rule the crop is sown in rows 2 ft. 6 in. to 3 ft. apart and the seed m 6 to 9 in. apart in the rows. This enables the crop to be cultivated. wing with a drill is much better than broadcasting and harrowing in, if in this case heavy rain falls a quantity of seed may become exposed d does not germinate. As with other legumes, nodules form on the ots of cowpeas, whence frequently the second and successive crops succeed tter than the first, and but rarely require nitrogenous manures of any nd. In manurial trials at the Hawkesbury College phosphoric acid was oved to be the most important manurial ingredient. Sulphate of potash, ough it increased the yields, was too expensive, while nitrate of soda and lphate of ammonia were decidedly detrimental, reducing the yield to e half that of the unmanured plots.

The varieties of cowpeas are very numerous. The Black is the most pular, while the Poona, a variety introduced from India, has rivalled it does not excel the Black at the College in the production of green fod- r; but when grown for seed it does not ripen its pods so evenly. Both e late maturing, while the White or Black Eye and the Upright-growing e early; the Iron is a mid-season variety and it is claimed to be immune m the attacks of eelworms.

Cowpeas form a very valuable green manure crop for orchard and gen- al farm work, though it is difficult to plough the vines in. At Hawkes- ry it is usual to roll the crop first, and then after running over it with a sk cultivator to plough it in with a single-furrow disk plough. The crop ould be ploughed in soon after the pods are set, as at a later stage the ems become woody. Considering its very high feeding value, the writer nsiders ploughing in the whole crop as being sometimes a very wasteful actice. If the crop be fed off on the ground where it is grown, at least

50 to 75 per cent. of the manurial value will be returned, while the full feeding value of the crop will also have been obtained.

As fodder crop, cowpeas give a better balanced and somewhat more abundant fodder when they are grown with maize, or still better sorghum and millet.

A system that has proved very profitable on the North Coast is to sow the cowpeas down between the rows of early corn. They are sown with a maize dropper immediately after the last cultivation of the corn, which should be not later than January if it is intended to harvest the cowpeas for seed. Yields of 10 bushels per acre are quite common, and sometimes even 16 bushels.

Cowpeas by themselves usually form an inferior kind of silage, often acid in character and poor in colour and smell, and more or less decomposed. They are much better when mixed with sorghum, maize or millet. American experience indicates that the best plan is to broadcast the cowpeas at one bushel per acre, and the sorghum or kaffir corn at about 10 lb. of seed per acre.

If cowpeas have to be cut and turned into hay a difficulty is met with, as there is no satisfactorily rapid method of harvesting. Machinery for the purpose has been devised, but hitherto without much success. Cowpea makes good hay, but its leaves fall very readily when dry and without the greatest care the loss will be considerable. The upright-growing varieties, such as Poona and Upright-growing, especially when grown thickly, can be harvested with a scythe and sometimes with a mower.

No machinery for the purpose of harvesting the pods has been perfected, and with present methods the whole plant has to be harvested and threshed, or the pods picked by hand. Three cwt. of these peas in the pod give, when threshed, one bag of peas weighing 240 lb.

The sale prices of cowpeas in New South Wales have been practically stationary during the last twenty years, namely, for the Black cowpeas about 10*s* per bushel on the Rivers and about 12*s* 6*d*. delivered at Sydney to seedsmen. The average retail price for cowpea seed is about 15*s* per bushel. The price of Poona, which has a very small seed, is usually something over £1 per bushel.

FIBRE CROPS

1001 – **Flax Experiments in Ireland.** — *Department of Agriculture and Technical Instruction for Ireland, Journal*, Vol. XIV, No. 3, pp. 515-534. Dublin, 1914.

Manurial experiments. — The following is a summary of the results obtained from the two series of experiments conducted by the Department during the eight years 1901 to 1908 inclusive:

1. The use of potash manures gave profitable increases; kainit and chloride of potash showed almost equal merits, were more regular in their effects and, on the average, gave better results than sulphate of potash.

2. The application of kainit and chloride of potash in winter gave results as good as when these manures were applied at the time of sowing.

(1) See also No. 825, *B.* March 1914. (*Ed.*)

3. Phosphatic manures, when applied either singly or in combination with a potash manure, or as part of a complete mixture, encouraged the growth of weeds at the expense of the flax, and their use was almost invariably attended with a loss, and very frequently even with smaller yields of scutched flax.

4. In some seasons profitable increases were obtained from the addition of the nitrogenous manure, rape meal, to kainit. Its effects, which appeared to depend on the nature of the season, were too irregular to warrant the general adoption of such a mixture in preference to the kainit or chloride of potash dressings now so commonly used.

5. The application of agricultural salt was not remunerative.

As in these two series of experiments the results obtained from the addition of a nitrogenous to a potassic manure were very irregular, it was considered advisable to carry out a third series of experiments with sulphate of ammonia added in varied proportions to chloride of potash. Still further, as the application of phosphates as superphosphate or basic slag resulted in a loss, it was also decided to test bone flour as part of a complete mixture.

This third series of experiments was started in 1909 at ten centres and repeated in 1910 and 1911 in eight and nine centres. The following dressings per statute acre were tested :

Plot 1. — Unmanured.
2. — ½ cwt. chloride of potash.
½ cwt. sulphate of ammonia.
3. — 1 cwt. chloride of potash.
¼ cwt sulphate of ammonia.
4. — 1 cwt. chloride of potash.
½ cwt. sulphate of ammonia.
5. — 1 cwt. chloride of potash.
— ¼ cwt. sulphate of ammonia.
— 2 cwt. steamed bone flour.
6. — 1 cwt. chloride of potash.

Whilst in 1911 the summer was extremely warm and dry, in 1912 it was abnormally wet and cold.

The average results per acre from the application of the different manures to the flax crop were as follows :

Number of plot	1	2	3	4	5	
Yield of retted flax . . .	3 229 lb.	3 614 lb.	3 593 lb.	3 739 lb.	3 294 lb.	3 285 lb.
" of scutched flax,	33 st. 12 lb.	38 st. 11 lb.	37 st. 5 lb.	39 st. 13 lb.	31 st. 2 lb.	35 st. 1 lb.
Returns from flax and tow	£14 8s. 8d.	£16 13s. 5d.	£16 3s. 0d.	£17 12s. 9d.	£12 19s. 9d.	£14 16s. 9d.
Cost of manure	—	12s. 6d.	13s. 6d.	17s. 6d.	£ 1 4s. 3d.	10s. 0d.
Estimated profit from use of manures	—	£ 1 12s. 3d.	£ 1 0s 7d.	£ 2 6s. 7d.	£ 2 13s. 2d. (loss)	1s 11d. (loss)

In valuing these results it must be borne in mind that contrary to usual experience the flax on the unmanured plots in 1912 showed no signs of yellowing, which caused the advantage derived from chloride of potash alone (Plot 6) to disappear.

Plots 2 and 3 showed a profit over Plot 6 in the years 1909, 1910 and 1912 and a loss in 1911; Plot 4 yielded a profit in 1910 and 1912 and a loss in 1909 and 1911 These different results cannot be attributed to the respective fertility of the various soils; it appears more probable that they are due to the climatic condition of the seasons. No definite recommendation can therefore yet be made as to the use of sulphate of ammonia with chloride of potash. Plot 5 showed that when given under the form of bone flour phosphates caused a loss: they favoured the growth of weeds and diminished the yield in scutched flax.

Liming experiments. — An experiment designed to test the value of liming was made on four plots, each one quarter of an acre in extent. After the application of the lime in 1911 all plots were cropped with oats and in 1912 with flax.

The treatment of the respective plots per acre was as follows:

Plot	1911 Oats	1912 lax
1.	no lime	no chloride of potash
2.	no lime	1 cwt do. do.
3.	1 ton burnt lime	no chloride of potash
4.	1 ton burnt lime	1 cwt. do. do.

The average results per acre are shown in the following table:

Number of plot	1	2	3	4
Yield of retted flax	2 724 lb.	3 142 lb.	2 896 lb.	3 343 lb.
Yield of scutched flax	37 st. 8 lb.	44 st.	42 st.	47 st. 8 lb.
Value of scutched flax	£16 3s. 2d.	£18 6s. 0d.	£18 6s. 9d.	£20 15s. 0d.
Cost of manure	—	10s.	5s.	15s.
Estimated profit	—	£ 1 3s. 3d.	£ 2 2s. 1d.	£ 3 17s. 0d.

Seed trials. — Each year since 1901 experiments have been conducted with seed imported by the Department of Agriculture for Ireland direct from Holland and Russia, in comparison with Dutch and Russian seed imported by Ulster merchants. The results are given in the following table:

	Russian seed imported by the Department	Belfast brand of Riga seed	Dutch seed imported by the Department	Belfast brand of Dutch seed	Irish seed 2nd. year of selection
Average 1901-1911, excluding 1903. Yield of scutched flax per acre	£14 15s. 6d.	£13 17s. 0d.	£14 11s. 5d.	£13 11s. 6d.	—
1912. Yield of scutched flax per acre	£14 8s. 7d.	£14 4s. 6d.	£15 1s. 0d.	£14 3s. 6d.	£8 18s. 8d.
1912. Yield of scutched flax per acre	35 st. 1 lb.	34 st.	38 st.	36 st. 1 lb.	22 st. 3 lb.

From these and preceding experiments the conclusions may be drawn that the variety of flax seed to be sown (whether Dutch or Riga) should not be governed by the class of soil for which it is intended but by the quality of the seed itself, which depends on the climatic conditions prevailing in the seed-producing countries. Thus in 1910 and 1911 Russian seed gave the better average results on the various classes of soil, while in 1909 and 1912 the Dutch seed proved the more productive. Farmers should, therefore, before purchasing seed, consult the leaflets of the Department which give information as to the harvest conditions during the previous year in Holland and Russia.

In comparative seed tests, "Pernan Crown" seed, another seed selected and grown on a farm in Russia for a number of years, Irish seed and Dutch Riga Child were tested. The first gave, on the whole, better returns than the second, and both better than the Dutch Riga Child. The crops from the selected Irish seed were much inferior.

Other tests were made with Irish seeds saved from the same crop, but at different stages of maturity. The perfectly ripe seed yielded 41 st. 10 lb. of scutched flax per acre, or 16.72 per cent. of the retted straw, the average returns of flax and tow per acre being £18 16s. 9d. The immature seed yielded 39 st. 10 lb. of scutched flax, or 16.60 per cent, and the total value of flax and tow was £15 19s. 7d. The higher return from the crop produced by the ripe seed is mainly due to the superior quality of the fibre.

In 1911 tests were commenced and will be continued on a large scale with a view to determining if it be possible to produce flax seed successfully in Ireland and to improve it for fibre production by selecting from long stalks. It has been observed that seeds detached from the stalks in the autumn and stored in granaries lost in germinative qualities, and that it is preferable not to ripple it until the following spring and to store the dried flax straw in small lots during the winter in lofts with open windows so that all the seed boll ends are exposed to a current of air. This straw was rippled in the latter end of February.

A definite conclusion cannot yet be drawn from these experiments. As the following table shows the selected Irish seed yielded less than the Pernan Crown, but a scutched flax of higher value.

	Selected Irish seed	Pernan Crown seed
Yield of dried retted straw per acre	25 cwt. 1 qr. 4lb.	26 cwt. 1 qr. 20 lb.
Yield of scutched flax per acre	33 st. 2 lb.	36 st. 0 lb
Percentage of scutched flax from retted straw	16.38	17.02
Value of scutched flax per cwt.	81*s.* 2*d.*	76 *s.*
Value of scutched flax per acre	£16 16*s.* 3*d.*	£17 2*s.* 0*d.*

1002 – **Contribution to the Study of the Lodging of Hemp.** — HAINSCH, HEINRICH, in *Mitteilungen der landwirtschaftlichen Lehrkanzeln der K. K. Hochschule für Bodenkultur in Wien*, Vol. II, Part 4, pp. 607-674. Vienna, August 8, 1914.

This study contains a detailed account of the cultural conditions of the experiment and the results of the examination of the hemp straw, the observations and measurements taken during growth, microscopic examination of the stems, determination of resistance to lodging and chemical analysis.

The possibility of lodging depends on the lower portion of the stem, and it is necessary to consider the histological conditions in this region in order to judge the resistance of the stem. Transverse sections at the base of lodged plants show a reduction of lignified fibres, and an increase of parenchyma. The pith is also generally more abundant in lodged stems and the lignified fibres are often arranged symmetrically, thus reducing the mechanical resistance along the line of symmetry. The histological differences between lodged and unlodged plants disappear in the upper parts of the stems.

The cells of the fibrous tissue of lodged plants are smaller, round and with a larger lumen. The fibres are smaller and less dense. As a result of lodging the growth of the cells is checked and they remain diminutive. The relative thickness of the cell-walls diminishes with lodging, but only in the lower portion of the stem. As a result of direct determinations of the resistance of the stems, it appears that the mechanical constants of the tissues are not influenced by the thickness of the cell-walls or of the stem.

Lodging considerably diminishes the mechanical resistance of the cells; the resistance of the stems to lateral forces is directly proportional to their weight, provided the thickness of the cell-wall is not abnormal. It has not been found that the degree of lignification has any influence on the power of resistance of the cells, though it is certainly greater on the lower portions of the stem.

Lodged plants show a higher percentage of ash. The percentage of silica diminishes from the base to the top of the stem and is greater in lodged plants, but as its total quantity is so small it cannot have any effect on the resistance to lodging; similarly also with regard to the percentage of calcium.

1003 – **Hemp Production in the United States.** — *Daily Consular and Trade Reports, Issued by the Bureau of Foreign and Domestic Commerce*, Year 17, No. 177. Washington, July, 30, 1914.

The falling off in the domestic production of hemp is due primarily to the increasing difficulty in securing sufficient labour to take care of the crop, to the lack of labour-saving machinery, to the increased profits in raising stock, tobacco and corn, and lastly to the rapidly increasing use of other fibres, especially of jute.

During the past three years interest in the hemp industry has been reawakened, and experiments are being tried with a view to the cultivation of the crop in new areas, such as large extents in the valley of the Mississippi and its tributaries, and in the Sacramento and San Joaquin Valleys in California.

Hemp cannot be economically grown in areas of less than 50 acres in any one locality, so as to warrant the use of machinery for harvesting and breaking.

The following is a general estimate of cost and returns for such an area of 50 acres:

Cost:	$
Ploughing (in fall) 50 acres, $ 2 per acre	100
Disking (in spring), 50 cents per acre	25
Harrowing, 30 cents per acre	15
Seed, 40 bushels, delivered, $ 4.50 per bushel	180
Seeding, 40 cents per acre	20
Rolling 30 cents per acre	15
Self-rake reaper for harvesting	75
Cutting with reaper, $ 1.50 per acre	50
Picking up from gavels and shocking, $ 1 per acre	50
Spreading for retting, $ 1.50 per acre	75
Picking up from retting swath and setting in shocks, $ 1.40 per acre	70
Breaking 50 000 lbs. fibre, including use of machine brake, 1 1/2 cents per lb.	750
Baling 125 bales (400 lbs. each), including use of baling press, $1.40 per bale	175
Marketing and miscellaneous expenses	150
Total cost	$ 1 750
Returns:	
Long fibre 37 500 lbs., 6 cents per lb.	2 250
Tow 12 500 lbs., 4 cents per lb.	500
Total returns	$ 2 750

1004 – **Cotton in Paraguay and Argentina.** — *Boletín del Departamento Nacional de Fomento*, Year 1914, No. 5, pp. 5-31. Asunción, May-June, 1914.

The results of an enquiry on the cultivation, marketing and trade in cotton made by the " Departamento Nacional de Fomento " of Paraguay are here presented.

Cotton in Paraguay. — Suitable cotton soils are plentiful in Paraguay and the crop was formerly grown in all districts. According to statistics for 1863 the yield was nearly 5 000 000 lbs. of ginned cotton.

All the best varieties except Caravonica have been tried in Paraguay, and it has been found that the tree cottons are more suitable to the climate

especially *Gossypium barbadense*, with *G. peruvianum* and *G. maritimum* which are really varieties of it. These like abundant rains, and Paraguay is more favoured in this respect than any other cotton-growing country. Good results have also been obtained at some places, in particular at the Agricultural Experiment Station of Puerto Bertoni, with varieties of *G. herbaceum*, especially Peterkin, Hawkins, and Allen. These varieties succeed in places where the others will not do, as in poor shallow soils. *G. barbadense rufum*, known in Paraguay as Mandipwita, is indigenous. It is used to a certain extent in the industry and sometimes makes a good price. If a steady market could be obtained for it, this species of cotton would be of great importance, since it yields well and is more resistant than other species.

Seeding is effected from June to the beginning of September; with late sowing the yield of the first crop is reduced, but the second is much greater. Sr. M. S. BERTONI made a successful experiment of sowing in January and February between rows of maize; if the maize is not sown too thickly the cotton grows well, though slender, and is protected from the cold. If cold weather prevails after the maize is harvested, the cotton is cut down to the ground, but if there is no likelihood of frost the young plants are left as they are. When the warm weather returns they grow rapidly and at the end of November the bolls begin to ripen.

Harvest begins in December, or January, or at the latest February, for the first year's crop and continues until the cold season or, if there is no fear of frosts, until June or July when the flowering period ceases and growth of the branches begins. In districts exposed to frost the plants are cut back in May, and the unopened bolls are collected and dried in sheds until they open: these pods yield the cleanest cotton.

Sr. Bertoni considers the yield per acre in Paraguay as the highest in the world, the average yield of the country being 534 lbs. per acre. At the experiment station at Puerto Bertoni he has obtained yields of 710 to 890 lbs. per acre of ginned cotton.

The following figures show the comparative yields of the different countries (in lbs. per acre):

	Minimum	Average	Maximum
Italy and Spain	68	135	225
Africa	90	180	360
United States	126	200	604
Argentine	180	305	630
Paraguay	360	540	923

In spite of natural conditions so favourable, the cultivation of cotton has not been seriously developed owing to a number of social factors.

Cotton in the Argentine Republic. — The following data have been obtained from the "Dirección General de Comercio e Industrias" of the "Departamento de Fomento" of the Argentine.

Almost all the Argentine cotton is produced in the region of Chaco, in loamy soils; the rainfall is 80 to 150 cm. (32 to 60 in.), fairly well distri-

buted. The common varieties grown are Texas Woods, Culpeper, Simkin, King, Russell, Peterkin, Allen, etc., all of American origin and of short staple. The " Departamento de Fomento " has begun a policy for the standardisation of the cotton of Chaco. The estimated area of cotton in 1914 is about 7000 acres ; it would have been much greater but for the depredations of locusts and prolonged drought. The average yield is about 1340 lbs. per acre of raw cotton, but of recent years it has been only 1080 lbs. per acre. Unginned cotton is bought by local merchants, who gin it and pack it for export. The seed is partly exported and partly used locally for oil extraction. Under normal conditions an acre of cotton yields a profit of £3 10s to £5 10s ; the initial expenditure, together with cost of seeding and picking, may be estimated at the same sum. Owing to scarcity of labour, the extension of this crop presents difficulties.

1005 – **The Indian Jute Industry.** — *The Agricultural Gazette of New South Wales*, Vol. XXV, Part 7, pp. 577-580. Sydney, July 1914.

The following data are taken from a report drawn up by J. B. SUTTOR, who was instructed by the Minister of Agriculture of New South Wales to visit the jute-producing districts of India.

India has practically a monopoly of the production of jute, the result being that the market fluctuates to a great extent and is subject to much speculation. The world's annual demand for raw jute is estimated by the Commercial Intelligence Department of India at about 1 700 000 tons ; 791 000 tons is the estimated mill consumption; the surplus is exported to the following countries :

England	340 000	tons
Germany	180 000	»
U. S. America	124 000	»
France	86 000	»
Other countries	179 000	»
Total	909 000	»

The jute manufactures represent 40 per cent. of the total value of exports of Indian manufactures, and the raw jute over 26 per cent. of Indian raw materials exported. During the financial year 1912-13 the exports of jute fabrics to the principal countries were as follows :

	Amount — £	Principal form of export —
U. S. America	5 840 333	Cloth
Argentine	1 944 687	»
Australia	1 433 733	Bags and bales
England	960 933	» » cloth
Chile	564 067	Bags
China	530 200	»

The above countries are followed in decreasing order by Canada, Java, Egypt, West Indian Islands, Straits Settlements, etc.

Bengal is the chief jute-producing centre of India. The area under jute is estimated at 3 400 000 acres and that an average crop yields about 1000 lbs. of jute fibre per acre, the quality of which is largely governed by soil and climatic conditions. The most satisfactory results are obtainable from rich loams provided with plenty of moisture. Jute is mostly grown in small holdings and solely worked by natives. The soil is frequently ploughed several times to pulverize it thoroughly before sowing, No special care appears to be bestowed on seed selection. The sowing takes place from February to April, broadcasting being generally adopted: about 8 lbs. of seed to the acre are used. While moisture is necessary, the jute areas are not irrigated except in cases where there is a falling off in rainfall or a great absence of humidity.

When the crop is about to flower, it is harvested. The stalks are then generally from 4 to 12 feet high or even more, according to climatic conditions. The harvesting takes place from June to August and sometimes up to September. The bundles of jute stems are submerged in water to ret for 10 or 15 days; then the fibre is removed from the core by hand with the help of very primitive implements, after which it is dried and bleached in the sun for two or three days.

The fibres are collected in small bundles and are then ready for sale. There are usually three middlemen between the grower and the mill or manufacturer. The bales for the local mills weigh 330 lbs. and those for exportation 400. The raw jute is classified as follows:

Nº. 1 quality, 80 to 90 per cent. suitable for Hessian warp and 10 to 20 per cent. of weft.

Nº. 2 quality, 60 to 70 per cent. of the former, and 30 to 40 per cent. of the latter.

Nº. 3,70 per cent. of sacking warp and 30 per cent. of weft.

Nº. 4,40 per cent. of weft.

For foreign markets the standard quality is usually quoted as of M group or "cracks", and means an equal proportion of Nº. 2 and Nº. 3 qualities.

Besides the above there are also lower grades called "cuttings" and "rejections".

In the mills the jute passes first of all through a softening machine with fluted rollers; it is then carded and spun. Thence it proceeds to the looms and when woven it passes through a callender with rollers heated up to 600° F., givng a smooth surface. In the case of cloth for wool bales, the fabric passes through another machine known as the "cropper", which removes any loose fibres from the surface of the cloth in order to avoid any jute fibre getting mixed with the wool.

STIMULANT, AROMATIC, NARCOTIC, AND MEDICINAL CROPS

1006 - **Composition of Essence of *Artemisia arborescens* and of *A. Absinthium* collected in Italy.** — 1. Jona, T., in *Annali di Chimica applicata*, Vol. II, No. 3 and 4, pp. 63-68. Rome, 1914. – 2. Paolini, V., and Lo Monaco, R., in *Atti della Reale Accademia dei Lincei, Rendiconti di scienze fisiche, matematiche e naturali* Vol. XXIII, Part 4, pp. 123-129. Rome, August 16, 1914.

1. — The essence of *Artemisia arborescens* was obtained by the distillation of the dried tops collected near Sassari (Sardinia), a little before flower-

ing. The yield was 0.57 per cent. of essence, with the following characters: deep blue colour, aromatic, slightly mobile, density at 15° 0.9458, soluble in 10 volumes of 80 per cent. alcohol and in all proportions of 90 per cent. alcohol, contains no nitrogen or sulphur, saponification value 29.3, acid value 9.8, etherification index 19.5. At normal pressures the essence distils between 90° and 210° C.

According to the researches of the writer it contains: *a*) 13.94 per cent. of alcohol of the formula $C_{10}H_{18}O$ (thuyol and a small quantity of another alcohol, probably borneol), 8.58 being free and 5.36 combined with fatty acids; *b*) formic, acetic, isovalerianic, pelargonic, palmitic and stearic acids, partly in combination with the above-mentioned alcohols; *c*) about 13 per cent. of β thuyone; *d*) a mixture of hydro-carbons of high boiling-point.

2. — Essence of *Artemisia Absinthium* obtained from fresh cultivated plants grown near Rome and Perugia, by distillation in a current of vapour gave the following analysis: *a*) about 10 per cent. of thuyone, consisting of the isomeric β dextro-rotary and the isomeric α thuyone; *b*) about 48 per cent. of thuylic alcohol, free and in combination with acetic, isovalerianic and palmitic acids; a mixture of at least two chemical compounds in which dextro-rotary δ thuylic alcohol predominates; *c*) phellandrene; *d*) cadinene; *e*) a blue oil of unknown composition.

1007 – **Two Crosses of Strong Tobacco in Italy.** — Aielli Donnarumma, in *Bollettino tecnico della coltivazione dei tabacchi*, Year XIII, No. 1, pp. 7-8. Scafati, January-February 1914.

With a view to improving the type of plant and the shape of the leaves of strong hybrids obtained by crossing "Italia" tobacco with Kentucky and Salento × Kentucky, crosses were made between the two hybrids themselves. The parental forms were immune from *Thielavia basicola* which causes so much damage to Kentucky tobacco. Four of the typical hybrids were selected, two of each kind, and reciprocal crosses were made. Thirty flowers were crossed and 30 seed capsules obtained. In the following year the two hybrids Italia-Kentucky × Salento-Kentucky and Salento-Kentucky × Italia Kentucky, were grown in land freely infested with disease and in which the Kentucky variety had failed during previous years. Although the season was not very favourable the two crops succeeded admirably. No plant showed the least attack of *Thielavia*, and the growth was so rapid that they considerably out-grew the rows of control plants in the centre of the plots.

The object of the cross was completely attained in the new hybrids, which combined the length of leaf of the Italia-Kentucky parent and the breadth of leaf of the Salento-Kentucky parent. The characters of the parents were so completely combined in the offspring that it required an experienced eye to distinguish between the reciprocal crosses. Cultural experiments will be made to ensure constancy of type.

1008 – **The Chemical Composition of the Tobacco Plant in its Various Stages of Growth** — Note I, on Xanthi Yaka grown in the Abruzzi. — *Communicated to the Institute by Professor* E. PANNAIN, *of the Royal University of Rome.*

With a view to contributing to the knowledge of the tobaccos grown in Italy and of resolving certain problems of biological and technological chemistry, it was considered advisable to determine the variation in chemical composition of the plant during its growth and the effects produced by the different treatments of drying and fermenting to which the green leaves are subjected during the process of manufacture. These results were obtained in researches on the variety Xanthi Yaka, grown at Francavilla al Mare (Abruzzi). Analyses were made of seedlings in the nursery, plants before flowering, ripe leaves from each picking and the bare stems and roots remaining in the field after harvest.

In this preliminary study the following determinations were made of different parts of the plant after drying in a water oven : ash, total nitrogen, nicotine, organic acids, ether extract, alcoholic extract. Ordinary methods were used except in the case of nicotine, for which a slight modification of Keller's process was preferred on account of its rapidity : the nicotine was displaced by 20 per cent. potash and extracted by a mixture of equal parts of sulphuric and petroleum ether, then titrated against $\frac{N}{10}$ sulphuric

TABLE I. — *Analyses of seedlings.*

Parts analysed	Ash	Total nitrogen	Nicotine	Organic acids	Ether extract	Alcohol extract
Leaves	15.92	4.45	1.13	5.03	9.03	21.84
Stem	18.40	2.90	0.48	5.40	8.20	21.40
Roots	14.33	3.04	0.80	3.93	4.00	12.00
Whole plant	15.85	3.81	0.65	4.45	7.30	18.10

TABLE II — *Analyses of plants before flowering.*

Parts analysed		Ash	Total nitrogen	Nicotine	Organic acids	Ether extract	Alcohol extract
Leaves from middle and lower portion of plant.	whole	10.50	2.86	1.18	3.56	8.01	23.80
	blade	10.40	2.92	1.23	3.47	8.30	24.90
	ribs	10.60	2.02	0.80	4.01	5.06	16.21
Apical leaves	complete	11.10	4.30	0.89	3.36	9.21	24.50
	blade	12.45	4.70	0.91	3.45	9.45	25.50
	ribs	10.55	2.08	0.81	4.01	5.00	16.15
Stems		6.40	1.25	0.29	3.65	2.40	21.10
Roots		6.85	1.69	0.65	4.23	1.85	18.60

acid with congo red as indicator. The organic acids were displaced by sulphuric acid 1 : 3, extracted with ether, titrated against soda using phenolphthalein as indicator, and expressed as oxalic acid.

The seedlings were analysed as a whole as well as in portions, and gave results as shown in Table I.

The analyses of the plant before flowering are given in Table II.

The leaves harvested at the 1st (basal), 2nd, 3rd and 4th (apical) periods were analysed whole and in parts (blades and ribs). The bare stems and roots remaining in the field were also analysed. The results are set out in Table III.

TABLE III — *Analyses of leaves of the various pickings.*

		Ash	Total nitrogen	Nicotine	Organic acids	Ether extract	Alcohol extract
1st picking	whole leaves	16.10	1.57	1.42	4.61	9.95	32.15
	blades	16.40	1.69	1.56	4.50	10.15	32.75
	ribs	14.70	1.23	0.46	4.64	4.90	24.95
2nd picking	whole leaves	12.30	1.00	1.52	4.52	10.00	34.15
	blades	12.35	1.02	1.94	4.50	10.40	40.55
	ribs	12.10	0.77	0.73	4.54	4.90	27.35
3rd picking	whole leaves	8.55	1.26	0.75	3.75	9.65	45.10
	blades	8.25	1.35	0.84	3.52	10.40	46.05
	ribs	9.80	0.96	0.24	3.91	3.15	33.60
4th picking	whole leaves	7.50	1.50	0.74	4.07	10.80	43.25
	blades	7.20	1.58	0.81	3.76		
	ribs	9.00	1.34	0.32	4.95		
Bare stems		6.40	0.55	0.19	3.92	1.80	10.20
Roots		7.40	0.72	0.16	7.78	1.25	8.60

These results show that :

1. Seedlings are richer in ash, nitrogen and organic acids than half-grown or full-grown plants.

2. In plants before flowering, the apical leaves are richer in ash, nitrogen, and substances soluble in ether and alcohol than the lower leaves, but they contain less nicotine and organic acids.

3. In ripe leaves, the ash content decreases from the basal (1st picking) to the apical leaves (4th picking), and the leaves of the 1st and 2nd pickings are also richer in nicotine, containing double the quantity of the leaves of the 3rd and 4th pickings.

4. The leaf blades are always richer in nitrogen, nicotine and substances soluble in alcohol and ether than the ribs, and generally also in ash, but they are poorer in organic acids.

5. The stems and roots contain less ash, nitrogen, substances soluble in ether and alcohol, and nicotine than other parts of the plant, but the roots contain more nicotine than the stems.

1009 – **The Cultivation and Collection of Medicinal Plants in England.** — WHATMOUGH W. A., in *The Journal of the Board of Agriculture*, Vol. XXI No. 6, pp, 492-510 + 13 figs. London, September 1914.

The cultivation of medicinal herbs in England began in very ancient times and gained gradually in importance with the decrease of uncultivated lands and of wild plants. During recent years the acreage devoted to drug cultivation has been more and more restricted by competition with wild foreign products; nevertheless English drugs and essences have still a reputation which allows of their being sold at about four times the price of the Continental article.

The limited outlet for most drugs makes overloading the market a comparatively easy matter; prices then become excessively low for the producer, with the result of restricted production, which in its turn leads again to high prices. As an illustration the writer instances Belladonna; in 1900 the supply of home grown Belladonna was in excess of the amount required for making green extract, and the price of the surplus leaves, after drying, was gradually reduced until being sold in competition with the wild foreign supplies they were disposed of at a loss. The result was that cultivation was practically limited to four drug farms having factories for making Belladonna preparations. But in 1912-13 there was an interruption in the continuity of Belladonna leaf and root exports from Croatia and Slavonia in South Hungary, the chief centres for foreign Belladonna; prices rose to such an extent that roots which realized 45*s* per cwt. in January sold for 150*s* before the end of August. Belladonna leaves from abroad, which sell at normal times for 45*s* to 50*s* per cwt., are now unobtainable at 1*s* per lb. In order to avoid as much as possible such fluctuations, the writer suggests adopting cooperation between growers and wholesale druggists.

The south of England is especially suited to drug growing and is further favoured by being close to the principal consuming market.

The writer then reviews the most important medicinal plants grown in England, namely:

Aconite (*Aconitum Napellus* L.). — The roots are mostly used, the leaves being of little importance. The chief collecting centres for the foreign root are the Swiss Alps, Salzburg, North Tyrol and Vorarlberg; Spain supplies some also and Japanese root (usually ascribed to *A. Fischeri* Reichb.) is plentiful.

Anise (*Rimpinella Anisum* L.). — It is cultivated at Westington near Chipping Norton, but the English climate is hardly warm enough to ripen the fruit properly and does not warrant further attempts at cultivation, even if market conditions, should be favourable.

Belladonna (*Atropa Belladonna*, L.). — The plant grows wild in the southern counties of England. When cultivated it yields an average crop of fresh herb in the second and third years of 5 to 6 tons to the acre. A second

crop is obtained in September in good seasons. It is sometimes attacked by a small beetle, *Epitrix atropae*. Paraffin and soap emulsion is stated to kill this.

Caraway (*Carum Carvi*, L.). — Caraway is largely grown in the Netherlands. In England it is mostly cultivated in Essex and Kent; it appears naturalized in some parts of Lincolnshire.

Chamomile (*Anthemis nobilis* L.). — Belgium is the chief grower of this plant. English chamomile is normally practically all used for distillation of oil. The yield of dry flowers is about 4 cwt. per acre. From 5 to 6 lbs. of fresh flowers yield 1 lb. of dry flowers.

Coriander (*Coriandrum sativum*). — Coriander is grown in Lincolnshire and East Anglia, often in conjunction with caraway. It yields about 15 cwt. per acre. English-grown coriander has the reputation of possessing the finest flavour.

Dandelion (*Taraxacum officinale* L.). — Ordinarily English roots are sold in competition with German roots. The yield is about 4 or 5 tons of fresh roots to the acre in the second year. A hundred parts of fresh root yield twenty-two of dry material.

Foxglove (*Digitalis purpurea* L.). — The Continental supplies come chiefly from Thuringia and the Harz mountains. It grows wild in England, and is also cultivated by a few growers ; the yield is about 1 to 2 tons of fresh leaves per acre.

Dill (*Peucedanum graveolens* B. & H.). — It is grown chiefly in East Anglia, and produces from 5 to 7 cwt. of dill fruits per acre.

Fennel (*Foeniculum capillaceum* Gilibert). — The best fennel is supplied by France, Saxony and Russia. Fennel is largely used for cattle condiments. When grown in England it becomes an annual, and it would probably yield a crop of 15 cwt. per acre.

Golden Seal (*Hydrastis canadensis* L.). — Golden seal is an American drug. It was formerly so abundant in Ohio as to be considered a pestilent weed, but the drug collector and the improvement of land denuded the natural growing areas (deep shady nooks in forests with rich deep moist soil and now the supply is so limited that the price has quadrupled since 1905. In England it appears to be grown only in one locality — at the Wellcome Materia Medica Farm, near Darenth, Kent. It has also been successfully grown near Moscow in the shade of apple trees. In 1912 the United States Department of Agriculture reported that the cultivation of golden seal was "successfully established". After initial experiments commenced in 1899 by the above Department, 5120 lbs. of fresh roots per acre, corresponding to 1500 lbs. of marketable roots, were obtained.

Henbane (*Hyosciamus niger* L.). — This biennial is cultivated in England for the preparation of the extract; the dry commercial leaves imported from Germany and Russia are derived from the wild annual. The fresh leaves lose 80 per cent. of their weight on drying.

Egyptian Henbane (*Datura Metel* L.). — It thrives very well at the Wellcome Materia Medica Farm in Kent.

Opium Poppy (*Papaver somniferum* L.). — Though the crop is a precarious one, the white variety of opium poppy is still grown in several parts of England, notably Lincolnshire. Belgium ordinarily supplies a proportion of the poppy heads used in the United Kingdom.

Thorn Apple (*Datura Stramonium* L.). — It is not grown on a commercial scale in England ; considerable amounts of the wild leaves are imported from Germany and Hungary. The demand for seed is very limited. About 34 parts of dry leaves are produced from 100 parts of fresh ones.

Datura Tatula is occasionally used in medicine in place of *D. Stramonium.*

Valerian (*Valeriana officinalis* L.). — Valerian is common in England in moist situations. Most of the rhizomes of commerce are grown in Derbyshire or imported from Holland, Germany and France. About 24 parts of the dry product are obtained from 100 of fresh rhizomes.

Other Medicinal Plants.

Experimental growing of some American drugs such as senega, grindelia, pokeroot and lobelia is made at Darenth.

Medicinal herbs for sale are cultivated at Carshalton. The following are regularly grown :

Balm (*Melissa officinalis* L.).
Comfrey (*Symphytum officinale* L.).
Feverfew (*Chrysanthemum Parthenium* L.).
Greater Celandine (*Chelidonium majus* L.).
Germander (*Teucrium Scorodonia* L.).
Marsh Mallow (*Althaea officinalis* L.).
Mugwort (*Artemisia vulgaris* L.).
Pennyroyal (*Mentha Pulegium* L.).
Rue (*Ruta graveolens* L.).
Southernwood (*Artemisia abrotaneum*).
Tansy (*Tanacetum vulgare* L.).
Wormwood (*Artemisia Absinthium* L.).
Yarrow (*Achillea Millefolium* L.).

Among the medicinal plants which grow wild in England and which are, or might be, collected the writer mentions the following :

Barberry (*Berberis vulgaris* L.).
Bittersweet (*Solanum Dulcamara* L.).
Broom (*Cytisus scoparius* L.).
Buckbean (*Menyanthes trifoliata* L.).
Burdock (*Arctium Lappa* L.).
Centaury (*Erythraea Centaurium* Pers.).
Coltsfoot (*Tussilago Farfara* L.).
Elder (*Sambucus nigra* L.).
Figwort (*Scrophularia nodosa* L.).
Hemlock (*Conium maculatum* L.).
Horehound (*Marrubium vulgare* L.).

Male Fern (*Aspidium Filix-Mas* Sw.), a very common fern in moist sheltered stations ; hitherto Germany (Harz and Thuringia) supplied all the male fern rhizome or extract used in England.

Meadow Saffron (*Colchicum autumnale* L.).

Meadowsweet (*Spiraea Ulmaria* L.).

Mullein (*Verbascum Thapsus* L.).

Red Poppy (*Papaver Rhoeas* L.), the petals of which find a steady, if limited market.

Sweet Flag (*Acorus Calamus* L.).

Yarrow (*Achillea Millefolium* L.), etc.

Other medicinal herbs, such as squirting cucumber and *Lactuca virosa*, are cultivated in a small way.

A bibliography of 20 works is given as an appendix to the paper.

1010 – **New Garden Plants of the Year 1913.** — *Royal Botanic Gardens, Kew, Bulletin of Miscellaneous Information*, Appendix III. – 1914. 86 pp. London, 1914. MARKET GARDENING

The number of garden plants described yearly is so considerable that it has been thought desirable to publish a complete list of them in the Kew Bulletins each year. The present list comprises all the new introductions recorded during 1913. It includes not only plants brought into cultivation for the first time during 1913, but also the most noteworthy of those which have been re-introduced after being lost from cultivation, and new hybrids. The list contains 454 plants. Of each species or variety the description is given and the publication from which the description is drawn.

1011 – **Pruning Hardy Shrubs.** — BECKETT, E., in *The Journal of the Royal Horticultural Society*, Vol. XL, Part I, pp. 24-34 + 8 figs. London, August 1914.

The growing of ornamental shrubs has developed greatly in the United Kingdom during the last 20 years and a great number of new species have been introduced from the Far East ; most of them prove hardy and adapt themselves well to their new home.

The question of the most suitable pruning is very important in order to ensure their maximum ornamental effect. The writer bases the following advice on his own long experience :

Shrubs that require but little pruning, except to keep them in a shapely condition, are: *Arbutus Unedo*, which however, if it has been allowed to grow straggling, can be safely cut back to within 2 or 3 feet of the ground ; *Aristotelia Macqui ; Garrya elliptica ; Escallonia* spp. ; *Cassinia fulvida* (*Diplopappus chrysophyllis*) which much resents being cut into the hard wood ; *Cotoneaster* spp., especially the new varieties introduced from China, while some of the older and more common varieties, for example *Simonsii* and *microphylla*, may be cut to within a few inches of the ground if necessary ; *Cytisus* spp., which sufffer much when cut back into old, hard wood ; *Hymenanthera crassifolia*, to be pruned in spring ; *Baccharis patagonica* and *B. halimifolia ;* most varieties of *Ilex* require to be pruned in July ; many of the newer forms of *Viburnum* (while *V. Tinus* answers well when severely cut into the old wood) ; *Calycanthus floridus, C. glaucus* and *Chimonanthus*

fragrans should always be pruned immediately after flowering ; *Hamamelis*, which require very little pruning and that when necessary should be done after flowering ; *Paeonia Moutan*, the chief pruning they require is to prevent the stocks on which they are generally grafted getting the better of the variety ; *Abelias*, *Myrica Gale* (in early spring) ; *Exochorda* (directly after flowering) ; *Diervilla* or *Weigelas* (as soon as flowering is over) ; *Cydonia japonica genista ; Clerodendron tricholomum ; Coronilla Emerus ; Hippophae rhamnoides ; Hydrangea ; Rhodotypus kerrioides ; Potentillas ; Rhammus ; Spiraea discolor, S. arguta, S. bracteata, S. media, S. Henryi, S. Thunbergii*, and *S. Wilsonii* ; the various species of *Syringa*, which succeed better on their own roots than grafted on *S. vulgaris ;* they should be pruned immediately after flowering ; Ericas ; Azaleas ; Rhododendrons, Junipers, etc.

The following require light pruning while they are young, answer well to the knife when adult and when they are old may be cut down to the ground : *Aucuba japonica* and its varieties, the different kinds of *Phillyrea*, etc.

Other plants that answer well to pruning, even if it be severe are : the various species of *Berberis*, some of which, *B. japonica* for instance, may be cut down to the ground when on growing old they become unsightly ; it is a mistake to graft the newer choice species from China on *B. vulgaris ;* as the greatest possible care is needed to prevent the stock outgrowing the variety ; the arborescent forms of *Hedera Helix ; Ulex europaea, Corylopsis ; Hypericum* spp. which usually require only light pruning ; *Philadelphus ; Ceanothus ; Stephanandra Tanakae* and *S. flexuosa ; Thuja gigantea ; Taxus baccata*, etc.

The following require severe pruning : *Bupleurum fruticosum* (every year in March) the bushy *Loniceras*, which must be pruned after flowering ; most of the species of *Ligustrum ; Budleia* (second week in April) ; *Caryopteris Mastracanthus ; Leycesteria formosa ; Amorpha canescens, A. fruticosa ; Forsythia* (after flowering) ; the various species of *Cornus*, especially *C. alba*, which should be cut down to the ground every year in the first week of April ; *Sambucus ; Spiraea japonica, S. Douglasii, S. hypericifolia, S. salicifolia, S. chamaedrifolia* (during the winter months), *S. arborea, S. Lindleyana, S. sorbifolia* and *S. Aitchsoni* (require pretty severe pruning about the last week of March) ; *Rhus* (never before the first week of April) ; *Salix*, (in the first week of March) ; *Symphoricarpos racemosus* (which has to be cut down to the ground every year) ; *S. orbiculatus* about every seven years ; *Tamarix*, which should be cut to within two or three inches of the base of the previous year's growth ; the majority of the climbers, such as *Lonicera, Polygonum, Vitis* and *Wistaria*.

FRUIT GROWING

1012 — **Vine Growing and Wine Making in Rumania.** — Pisoschi, Elia, in *Le Mouvement Economique*, Vol. XX, No 116, pp. 73-88. Bucarest, July 1914.

Rumania is on the northern limit for the cultivation of the vine. Since the vine is more affected by cold damp summers than by severe winters, the dry warm summers of Rumania enable this crop to be grown successfully in spite of the rigorous winter.

The best lands for vine growing in this country are those situated at an altitude of 150 to 400 m. (500 to 1300 ft.). The nature of the soil enables vines to be planted in all districts within the above altitudes with the exception perhaps of the extreme northern districts of Botoshani and Dorohoi.

The area of land under vines in 1882 was 287 075 acres, but owing to the ravages of phylloxera it had decreased to 222 467 acres in 1913. The reconstitution of the destroyed vineyards with American stocks was begun in 1893. This work progresses slowly but surely, the area under American stocks having increased from 338 acres in 1893 to 25 403 acres in 1913.

According to the statistics of the Ministry of Lands, the distribution of the vineyards in 1913 was as follows :

		acres
In bearing	Native	112 195
	American	67 173
Reconstituted but not yet in bearing	Native	13 062
	American	30 037
	Total	222 467

Although the area occupied by vines only represents 0.69 per cent. of the total area of the country, the vine is of the greatest economic importance to Rumania, for with an average yield of 175 gallons per acre and an average price of 1*s* 4*d* per gallon, the gross returns are about £. 12 per acre, apart from the value of the residues.

The statistics of the number of vine-growers, grouped according to the area of their vineyards, show that 95 per cent. of them do not possess more than 1 hectare (2 ½ acres) of vines. The largest extents of vineyards are found in the following districts :

	acres
Putna	34 601
R. Sarat	21 155
Prahova	13 747
Valcea	13 720
Buzèu	12 894
Dolj	10 787
Tecuci	10 218

From the point of view of quality, the vineyards of Cotnari give white wines very much appreciated, but this region is to-day entirely infested by phylloxera and in course of replanting.

On account of the rigorous climate the vines are covered with soil during the winter, after the pruning, except when this is postponed till spring owing to cold weather setting in early ; in this case the vines are simply tipped before burial. They are unearthed during the last weeks of March and begin to shoot early in April in the south, a fortnight later in the north.

The varieties planted are either old native sorts grafted on American stocks, or foreign vines. The choice of varieties has not always been made

prudently or competently. The most important native varieties are as follows:

White: Grasa (Cotnari region), Feteasca Galbena (Odobeshti), Cramposhia (Dragashani), Gardanul (Dragashani), Gordinul (Dealul Mare).

Red: Babeasca (Nicoreshti), Brgahina (Dragashani), Roshu Vartos and Roshu Moale (throughout the country).

The most common foreign varieties are:

French: Cabernet, Malbec, Sauvignon, Cinsaut, Clairette, Pinot, Aligoté, Gamay, Aramon, Carignan, Muscat, Alicante, Bouschet, Colombaud.

German: Riesling.

Austro-Huangarian: Sylvaner, Veltliner, Kadárka.

Wine making is still in a primitive state, owing to the number of small growers who cannot afford the expense of modern apparatus. In 1913 Rumania produced, from the 179 368 acres of vines in bearing, 33 515 430 gallons of wine, valued at £2 188 250. According to the statistics of the Ministry of Industry and Commerce, the movement of wines in 1911 was:

		gallons	£	s
Imports	In bottle	14 831	4 547	18
	Otherwise	132 131	28 599	16
	Total	146 962	£33 147	14
Exports	In bottle	625	191	14
	Otherwise	3 620	197	16
	Total	4 245	£389	10

Experiments on the production of sparkling wines are very numerous at the present time, but the future of such wines is still doubtful.

FORESTRY

1013 – **The Resin Pine of Tonking.** — CARRIÈRE (Inspector of Waters and Forests) in *Gouvernement général de l'Indochine, Bulletin économique de l'Indochine*, Year 17, No 108, pp. 329-335 + 3 figs. Hanoï-Haiphong, May-June 1914.

Pinus Massoniana, which yields more resin with a higher strength of essence than *P. maritima*, abounds in Indo-China, especially in the region of Quang-Yên. Pines also occur in Tran-Ninh, Lang-Bian, in the mountains of Ha-Giang and in Cambodia, especially in the first two regions; but they are not the same species as those in Quang-Yêen and may be considered as allied to *P. montana*.

In order to realise the value of this natural wealth, the Forest Department of Tonking has taken over the control of the cutting and instructed the natives in the methods employed with *P. maritima* in the Landes. At the present time some 70 000 pines are being cut in Quang-Yên, and this number may be increased by at least 5000 trees a year for at least 20 years.

The natural regeneration of the *P. Massoniana* forests is rapid and vigorous, and the Forestry Department has undertaken the reafforestation of certain cleared areas. Under average conditions the percentage of trees obtained by sowing in pots is about 20. One tree will yield about

lbs. of resin, containing 17 to 22 per cent. of essence. The resin is valued at about 7*s* 6*d* per 100 lbs.

There are numerous unproductive areas in the delta region of Tonking that would yield good returns if planted with resin pines. *P. Massoniana* (the variety with needles in pairs) flourishes in Yên-Thê and the province of Thai-Nguyên.

1014 – **The Balsam Fir.** — ZON, R., in *U. S. Department of Agriculture, Bulletin* 55, pp. 68 + 8 figs. + 2 tables. Washington, D. C., 1914.

This monograph on the Balsam fir (*Abies balsamea* Mill.) deals with its distribution, the forest types in which it occurs, its yield of timber, economic importance specially from the point of view of the pulp industry, methods and cost of working, biology, characters of the timber, rate of growth and proposed methods of cultivation.

The total volume of timber in the zone of commercial exploitation is estimated at about 5 billions of board feet, or sufficient to last 30 years at the present rate of consumption.

With the present methods of cutting, the balsam fir gradually predominates over the American red fir (*Picea rubens* Sargent) in mixed plantations (1).

The growth of the balsam fir is more rapid than that of the red fir, but its life cycle is shorter and it reaches maturity earlier. It should be cut at 100 to 125 years, whilst the red fir under natural forest conditions requires 175 to 200 years. The annual growth of the balsam fir varies from 21 to 42 cubic ft. per acre.

The cultivation in small groups is recommended as the best method of management for this fir, and ensures a better proportion of the red fir during the natural regeneration of the forest.

The chief objections to the utilization of the balsam fir in the production of pulp are as follows: 1) the resin present in the wood; 2) the shortness and weakness of the fibre; 3) the inferior yield of cellulose. The first drawback depends more on the manner of treating the wood than on its contents, the balsam fir being one of the rare conifers with a complete absence of resin canals.

1015 – **The Manchurian Timber Industry.** — BISHOP, C. M., in *Daily Consular and Trade Reports*, Year 17, No. 173, pp. 504-506. Washington, July 25, 1914.

The principal forests of North Manchuria are located in the upper valleys of the Sungari, Tumen, Yalu and Ussuri Rivers and the beginning of the Long White Mountain ranges.

Chinese official statistics are so far available for only one of the " Three Eastern Provinces ", *i. e.* Kirin. In this province alone it is estimated that 7 500 000 trees were cut in 3 years (1910-1912), this figure including pine,

(1) The distribution of the Balsam fir extends from Newfoundland to Great Bear Lake in the West and southwards to the uplands of Virginia; the distribution of the red fir is analogous but less determined (Cf. RATTINGER, K. K.: Die Nutzhölzer der Vereinigten Staaten. I. Teil: Die Nadelhölzer, *passim*. Wiesbaden, 1910). (*Ed.*).

cypress, walnut, chestnut, willow and oak. Chinese statistics give a total area of 2 111 square miles of timberland in Kirin Province.

There are two varieties of oak cut in Manchuria, — Mongolian oak (*Quercus mongolica*) and Chinese oak (*Quercus castaneifolia* or *sinensis*). The Mongolian oak is met with all over the regions drained by the Amur, Sungari and Ussuri Rivers, and everywhere in South Manchuria, where it reaches a height of 70 feet and a diameter of 2 to 4 feet. The Chinese oak occurs only in North Manchuria and is smaller than the Mongolian with leaves resembling those of the chestnut.

The granting of timber concessions in North Manchuria is governed by the " Regulations of 20 rules, governing the granting of concessions in national forests in the three Eastern Provinces (Manchuria) ", enforced by order No. 21, of the first year of the Republic of China (1912), issued by the Department of Agriculture and Forestry. Concessions are granted only to those possessing citizenship in the Republic ; and when a concessionaire desires to transfer or mortgage his certificate to another person, he must first obtain the sanction of the Bureau of Forestry.

Lumber taxes are of two classes : *a*) Royalty of national forests at the rate of 8 % according to market value, to be used in defraying the expenses in the administration of national forests, and *b*) Government tax at the rate of 10 % of the market value, and collected by the Department of Finance for the administrative expenses of the Government ; *c*) a local tax may be imposed depending on the size and quality of the timber.

The Russian timber concessionaries, who formerly supplied only the needs of the Chinese Eastern Railway, have begun to receive orders from Europe and England for timber. There were exported to European ports in 1913 via Vladivostock 200 000 cubic feet in round and square logs and boards. It is probable that in the future this timber will be shipped in increasing quantities from Nikolaievsk ; but it is doubtful if this export of timber will continue, for as soon as the present plans for the construction of the new railways in Manchuria are put into operation, there will be a greatly increased local demand for timber. Also there is an increased demand for Manchurian timber in China and the Far East generally, since it is valued more highly than Japanese or Korean timber.

According to Chinese customs statistics, about 9 000 000 cubic feet of timber material were exported to Vladivostok and over 3 000 000 in pieces during 1909. An increase in the duty reduced the export to 1 570 000 cubic feet in material and 147 000 in pieces in 1911. Further, a considerable amount of timber in the form of firewood, sleepers, round logs and boards are required in the construction of the Chinese Eastern Railway.

LIVE STOCK AND BREEDING.

HYGIENE

1016 - ***Eleusine indica* (Crowfoot Grass) in Queensland, Dangerous to Stock.** — Smith, Frank, and White, C. T., in *Queensland Agricultural Journal*, Vol. II, Part 2, pp. 158-160 + 1 fig. Brisbane, August 1914.

Eleusine indica had already been reported as a plant dangerous to live-stock in New South Wales. The writers have observed its occurrence in

Queensland, where it grows throughout the State, though mostly in coastal localities. They ascertained the presence in it of compounds containing hydrocyanic acid. The freshly cut grass (in June of the present year) yielded by maceration with water and distillation 0.92 grain of hydrocyanic acid per pound. The quantity would probably have been still larger if the plant had been cut when in vigorous growth, that is during the summer months. Cases of sickness in horses and sudden mortality of poultry in Queensland runs infested with *Eleusine* are attributable to this plant.

1017 – **The Sheep Maggot Fly (*Calliphora rufifacies*) and its Parasite.** — FROGGATT, WALTER W. (Government Entomologist), in *The Agricultural Gazette of New South Wales*, Vol. XXV, Part 2, pp. 107-111 + 1 plate. Sydney, February 1914.

In the first records of flies that deposit their eggs on sheep in Australia, the Sheep Maggot Fly was not included among those that bred in the soiled wool of living sheep. Nor was it included among sheep flies in a paper by the author published in 1905. In 1910 he had not yet bred it from the maggots found in soiled wool of New South Wales, though in the West it was very plentiful about killing yards, freshly skinned sheep and dead animals.

After 1910 it was soon found that the so-called "hairy maggots" were the larvae of this fly and that it also bred in soiled wool. But at that date *Calliphora rufifacies* was not as common as *C. oceaniae* and *C. villosa*, which till then had been the most injurious. This is another case of the adoption of new habits by a previously harmless insect on account of new conditions arising through the presence of strong smelling wool. From the writer's investigations in the northern and western districts of New South Wales and Western Queensland it is evident that this is now the common sheep fly, while the other two species, from which it probably first acquired the habit, have almost disappeared from this great area and do comparatively very little damage.

Lucilia sericata, the sheep maggot fly of Great Britain, lays its eggs on meat and has been a pest chiefly in Ireland and Scotland from a very early date. It is a common meat blowing pest about Sydney and suburbs, but in earlier investigations it had never been noted in the West or North-West, though now well established, and it has been bred from soiled wool. Hitherto it had never been recorded from the wool or wounds on sheep.

In September 1913 the Minister of Agriculture of New South Wales instituted an Experiment Station for the study of Sheep Maggot Flies near Yarrawin, district of Brewarrina, where sheep maggot flies have been a very serious pest for some years. This Station has discovered that an indigenous chalcid parasitizes very actively the larvae of *Calliphora rufifacies*, as well as those of *C. villosa* and *C. oceaniae*, and that it multiplies very rapidly when bred under artificial conditions. It takes about eleven days to develop from the egg to the perfect insect, which is a small wasp one-twelfth of an inch in length.

1018 – **Typhus in Young Pigs in Germany.** — PFEILER and HURLER, in *Mitteilungen des Kaiser Wilhems Instituts für Landwirtschaft in Bromberg*. Vol. 6, Part 4, pp. 261-283. Berlin, March 1914.

This paper contains many bacteriological, pathological and anatomical data on the typhus of young pigs and on its diffusion in the German Empire.

So far as it has been studied by the writers in many localities, it is easy to recognize by anatomical examination.

The disease is undoubtedly very widely spread and it has been found by the writers once or more in the provinces of Brandenburg, Hanover, East Prussia, West Prussia, Pomerania, Posen, the Grandduchy of Mecklemburg and in Alsace and Lorraine. Altogether in the course of two years the dangerous disease was observed by them in upwards of a hundred young pigs in twenty-two herds. The writers are convinced that if other countries also were to pay more attention than they have hitherto given to this disease it would be found to be no less frequent abroad than in Germany.

From the point of view of its epidemic character the disease should be considered as important as swine fever. Economically also, owing to the great mortality which it causes, it should command the greatest attention. Of the cases observed by the writers 78 per cent were fatal. According to the information given by the owners in whose herds the disease was rife, it caused a loss of from 25 to 50 per cent. According to other informants the mortality was valued at 60 per cent. Anyhow, where the disease appears pig breeding and its profits are seriously endangered.

In order to check the spread of the disease, veterinary police regulations would be useful; practically it can be successfully controlled by the vaccination of all young pigs.

1019 – **Control of Cattle Ticks and of the Diseases Spread by them** (1). — BRÜNNICH, J. C. and SMITH, F. Factors Influencing Efficacy and Deterioration of Cattle-dipping Fluids, in *Queensland Agricultural Journal*, Vol. II, Part I, pp. 81-92. Brisbane, July 1914. — II. THEILER, A., Arsenic Dips and their Use in the Control of Ticks and of the Diseases Spread by them in South Africa, in *Zeitschrift für Infektionskrankheiten, parasitäre Krankheiten und Hygiene der Haustiere*, Vol. 16, Part 1-2, pp. 1-26. Berlin, September 12, 1914.

I. — A series of experiments was undertaken to investigate the mode of action in the extermination of cattle ticks by means of dipping fluids. Two steers were sprayed with an arsenic dipping fluid (Queensland Government formula) to avoid accidental swallowing. Blood drawn before and after the spraying showed that the effect of the dip on the animal was to increase the arsenic content of the blood during the twenty-four hours immediately following the application of the dip. Two infected heifers were then treated, on small areas of the skin, as follows.

A) Ticks were painted carefully with dipping fluid without wetting the skin of the host.

(1) See also: *B.* 1911, Nos. 2198, 2425, 2753; *B.* 1912, Nos. 146, 358, 359, 810, 934; *B.* 1913, Nos. 42, 43, 691, 815, 1264. (*Ed.*).

B) The skin of the host was wetted without wetting the ticks.

C) Small quantities of the dip (5 cc.) were injected subcutaneously.

D) Larger areas of skin with ticks were thoroughly wetted with dipping fluid.

Only D proved an effective method of destroying ticks, though some of the ticks in trials A and C appeared to sicken. These experiments, together with the fact that the ticks on small areas which escape wetting in ordinary dipping operations (such as the head) do not die, led the writers to conclude that when an arsenic dip of minimum concentration is used, the death of the ticks within a few days is due to the combined effect of *a*) absorption of the poison through the skin of the tick after dipping, and *b*) absorption of the poison by the skin of the animal from which it is subsequently sucked by the tick.

The efficacy of any dipping fluid depends largely on its power of thoroughly wetting the skin of host and tick, leaving a uniform thin film of liquid, *i. e.* on its degree of emulsification. In order to determine the emulsifying power of certain agents, a series of experiments was carried out in which the surface tension of solutions of different recognised or supposed emulsifiants was determined by observing the number of drops formed when a measured quantity of liquid was allowed to run through a fine opening. The result showed the superiority of oleic over the stearic acid soaps, while Stockholm tar also proved very satisfactory ; the good qualities of the latter product and of the oleic acid soaps were not diminished by use with acid arsenite as recommended in the Government formula. Further, Stockholm tar did not lose its emulsifying power to the same extent as other emulsifying agents when the dip was made up with hard water, and for that reason should be a valuable ingredient in dipping fluids.

The conversion of arsenite to arsenate on keeping was also investigated. This process had occurred in about 25 per cent. of the dips examined during the three previous years ; it decreases the value of the dip, as the tick-killing property of the arsenate is only about half that of the arsenite. A series of tests was made, in which *a*) pure arsenite solution, and *b*) an arsenite solution containing tar and soap and approximating to the Government formula, received a small amount of nutritive material, were sterilized, inoculated with oxidised dipping fluid and incubated under various conditions of illumination. The results were as follows :

1. Pure arsenite solutions under sterile conditions remained unoxidised in darkness or in diffused light, but underwent marked oxidation in direct sunlight.

2. In the presence of tar, sterile arsenite solutions underwent marked oxidation in darkness ; in diffused light and direct sunlight the oxidation was still more marked.

3. The oxidation of arsenious to arsenic acid was also effected by bacterial agency ; the oxidising bacteria seemed to be equally active both in light and in darkness, but there appeared to be a marked difference in the activity of different strains of organisms.

4. Tar, apart from its effect in itself inducing oxidation, appeared to exert an inhibitive effect on the activity of oxidising bacteria, and this inhibitive effect seemed to be exerted to a greater extent in sunlight, direct sunlight in tar solution almost completely preventing the activity of certain strains of bacteria.

5. Bactericides, such as mercuric cyanide and formalin, were effective in preventing growth of oxidising organisms, and bacterial activity was necessarily not evident except in presence of nutritive material.

In the 75 per cent. of cases in which oxidation does not occur in dipping fluids, it has been suggested that the apparent inhibition is due to the agency of organisms capable of reducing arsenic to arsenious acid. In order to test this point, sterile arsenate solutions, with and without tar and soap, provided with nutritive material and equivalent to 0.2 per cent. As_2O_3, were inoculated with various media likely to gain access to dipping fluids in dipping practice (dung, soil, grass, etc.); they were maintained under conditions of light and complete darkness during periods of two and four weeks, when they were examined for arsenic in the reduced form of arsenite. Reduction was found to have taken place in all cases where tar and soap were present, but only in a few cases where tar and soap were absent; it would thus appear that the tar has a less well marked inhibitive effect on reducing than on oxidising bacteria and that the former only gain the upper hand when the latter have been weakened. The maintenance of the arsenite concentration of dipping fluids would therefore seem to rest mainly on the growth and activity of organisms capable of preserving it in opposition to the oxidising influence of tar, light and the opposing oxidising bacteria; the determination of the environmental conditions most conducive to their multiplication presents the most promising field for further investigation.

For the present the recommendations for cleaning out dips, when the dipping-fluids show persistent rapid oxidation, are to empty and cleanse thoroughly, spray walls, woodwork and dripping yards with formalin solution, whitewash dip and timber, and allow at least a week's interval before recharging.

II. — In South Africa the most dangerous cattle disease of recent years is the East Coast fever caused by a blood parasite, *Theileria parva*, which was introduced in 1902 from German East Africa. This parasite develops in the lymphatic organs, whence, on attaining maturity, it passes into the blood corpuscles. According to the writer the disease is spread by ticks, especially by the brown tick (*Rhipicephalus appendiculatus*) which has three hosts, and the red tick (*R. evertsii*) with two hosts; but the black tick (*R. Simus*) and the blue tick (*Boophilus decoloratus*) may also be considered as carriers of the disease. The writer gives a short description of the life history of each of these ticks.

For the prevention and cure of the disease, the first thing is the destruction of the ticks, but it took a considerable time for this desideratum to be adopted in practice. An impulse in this direction was given by the steady spread of the Coast fever in Natal, where the measures successfully

dopted in the Transvaal were of no avail. At first it was tried to dip the nimals once every four weeks in an arsenical fluid, but as no effect ollowed, the interval between the successive dips was shortened to three, wo and one week, without however obtaining any better results. Whereupon PITCHFORD experimented in Natal with dips repeated every five and hen every three days and found that with three-day intervals the disease ould be stopped. The efficacy of the latter method lies in the fact that nfection in cattle sets in between 60 and 120 hours after the ticks have astened on to their hosts.

The composition of the dip originally recommended by PITCHFORD was 8 ½ lbs. sodium arsenite, 5 ½ lbs. soft soap, 2 gallons petroleum and 400 gals. water. It was later discovered that the dip was more efficient without petroleum or soap.

For dips repeated at short intervals, farmers in South Africa use commonly 4 to 4 ½ lbs. of the arsenic salt to 400 gallons of water. When the animals are dipped at longer intervals the proportion of arsenic is correspondingly increased.

On the occurrence of an outbreak of the disease dipping must be continued until the ticks living in the grass have been starved to death this may require as much as 14 months. As a general rule all the animals that are out grazing must be dipped, including pregnant cows and calves. Horses, sheep and pigs are not so frequently dipped as cattle. The average time required for each animal does not exceed 6 seconds.

As secondary effects of these dips, a temporary diminution of the milk yield of the cows and of the capacity for work of the oxen are generally noted in South Africa, but no cases of poisoning through drinking the arsenical liquid while dipping have been observed.

The ticks begin to diminish after the first dip; the first to die are those that are not fully gorged, the last the fully gorged ones. The parts of the tody that are first freed from the ticks are the udder, the insides of the bhighs and the barrel. The most easily destroyed ticks are the one-host blue ticks, the most difficult to eradicate are the two-host red ones. Besides Coast fever, all the other diseases which are spread by ticks in South Africa, such as Texas fever, anaplasmosis and the like, are controlled wherever arsenic dips are practised. Besides which, in many localities, the mortality among calves has been considerably reduced. The disappearance of white scour in calves and of a contagious inflammation of the eyes in cattle caused by *Filaria lacrymalis* wherever arsenic dips have been used, has been remarkable.

The only drawback that can be mentioned in connection with these dips is that the young animals can no longer be immunized against Texas fever and anaplasmosis.

The writer concludes with the observation that the use of arsenic dips in South Africa has solved at one stroke the problem of the prevention and cure of all diseases transmitted by ticks.

ANATOMY AND PHYSIOLOGY

1020 – **The Effect on the Milk Glands of Volatile Fatty Acids from the Food.** — BEGER, C. in *Die landwirtschaftlichen Versuchs-Stationen*, Vol. 85, Part 1-2, pp. 155-163. Berlin, August 3, 1914.

The writer gave alternately to two goats, together with a certain basal ration, first an oil having a very high Reichert-Meissl value (guinea-pig cheek oil) and then one with a very low R. M. value (earthnut oil) and observed to what extent the addition of volatile fatty acids to the fodder acted upon the R. M. value of the butterfat and generally upon lactation.

The two animals experimented upon were of the same breed and in an advanced period of lactation. The experiments showed that the addition of volatile fatty acids to the fodder had no sensible effect upon the R. M. value of the butterfat, but that it had a stimulating effect upon the absolute quantity of milk and upon its composition.

Though the guinea-pig cheek oil is a fat which owing to its specific characters (it consists chiefly of valerianic acid) does not pass directly into the milk glands and thence into the milk fat, it must contain other substances similar to the components of milk which act favourably on the nutrition of the milk glands. It can consequently be assumed that in the fat contained in food there are substances which can act as stimulants upon the milk glands independently of their nutritive value.

According to the writer the composition of the milk fat seems to be influenced only by such components of the fat in the food as already exist in the milk. The milk glands have the power of rejecting those substances which do not already exist in the milk or of utilizing them only under quite special conditions. In consequence of this fact the writer does not think that experiments with iodized or coloured fats made with the object of determining the passage of fats contained in the food into the milk can give conclusive results. The udder decomposes the available material and then selects among these components. The loosely combined iodine and similar substances are probably first separated, after which they act as if they had not been joined to the fat.

FEEDS AND FEEDING

1021 – **The Presence of Arsenic and Manganese in some Feeding Stuffs.** — JADEN, F., and ASTRUC, A., in *Comptes Rendus hebdomadaires des Séances de l'Académie des Sciences*, Vol. 159, No. 3, pp. 268-270. Paris, July 20, 1914.

The presence of minute quantities of arsenic and manganese in animal tissues has previously been recorded. The same fact has now been proved in the case of vegetable tissues. In order to show the source of supply of the arsenic and manganese in animals, the writers have determined their presence and percentage in the more common feeding stuffs. The results are shown in the accompanying table.

Forage.	Composition		Manganese		Arsenic
	Water	Ash	Mgms. per 100 gms. of dry matter	Mgms. per 100 gms. of ash	Mgms. per 100 gms. of dry matter
Medicago sativa	64.00	3.35	5.00	53.73	0.050
Hedysarum humile	73.50	2.00	4.33	57.50	0.056
Vicia sativa	62.90	4.75	2.68	21.05	0.054
Trifolium pratense	67.50	3.55	5.38	49.29	0.037
Solanum tuberosum	74.46	0.85	0.14	4.23	0.031
Beta vulgaris	91.83	1.16	1.63	11.43	0.061
Populus nigra	64.20	2.48	17.46	322.58	0.019
Castanea vulgaris	55.45	1.00	1.56	140.00	0.011
Oryza sativa	13.66	1.11	0.93	72.00	0.008
Zea Mays (seed)	17.65	1.52	1.94	105.26	0.036
Zea Mays (stems and leaves)	85.50	1.45	4.13	41.37	0.027
Hordeum distichum	10.06	2.60	3.78	130.76	0.055
Avena sativa	19.66	2.99	4.97	133.77	0.062
Bran	17.20	4.74	8.59	150.21	0.012
Grass (1)	52.75	6.80	16.93	117.64	0.053

(1) Consisting of 96-98 per cent. Gramineae, the species present being: *Anthoxanthum odoratum, Holcus mollis, Agrostis canina, Lolium perenne, Ranunculus acris, Cerastium brachypetalum, Linum angustifolium, Trifolium minus.*

1022 – **The Bacterial Flora of Some Fresh or Fermenting Concentrated Foods and its Effect on Milk.** — WIGGER, A., in *Centralblatt für Bakteriologie, Parasitenkunde und Infektionskrankheiten*, Vol. 41, No. 1-8, pp. 1-227. Jena, May 27, 1914.

The three concentrated foods most frequently used in Switzerland, namely bran, earthnut meal or cake, and sesame meal or cake, were examined. The fodder containing the highest number of germs was bran, which, as an average of 15 samples, contained 6 million germs per gram. Earthnut meal and cake contained, as an average of 18 samples, 1 ¼ million. Sesame meal and cake, average of 24 samples, contained about ½ a million per gram.

Pollards were by 57.5 per cent. richer in germs than bran. Earthnut cake contained more of them than the meal, while, with sesame no difference in this respect was found to exist between the cake and the meal. The variation in the germ content of the individual fresh samples was relatively greatest in bran and smallest in sesame.

The bacteria in the fresh sesame and earthnut foods are much the same, and much richer in species than in bran. The latter contained 21 different species of schizomycetes, earthnut concentrates 44, and sesame 48. As typical species in bran the writer found: *Bact. coli*, var. *luteoliquefaciens* Lehmann and Levy, yellow acid producers Levy (1), *Bact. herbi-*

(1) Not yet named in Latin. (*Ed.*).

cola aureum Burri and Duggeli, and *B. fluorescens liquefaciens* Lehmann and Neumann. The earthnut foods contained in prevalence *Bact. mesentericum vulgatus* Flügge, *B. subtilis* Cohen, *B. coli* var. *luteoliquefaciens* L. and L., yellow acid producer Levy, and gas-forming lactic acid bacteria. As typical sesame bacteria the following were found: *Bact. mesentericus vulgatus* Flügge, *B. subtilis Colon*, *B. coli* var. *luteoliquefaciens* L. and L., yellow acid producers, gas producers and cocci.

In moistened concentrates the number of germs increases to an extraordinary degree and at 37° C. after 24 hours reaches its maximum, after which it sinks. During this time there is such a constant change in the nature of the flora that the fermentation may be considered as a metabiotic process. The changes thus brought about are, during the first days, principally a lactic acid fermentation; later more mixed fermentations prevail. The former was more clearly visible in the earthnut foods and less so in the sesame. Fluorescent bacteria are fairly common in both.

The typical bacterium of putrefaction, *Bact. putrificus coli*, is especially abundant in earthnut meal and cake (in 55 per cent. of the samples), in bran rarer. Through the multiplication of these bacteria, the concentrated food can undergo such changes that animals refuse to eat it, or if it is eaten it produces symptoms of poisoning, as the writer proved by examples. He has found in bran also the virulent bacillus of anthrax, as he was able to demonstrate experimentally on animals. Thus the sudden unexpected breaking out of anthrax may be explained in many cases.

As for the influence of these feeds, fresh or fermented, on the bacterial contents of milk, the writer says that small contaminations with them at normal temperatures have no noticeable effect upon the fermentation of milk, but at higher temperatures, 37° C. (98.6° F.), changes in the milk and the evolution of gas are accelerated. In dirty milk or in ordinary somewhat older milk, small additions of these concentrates do not cause noticeable differences in the bacterial content, while in sterilized milk the changes brought about by such additions are somewhat more marked.

1023 – **The Food Value of the Jack Bean *(Canavalia ensiformis)*** (1). — BARNSTEIN, F., in *Die landwirtschaftlichen Versuchsstationen*, Vol. 85, Part 1-2, pp. 113-122. Berlin, August 3, 1914.

The Jack bean (*Canavalia ensiformis*) is a leguminous plant cultivated in German East Africa and in many other tropical countries and distinguished by its abundant yield and great resistance. On account of its abundant yield attempts have been made in German East Africa to utilize the seeds in the country itself and also to export them.

Notwithstanding that a certain quantity of these beans are exported to Hamburg, their sale abroad has not hitherto amounted to much.

The chief obstacles to their utilization in the German East African protectorate are that the natives, not knowing the plant, are not inclined to eat the seeds, and that it is not yet well known whether the beans are poisonous, as is believed in many localities, or not. If they are found

(1) See also No. 498, *B.* May 1913. (*Ed.*).

o be harmless, they may be of considerable importance as a feedingstuff, ince they are very rich in nutritive material.

Chemical analyses of Jack beans were carried out by BONAME in 1911, nd they give the following composition for seeds and pods :

	Seeds	Pods
	percentage	
Water	13	15.2
Protein	25.62	5
Fat	2.32	0.64
Crude fibre	7.9	57.91
N-free extract	47.94	15.47
Ash	3.22	5.78

According to a recent analysis by the writer the seed in its original condition contains :

Water	13.16 per cent.
Crude protein	31.51 »
Pure protein	24.82 »
Fat	2.18 »
N-free extract	41.99 »
Crude fibre	8.59 »
Ash	2.47 »

The digestibility of the beans as it resulted from a four-weeks test carried out by the writer on two young sheep was as follows :

Dry matter	87.5 per cent.
Organic matter	88.6 »
Crude protein	80.5 »
Crude fat	72.1 »
N-free extract	99.1 »
Crude fibre	72.9 »

With these coefficients of digestibility, the starch value works out at 63.7 per cent., with 18.69 digestible pure protein. The jack bean stands thus, as regards its nutritive value, somewhat lower than the common field bean, which according to Kellner has a starch value of 66.6 per cent. and 19.3 per cent. digestible pure protein.

During the experiment the animals were given the relatively high ration of 0.44 lb. of crushed beans, without apparently suffering any ill effects. Of course it would be premature to draw the conclusion that these beans, under all conditions, are a harmless fodder and it would be advisable to repeat the experiments.

1024 – **Has the Dry Matter in the Various Root Crops the Same Food Value?** — HANSSON, NILS, in *Mitteilungen der Zentralanstalt für das landwirtschaftliche Versuchswesen in Schweden*, pp. 11-12. Stockholm, 1914.

During the winter half-years 1908-09 and 1909-10 exhaustive feeding experiments were carried out with the object of determining whether the current assumption that the dry matter in the various root crops has the same value is correct or not. Thirty milch-cows were used, and divi-

ded into five equal groups. In the preparatory period they were all fed 66 lbs. of Bortfeld turnips per diem. During the time that the experiment proper lasted, about 1½ months, one group continued to be fed with the usual turnips, and the other groups were given other roots containing the same amount of dry matter. The rations of the various groups per head and per day were as follows :

Group	I	66	lbs.	Bortfeld turnips
»	II	36.70	»	Sarunner »
»	III	33.66	»	Hellrothe Flasche mangolds
»	IV	40.04	»	Swedes
»	V	41.80	»	Eckendorf mangolds

Owing to the different content of dry matter, the quantity of roots fed varied, the dry matter in all cases being 5.28 lbs. per head per day.

The experiment showed that the substitution of one root for another did not cause any appreciable difference in the milk yield nor in its fat content. The live weight of the cows was also not affected. The conclusion can thus be drawn that the dry matter in the various roots has practically the same food value.

1025 – **Common Salt as a Poison for Stock.** — GUTHRIE, F. R., in *The Agricultural Gazette of New South Wales*, Vol. XXV, Part 8, pp. 663-664. Sydney, August 3, 1914.

Although a certain amount of salt is a necessary adjunct to the food of animals, an excessive quantity is injurious.

In the case of pigs and sheep, 4 to 8 ounces is said to have produced poisoning (see LANDER, *Veterinary Toxicology*, 1912). In larger quantities it has proved fatal to horses and even to cattle. Fowls would appear to be particularly susceptible. According to experiments conducted by LUFFRAN, 4 grams per kilo live weight are fatal if injected in solution into the crop. Recently several instances have been brought under the notice of the Department of Agriculture of New South Wales, in which the deaths of poultry and pigs have been traced to an excessive amount of salt in the food. In a fowl which had died suddenly, the contents of the crop weighed 50 gms. and were found to contain 2.42 gms. of salt, or 4.84 per cent.

The Department therefore warns farmers of the necessity of care in using certain foods found on the market. One sample of pollard was discovered to contain no less than 32.2 per cent. by weight of common salt. Other samples contained varying amounts down to 5.8 per cent. One case of poisoning of pigs was reported, and it was found that the food supplied to them was a mixture of pollard, barley meal and 11.66 per cent. of salt.

The toxic effect of salt appears to be due to its action on the muscles, so that the animal becomes unable to walk and, finally, to stand. Death is caused by asphyxia, due to loss of power in the respiratory muscles.

26 – **Scale of Points for Judging a mixed Dairy Farm.** — *The Agricultural Gazette of New South Wales*, Vol. XXV, Part 2, p. 106. Sydney, February 1914.

An Agricultural Association wrote to the Department of Agriculture New South Wales asking for a scale of points suitable for a competition farms including dairying. Two experts of the Department compiled the llowing classification :

	Points	
A. *Management :*		
1. Checking production and quality of dairy produce and the working of dairy machinery	25	
2. Supervising, feeding and watering of stock ; making provision of fodder and pastures (calf feeding methods to have special attention)	30	
3. Attention to breeding with a view to improving yields and supply of heifers for the future; supervising with a view to disease prevention in calves, cows, etc.	35	
4. Book-keeping and milk record keeping; stud books for cattle and pigs	10	
		100
B. *Stock :*		
1. Cattle, quality and type, taking into consideration the character of land and purposes for which cattle are used, *viz.* cheese, butter or town milk supply. Milk and butter yields to be taken into account	100	
2. Pigs	30	
3. Horses	15	
4. Poultry	5	
		150
C. *Crops, including rotation, cultivation methods and manuring:*		
1. Most suitable fodder crops for dairy cattle	15	
2. Other crops	15	
3. Yield	15	
4. System of cultivation, including manuring methods, rotation and cleanliness of crop	15	
5. Freedom from disease in crop	8	
6. Trueness to type	7	
		75
D. *Pastures :*		
1. Improvement of pastures ; most suitable grasses, sown according to locality ; grass experiment plots	50	
2. Subdivision into most suitable paddocks	25	
		75
E. *Buildings and Fences :*		
1. Dairy and bails	18	
2. Homestead	12	
3. Piggery and poultry farm	10	
4. Fences and gates	10	
		50
F. *Machinery and Tools*		50
Grand Total		500 points

1027 – **Some Data on the Animal Products and the Control of Rabbits in N South Wales, 1913.** — JACKSON, H. V., in *The Agricultural Gazette of New So Wales*, Vol. XXV, Part 6, pp. 504-506. Sydney, June 1914.

During the year ending 31st December 1913 the value of the anim products exported from New South Wales was as follows:

	£
Wool	11 699 858
Meats: Beef	247 934
Mutton and Lamb	1 215 878
Rabbits and Hares	373 633

Live animals	54 098

The number of rabbits exported was 13 556 160 head; the hares 325 77

The number of poultry on farms of 1 acre and upwards, at the en of 1912, was 3 351 000 fowls, 261 100 ducks, 23 900 geese, 216 300 turkeys 6000 other birds. The estimated number of eggs obtained during the yea was 13 769 000 dozen. During the season 1913-14, 476 312 dozen eggs were held in cool stores. In addition there were also stored 9 802 tins o pulped eggs of 40 dozen each.

CATTLE

1028 – **Comparison between the Observed and Calculated Production of Heat in Cattle.** — PRENTISS, ARMSBY HENRY, in *Landwirtschaftliche Jahrbücher*, Vol. 46, Part 5, pp. 753-759, Berlin July 14, 1914.

After a review of the experiments of RUBNER, LAULANIE, ATWATER and BENEDICT, and BENEDICT and MILNER, all of whom have shown that the relations between chemical, thermic and mechanical energy are the same in man and in carnivora as everywhere in nature, the writer reports upon his own experiments on herbivorous animals, which have been carried out as usual by measuring the production of heat by means of a respiratory calorimeter (Atwater-Rosa system) and then comparing the results with the production of heat calculated from the balance of the nutritive elements. Altogether 57 experiments with oxen, nearly or quite mature, have been carried out since 1902, the results of which are available for comparison. They show, as was to be expected, that the results of the individual experiments do not always agree perfectly with the requirements of the law on the conservation of energy. The greatest deviations were + 7.6 per cent. and — 5.1 per cent. The average of the 57 experiments, however, shows that the observed production of heat differs from the calculated heat only by 0.4 per cent. This difference is about the same as that found by the above-mentioned observers.

The conclusion is thus justified that in herbivorous animals the same relations between chemical, thermic and mechanical energy exist as in carnivora and in nature generally.

029 – **Calf Rearing Experiments in Hungary.** — KEREKES, GÉZA, in *Köztelek*; Year 24, No. 61, pp. 2172-2173. Budapest, August 15, 1914.

These experiments were carried out with 18 calves on the Vitka farm belonging to Count Károlyi. One batch of animals was fed on separated milk, the cream being replaced by rye flour: the writer was led to make this choice on the principle that carbohydrates can take the place of fats in animal nutrition. The flour was given at the rate of first 4 oz., later 5 oz. per gallon of separated milk, the formation of lumps being avoided by vigorous turning in a churn. The emulsion was then warmed to the temperature of the cow's udder.

The 18 calves were divided into two groups, one of which (Group I) was fed naturally, while the other (Group II) received the following treatment during four successive periods: 1) whole milk up to the age of 4 weeks; 2) gradual substitution of whole milk by the emulsion until the quantity of flour reached 5 oz. per gallon at the end of about 8 weeks; 3) milk emulsion with a gradual reduction in the quantity of flour toward the end of the period, *viz.* to about 3 months old; 4) separated milk at the rate of 2 ¼ to 2 ½ gallons per calf daily. The determination of the rations during the three earlier periods was based on the eighth part of the live-weight of the animals, which were weighed each week.

Table I gives the live-weight of the calves at birth and at 12 weeks. During the 4th period the artificially fed calves continued to drink their daily allowance of separated milk, whilst all except three of the calves of the other group refused to take skimmed milk when taken off whole milk at three months (see Table II).

TABLE I. *Weight of calves at birth and at 3 months (lbs).*

Group II			Group I		
Nos. of calves	Weight at birth	Weight at 3 months	Nos. of calves	Weight at birth	Weight at 3 months

Average	380.0	Average	305.0	

TABLE III. — *Average weehly rations per calf from the 1st to the 12th week.*

Period	Group I	Group II		
	whole milk — gals.	whole milk — gals.	separated milk — gals.	rye flour — lbs.
1st week	. . . . . Colostrum			
2	7.2	7.2	—	—
3	8.0	8.0	—	—
4	9.2	9.2	—	—
5	10.5	8.8	1.7	0.42
6	13.1	9.9	3.2	1.17
7	14.2	7.9	6.2	1.87
8	15.4	3.1	12.3	3.70
9	16.6	—	16.6	5.00
10	12.5	—	12.5	3.74
11	7.8	—	7.8	2.35
12	4.6	—	4.6	1.14
Totals . . .	119.2	54.2	65.0	19.41

Omitting the cost of hay and oatmeal, which was the same in both groups, the cost of feeding works out as follows:

Whole milk calves:

119 gals. at 1 *s* 1 ½ *d* per gal.	£6	15 *s*	
Emulsion calves:			
54.2 gals. of whole milk at 1 *s* 1 ½ *d*	£3	1 *s*	7 *d*
65 » » separated milk at 3.6 *d*		19	8
19.4 lbs of rye flour at 1.1 *d*		1	9
	£4	3 *s*	0 *d*

Thus the difference is £2 12 *s* in favour of artificial feeding.

These figures show a considerable economy.

1030 – **Indian Cattle in the Philippines.** — EDWARDS, C. W., in *The Philippine Agricultural Review*, Vol. VII, No. 7, pp. 288-291 + 2 plates. Manila, July 1914.

The Philippine Archipelago, with its extensive pasture area, abundant water supply and tropical climate, is principally a live-stock country; nevertheless there is a great deficiency of both meat and work stock. This state of things cannot well be remedied by the importation of animals from abroad, as these would be more liable than the native cattle to the diseases that have caused the depletion in numbers. On the other hand the lack of good local breeds is a serious obstacle to the improvement of the native cattle. A considerable amount has been spent in an effort to raise pure-bred European and American cattle and their crosses with the native stock, but, except in a few cases, the attempt to raise pure-breds has failed, and the crosses, while showing good conformation and size, were more susceptible to disease. In fact this has been the general experience throughout the Tropics under natural range conditions. Considerable numbers of cattle have been introduced from tropical China and Indo-China, but they, and especially the former, are susceptible to rinderpest and are not in general as great an improvement as would be desirable, as they are lacking in the prepotency of their characters.

Of recent years Zebus from British India have been imported into the Philippines and successful results have been obtained in breeding both pure-breds and crosses.

Lieut. Col. W. D. Gunn, formerly superintendent of the civil veterinary department, Madras, distinguishes seven principal breeds of Zebu (*Bos indicus*) cattle:

1. Mysore breed or Amrat Mahal.
2. Mahadeswarabetta or Alumbadi.
3. Ongole or Nellore.
4. Kangayan.
5. Pulikolum, Jellicut.
6. Kappliyan.
7. Gumsur.

Of these breeds the most important are the Ongoles and Mysores; the former are particularly noted for their suitability for heavy draught and the latter for their extremely hard feet and aptitude for road work. The Ongole is bred in greatest numbers in the Guntur district, Madras presi-

dency. This breed has been imported into Brazil, Argentina, Java and Africa and a few into the United States, particularly into Texas. It is the only breed with which any definite breeding experiments have been carried on in the Philippines. It has been imported by local dealers and by the Bureau of Agriculture, which experimented with these cattle at the La Carlota station, Occidental Negros Province, at the Trinidad stock farm, Benguet, in the subprovince of Bukidnon, and at Alabang.

The results have been excellent. These animals showed a high resistance or apparent nearly complete immunity to rinderpest, immunity to tick-fever and a resistance to insect pests nearly equal to that of the native animals. In all sections execepting those at high altitudes where the temperature is comparatively low during the rainy season, these animals have exhibited remarkable qualities of thrift and hardiness, superior to those of the native stock; they have proved also successful for road and light field work. Their crosses with the native stock are highly resistant to rinderpest; they are a great improvement in size and conformation over the native dams and exhibit to a great degree most of the desirable characters of their Zebu parents.

In many respects Indian cattle are not to be compared with improved European and American breeds, but they are far better adapted to existing conditions in the Philippines.

PIGS

1031 – **Rearing Pigs in Movable Pens.** — HVENEGAARD, M., in *Gaceta Rural*, Year 8, No. 85, pp. 37-45 + 9 figs. Buenos Aires, August 1914.

The writer has obtained very good results in the Argentine with a system of rearing pigs in movable pens; he has obtained an average of 12 pigs per sow per annum with a herd of 1000 sows.

The pen measures 9 ft. 9 in. by 6 ft. 6 in. and is 2 ft. 9 in. high; it is made of six 2 in. × 3 in. uprights to which are nailed four rows of 1 in × 3 in. bars, 7 ½ in. apart; shelter is provided by a piece of corrugated iron at one end sloping from the top bar to the second bar and by two other pieces fixed to the lower three bars below it. The 7 ½ in. space allows the young pigs to pass to and fro. A trough of 5 gallons capacity is placed in each pen. The cost of such a pen does not exceed 15 pesos (about 26*s*).

The pens are placed in lucerne fields 20 yds. apart in rows 120 yds. apart. Litters of different ages should not be allowed in the same row, or the bigger ones will enter the pens of the younger and interfere with their sucking. When breeding is carried out all through the year, 100 pens are sufficient for 300 sows. After the pigs are weaned the sows are allowed to pasture with the boar (1 boar for each 25 to 30 sows) and the sows near farrowing are removed to the pens each week.

The pens are moved each day to provide fresh clean pasture; three men can move 100 pens in an hour. Fresh water is supplied each morning and about 7lbs. of maize is allowed each sow in the afternoon. Weaning takes place at the age of 2 ½ to 3 months, and to simplify the work it is better to wean those of a row at the same time. After weaning the males are castrated, and all are marked and given an insecticidal bath. They are then put out to pasture until 1 year old.

At least one shed 25 yds. × 6 yds. should be provided for every 1000 pigs to afford them shelter in bad weather. From $^3/_4$ to 1 lb. of maize per head is allowed daily. At one year old they should weigh about 110 to 150 lbs.; they may then be fattened if desired by turning them into a maize field. With a good crop of maize 250 acres will fatten 1000 pigs in 2 to 4 months. During this period the fattest are chosen and sent to the market. If possible the crops should be arranged so that the lucerne fields surround the maize crop, thus enabling the pigs to prevent an attack of locusts.

The economics of this system under Argentine conditions are as follows (taking the dollar at 1*s* 9*d*):

	£
Capital Expenditure:	
6 200 acres at about £5 12*s*	35 000
Buildings, etc.	8 750
1 000 sows at £3 10*s*	3 500
40 boars at £8 15*s*	350
First year's expenses	6 562
Total £	54 162
Annual Expenditure:	
Interest on capital at 8 %	4 333
Labour; 8 or 10 peons	875
Maize for rearing purposes	3 500
Cultivation of 2 200 acres of maize for fattening	1 312
Sundry expenses	1 355
£	11 375
Receipts:	
10 000 pigs, weighing 220 lbs. each	29 875
Profit £	17 500

1032 – **Comparative Experiments on Pigs in the State-subventioned Breeding Districts of Denmark.** — *Eighty-fifth Report of the Royal Veterinary and Agricultural College in Copenhagen.*

In Denmark there are practically only two breeds of pigs: the Danish and the Large White Yorkshire.

The Danish breed, to which by far the majority of the pigs in the country belong, is the most resistant and prolific, and its offspring possess the greatest vitality, but at the slaughterhouse it is inferior to the Large White, which is especially good in this respect. A good breeding animal is produced by crossing the two breeds.

But the greatest efforts are being made to improve the native breed by selection and pure breeding, and encouragement for this is given in various ways, the chief of which is the granting by the State of a moderate yearly sum to owners of herds of pure-bred well built animals who are disposed to breed the pure strains and to place their herds under public control; for this, besides the grant, they get recognition from the State as belonging to a breeding district.

Such districts have been created for natives and for Yorks; in 1914 there were, in Denmark, 83 for the former, from which mostly young sows are sold, and 22 for the latter, which chiefly sell young boars.

In order to obtain abundant data on the development of the breeds and on their qualities, three control and experiment stations for pigs have been founded, where the offspring of the selected breeding animals (the only animals that the breeding district is empowered to sell) are fattened and slaughtered under State control. One of the conditions for the recognition and the grant is that the breeder obliges himself to sell every year two young pigs from each selected sow to the local experiment station at the current market price. A group of young pigs for experiments (4 head) consists, as a rule, of 4 animals of the same litter and when possible of two females and two males.

Every year a Report is issued on the results obtained at the experiment stations; the present is the fifth such Report. The result of the experiments is to the effect that the development of the two breeds is nearly the same, while the local breed is inferior at the slaughterhouse test, especially as regards hams and sides; the Yorks yield about 2 per cent. more bacon for exportation (thus less offal) than the native pig. In both breeds about 1.1 lb. of increase was obtained from 3 3/4 food units. The age of the pigs when slaughtered (weight about 198 lbs.) was on the average barely 200 days.

POULTRY

1033 – **Poultry Conditions in Indiana.** — PHILIPS, A. G. (Division of Poultry, Department of Animal Husbandry) in *Purdue University, Agricultural Experiment Station, Circular* No. 40, pp. 32 + 20 figs. Lafayette, Indiana.

The following figures are taken from the Fourteenth Biennial Report of the Department of Statistics of Indiana for 1911-12, but they do not ever show the whole value of the poultry raised because they do not include the numbers of hens kept inside town and city limits.

No. dozen eggs produced in 1910		68 672 724	
» » » » » 1900		38 987 348	
Increase . . .		29 685 376	or 76 per cent.

1911. — No. poultry sold	7 425 144	value	$	3 146 143
» laying hens on hand . . .	9 530 220	»	»	3 938 933
» ducks, turkeys, geese on hand	209 604	»	»	124 973
Total . . .			$	7 210 049
No. dozen eggs. produced 69 690 104		value	»	13 130 407
Grand total			$	20 340 456

Average value per dozen: 18 cents.
Average egg production per hen: 87.7 eggs.

Poultry keeping is especially developed in White, Kosciusko, Allen Adams, Cass, Jay, Randolph, Ripley and Grant counties.

Two thousand lists of questions were sent out in the State by the Purdue University Agricultural Experiment Station and elicited 704 answers. From these it appears that 704 farmers kept 94 589 fowls, or an average of

134.5 per farm; the average value of each bird is 42 cents so that the farmer's average investment in fowls is only $ 56.49. About one half of the birds are pure bred. For small farms Plymouth Rocks are most popular, while for the larger ones Leghorns seem to be preferred.

From the monthly records submitted to the Poultry Department of the Experiment Station by farmers of the State, it is found that where Leghorns, Plymouth Rocks, Wyandottes or Rhode Island Reds were fed grain only, the average egg production ran from 52 to 70 eggs per hen per year. Where mill by-products, and meat scraps or milk were added, with these same breeds the minimum production was 66 eggs and the maximum 124, most of them averaging over 85.

In 1911 and 1912 at the Purdue Experiment Station an experiment has been carried out with Leghorn pullets in which all pens were fed corn, wheat, oats, bran and shorts in the same proportion. One pen had in addition 10 per cent. meat scraps, and another pen sufficient skim milk to equalize the amount of protein contained in the meat scraps. In reality this meant about as much milk as the chickens would drink. The result of the two years' work was that the meat scrap pen produced an average of 135 eggs per year per hen, the skim milk pen 135.5, and the pen without meat or milk 36 eggs per bird per year. The cost of feed per hen was respectively $ 0.915, 1.085 and 0.73.

In the pen receiving milk, the egg production through the winter months (December-February) averaged almost seven per cent. more than in the pen fed meat scrap. For every $ 2.50 invested in 100 lbs. meat scraps there was $ 24.50 return and for every 30 cents invested in 100 lbs. of skim milk $ 1.73 was returned.

About one third of the farmers that answered the questions use incubators.

At the Purdue Experiment Station good results have been obtained from brooders. The best results have not been obtained from lamp-heated brooders but by a wooden brooder house heated by a gasoline burner. This brooder is an eight-foot square colony house 6 ft. 6 in. high to the comb with an A-shaped roof, placed on runners so that it can easily be moved. The wood and material for such a house will cost about $ 15 and the heater $ 11.

1034 – **Egg-Laying Competitions in Australia.** — I. Egg-laying Tests at the Hawkesbury Agricultural College, Twelfth Year's Results. — *The Agricultural Gazette of New South Wales*, Vol. XXV, Part 5, pp. 421-433 + 2 plates. Sydney, May 1914. — II. HART, A. (Chief Poultry Expert) Report on third Egg-laying Competition at Burnley, 1913-14. *The Journal of the Department of Agriculture of Victoria*, Vol. XII, Part 6, pp. 353-362 + 7 figs. Melbourne, June 1914.

I. — *Twelve years of egg-laying tests at the Hawkesbury Agricultural College.*

In the accompanying table are summarized the results of the twelve years of egg-laying competitions, the last of which concluded on March 31, 1914.

In this year the innovation introduced was the single-pen system of testing individual hens in groups of six, and it revealed great individual differences; for instance in one group the best laid 224 eggs, the worst 188, and five exceeded 200. The test of judgment in selection, in which ten breeders supplied duplicate pens of six hens each, selected respectively as "good" and "bad" layers, confirmed the results of the preceding year, the average laying of the "good" pens being 14 eggs, and the value 1*s* 8*d* per hen per annum more than the "bad" ones. The winner of this section was able to select hens that gave a return of £ 1 8*s* 7*d* more than his six "bad" hens.

In the 1913-14 competition in all the sections, 660 birds took part. The breeds represented were: White Leghorns, Brown Leghorns, Black Orpingtons (one group of which exceeded the collective total of any other pen of heavy breeds), Silver Wyandottes, White Wyandottes, Minorcas, Plymouth Rocks, and Langshans.

	Winning total	Lowest* total	Average per hen	Average value per hen		Cost of feed per hen		Profit over feed

II. — *Third egg-laying competition at Burnley*, 1913-14.

The first yearly test conducted in the State of Victoria was at Dookie College in 1904-05 under the supervision of the Principal. This test was won by six White Leghorns, which laid 1313 eggs during the twelve months. In the next two yearly tests the winners were six Silver Wyandottes with 1296 eggs and six White Leghorns with 1314 eggs respectively.

If these figures be compared with those of the winning birds at the recent test at Burnley, the great improvement in the egg-producing qualities of White Leghorns will be seen.

In the 1913-14 test 63 pens of six birds each competed. Of these 54 contained White Leghorns, 5 Black Orpingtons, 2 Black Spanish

and 1 each Golden Wyandottes and Rose-combed Brown Leghorns. The winning pen of White Leghorns produced 1667 eggs during the twelve months, being an average of over 277 eggs from each bird. This pen also produced the greatest number of eggs during the four winter months, namely 533. The value of the eggs produced by the winning pen, at 1*s* 2*d* per dozen, was £8 2*s* 2*d*, which leaves a profit of £1 1*s* 4*d* from each bird over the cost of food. The twelve best groups produced an average of 251 eggs each for the year. The whole of the birds competing in the test averaged over 212 eggs each for the year, with a profit of 15*s* per bird over the cost of the food. In the heavy breeds the best pen of six Black Orpingtons laid 1216 eggs in the year.

Taking the average egg production, the White Leghorns are easily first, with an average of 216 eggs per bird. The averages for the other breeds were: Black Orpingtons 190, Black Spanish 189.7, Golden Wyandottes 172, and Rose-combed Brown Leghorns 169.

1035 — **Bee-keeping in Portorico.** — PHILLIPS, E. F. (Bureau of Entomology, U. S. Department of Agriculture) in *Portorico Agricultural Experiment Station Bulletin* No. 15, 24 pp. + 4 figs. Washington, 1914. BEES

The Portorico Agricultural Experiment Station at Mayaquez has been interested in bee-keeping since 1908. In 1913 the Station and the Portorico Board of Agriculture requested the writer to inspect the conditions of bee-keeping in the Island. The present Bulletin is the report of the above inspection, which was carried out in May and June 1913.

Before the American occupation, it may be said that bee-keeping did not exist at all in Portorico. There were, however, numerous swarms of wild bees (introduced perhaps at the time of the Spanish conquest), the honey of which was collected. In 1908 the Portorico Agricultural Experiment Station imported five swarms of Italian bees and began to give practical instruction in bee-keeping. This was the beginning of the industry in the Island. Bees multiplied wonderfully in Portorico, and now the five initial swarms have become several thousand.

Bee-keeping is practised especially in the western part of the Island and chiefly in the neighbourhood of Mayaquez, mostly on an industrial scale, as every bee-keeper has from two to three hundred hives and some upwards of five hundred. Italian bees are almost the only ones kept. Some have experimented Cyprus or Carniola breeds; it must, however, be mentioned that the former gave decidedly negative results in the United States and in consequence are not to be recommended. The Langstroth hive with ten-bar frames is generally used with one or two lifts for the storage of honey, separated from the brood combs by a queen excluder. The bees collect honey almost all the year round, hence the production of honey is very heavy. Productions of from three hundred to five hundred pounds of honey per hive are recorded. It may be stated that a good bee-keeper in average localities produces about three hundred pounds of centrifugated honey per annum. The honey is collected several times in the course of the year. Only centrifugated honey is made, and it is sold in barrels containing 50 American

gallons. According to the writer sufficient attention is not paid to the production of and trade in wax.

Foul brood (1) is unknown in Portorico, and in order to prevent its introduction it is forbidden by the law of September 3, 1913, to import into the Island hives or parts of hives, eggs, larvae, etc. Only queens may be imported, each with not more than 30 workers and enclosed in boxes. These are examined at the port of entry by the Board of Commissioners of Agriculture. But as foul brood is more likely to be imported with infected honey than with bees, a Bill has been presented with the object of forbidding the importation of honey which cannot be proved to come from healthy hives.

The exportation of honey from Portorico has risen during the last five years (1909-14) from practically nothing to about $100 000. The difficulty and the cost of transport still constitute the most serious obstacles to the development and spread of bee-keeping in the mountainous Island of Portorico.

As for the plants supplying nectar for the bees, the trees used to shade coffee plantations are excellent; for this reason bee-keepimg is chiefly practised where coffee is grown. The principal plants for bees are: *Inga laurina* ("guama"), *Inga vera* ("guava"), very good shade plants for coffee, in bloom almost all the year round; *Boystonea boringuena* ("palma real"); *Cocos nucifera*, abundant throughout the Island; *Spondis lutea* ("jobo"); *S. purpurea* ("cirvela"); *Andira jamaicensis* ("moca" or "cabbage tree); *Drypetes glauca* ("palo blanco" or "varital"); *Coffea arabica*, largely cultivated in the mountainous part of the interior of the Island, but as its flowers fall soon it has not the same value for bees as its shade plants; *Cupania americana* ("guara"); *Jambosa jambos* ("pomarosa", rose apple); *Mangifera indica* — the bees are also found of the over-ripe fruit of this tree which fall to the ground, but they do not injure the sound fruit; *Persea gratissima* (alligator pear); *Lantana* spp. ("lantana" or "cariaquillo"); *Borreria ocymoides* ("botoncillo"); *Musa* spp.; oranges, lemons and other citrus fruit, plentiful in the island, either wild or extensively grown; *Agave* spp.; *Pithecolobium* spp.; *Hymenaea baril* ("algaroba").

The following plants, which in other countries have been observed as supplying food to bees, are frequent in Portorico: *Avicennia nitida*; *Cassia* spp.; *Gossypium* spp.; *Hippomane mancinella*; *Melilotus* spp.; *Nicotiana tabacum*; *Erythrina* spp.; *Paritium tiliaceum* or *Hibiscus tiliaceus*, the fibre of which is used for making ropes; *Haemotoxylon campechianum*; *Saccharum officinarum*; *Acacia* spp. etc.

SILKWORMS

1036 – **Economical Methods of Rearing Silkworms.** — FORNACI, C., in *L'Italia Agricola*, Year 51, No. 9, pp. 401-404. Piacenza, September 15, 1914.

This new system of rearing silkworms aims at more hygienic conditions and a greater economy in leaves and labour. It enables the same number of worms to be reared as by the Lombard method, without requiring too great changes from the system in general use. It consists essential-

(1) See No. 1202, *B.* August 1912. (*Ed.*).

ly in the use of shallow trays with permeable bottoms, which allow air to pass and the excreta to fall, while the largest possible quantity of the leaves can be fed attached to the twigs.

From the time of hatching to the third moult, the worms are reared on trays made from reeds covered with paper and fed on loose leaves. The innovation is used after the third moult and consists of tiers of trays made from reeds bound together with spaces nearly half an inch between each reed. The alternate trays are covered with paper or cloth so as to catch the excreta from the one above. The bases of such trays can thus be replaced by movable frames of metal wirework, bare or covered with paper or cloth according to requirements. The trays are placed in pairs 8 to 12 in. apart and 20 to 24 in. between the pairs. Two days after the third moult mulberry shoots 16 to 20 in. long are given plentifully to the worms; when they have been defoliated they are moved, with the worms on them, to the open trays. During the period between the third moult and pupation some of the accumulated branches should be removed and the worms thinned out; at the time of pupating the space allowed should be about 15 sq. feet per gram of eggs.

A further saving of space may be obtained by placing a light cloth on sticks under each tray to catch the excreta; this need be only 4 to 6 in. below the tray.

The superiority of this system has been demonstrated in the experiments carried out by the travelling lecturer of Gallarate in 1914.

This year's results show:

1) a greater economy of space than with the Lombard system;

2) more hygienic conditions for the worms and very low mortality from "flacherie" and "jaunisse";

3) a saving of 4 to 6 cwt. of leaves per ounce of eggs;

4) a saving of ¼ to ⅓ of the labour required by the old system;

5) a minimum of expense in effecting the improvements;

6) a better quality of silk and heavier cocoons, going 30 less to the kilo than with the old ystem.

1037 – **Report on Sericultural Experiments in France during 1913.** — LAMBERT, M., in *Bulletin Mensuel de l'Office de Renseignements Agricoles*, Year 13, No. 5, pp. 593-595. Paris, May 1914.

On the 30th of July 1913, the French Parliament voted a sum of £2 000 for the encouragement of sericultural experiments. This was distributed as follows: £160 was granted to the Department of Science and Repression of Frauds and £1 840 to the Department of Instruction and Agricultural Organization.

The latter amount was utilised as follows.

1. Institution of local sericultural competitions . . . . . £ 1 440
2. Creation of experiment fields and nurseries for mulberries at the Schools of Montpellier, Antibes, Ecully, Oraison and Valabre . . . . . » 200
3. Distribution of young mulberry trees and silkworm eggs in batches of 5 gms. for each experiment, to private persons, schools of agriculture and primary schools . . . . . » 120

4. Installation of material at the Sericultural Station of the School at Montpellier for comparative experiments on silkworm rearing by different methods, and expenses of the organisation of competitions and experiments . . . . . £ 80

The local competitions were held in 36 cantons belonging to 18 departments. The number of silkworm rearers, farmers or silkworm egg-breeders taking part was 743. The members of the visiting commission were chosen, as for previous competitions, as far as possible amongst persons living in the particular departments concerned.

The carrying out of these dispositions was entrusted to an Interdepartmental Commission nominated by the Minister of Agriculture, which visited the 743 farms between October 1913 and January 1914. Of this number 585 were considered worthy of being recommended to the Minister for reward.

In the course of its visits the Commission made the following observations:

1) It is easily possible to determine with sufficient accuracy the quality of the products of the competitors at other times than the rearing periods and to classify them according to their merits.

2) The great majority of rearers hatch under defective conditions; worms are often reared in small unhealthy rooms, and the cultivation of the mulberries leaves much to be desired.

3) The rearers accept the advice offered by the Commission and are disposed to profit thereby.

With regard to the distribution of young mulberry trees, it has not been possible to give satisfaction to all requests. The number distributed has reached about 10 000.

FISH BREEDING

1038 – **Fish Breeding in Switzerland in 1913.** — *Schweizerische Fischerei Zeitung*. Year 22, No. 5, pp. 122-126. Pfäffikon, May 1914.

During the breeding season 1912-13, 191 fish-breeding establishments were in activity, as against 192 in the preceding year. The area occupied by the incubation nurseries was 6943 square feet and the number of brood glasses was 591. Out of 121 55[illegible] 550 eggs 97 422 880 fishes were hatched. Of this number, including 60 302 summer fish and one-year-olds, 97 150 882 (in 1911-12 81 050 630) were placed under State control in public waters.

The kinds of fish that were incubated are as follows:

	numbers
Salmon	1 292 400
Salmon hybrids	103 000
Lake trout	2 546 800
River and brook trout	7 373 030
Char	4 350 050
Grayling	2 227 500
White Fish (coregouns)	70 809 100
Pike	8 370 500
Perch	90 000
Eels	146 000
Foreign species	93 500
Brook char	21 000
	97 422 880

In order to defray the expenses of incubating and setting out the fry, the Confederation granted the Cantons the sum of £ 1385 (against £ 1300 in the preceding year) which was distributed among the owners of the various establishments.

In the above figures the work done in the Canton Valais is not included, as no data have been supplied.

The number of fishery inspectors in the service of the Cantons was, in the year reported upon, 170, to which at times are added 11 assistants; the salaries, daily and travelling expenses, amounted to £ 3981, against £ 3747 in 1912. The Confederation contributed one half of these sums. For the destruction of animals injurious to fish the Cantons spent £ 35 7*s* 6*d*, to which the Confederation contributed £ 16 11*s*.

In these figures on the inspection of fisheries, the Canton of Geneva is not included, as it did not ask for a grant or send in any report.

The Swiss Fishery Association received, as usual, a grant from the Confederation of £158.

The International Fishery Association for the Lake of Constance was granted by the Confederation, as well as by the other States bordering on the lake, a sum of £ 12 towards the expense sustained in 1913 for restocking the lake with fry.

On May 2, 1913, the Federal Council issued an Order concerning fishing in waters common to Italy and to Switzerland, as a supplement to the agreement of June 13, 1906, and which entered into force on June 1, 1913.

FARM ENGINEERING.

1039 – **Report of the International Competition of Motor Tillage Machines at Chaouat, Tunis, in 1914.** — *Direction Générale de l'Agriculture, du Commerce et de la Colonisation, Bulletin*, Year 18, No. 79, pp. 445-503. Tunis, July 1914.

AGRICULTURAL MACHINERY AND IMPLEMENTS

An international competition of motor tillage machines was organized by the General Direction of Agriculture of Tunis and held at Chaouat from the 15th to the 23rd of April 1914.

About 750 acres of stubble land were devoted to the trials of the various machines, twenty-four of which were entered, but, owing to various circumstances, only nineteen took part in the trials. Of these, nine were tractors, two portable engines with windlasses, four motor ploughs and four rotary tillage machines, including one hoeing machine.

The machines tried were the following :

Tractors. — America; Avery; Caterpillar; Case; Emerson (Big Four); Mogul; Ransomes; Rumely; Titan.

Portable engines with windlasses. — Two Franco-Hungarian portable gas engines.

Motor ploughs. — Moto-aratrice (Pavesi and Tolotti); D. K.; Stock; Akra.

Rotary tillage machines. — Charmes; Coupin; Motoculture française,

Hoeing machine. — Bauche.

Machine	Time employed in actual working		Area ploughed	Depth of furrow	Consumption of fuel and oil	Fuel per acre	Cost of fuel per acre (2)		Area ploughed in 10 hours
	hrs.	mins.	acres	inches			s	d	acres
Tractors:									
America (1) 40-50 HP. With six-furrow plough	2	3	2.47	7.87	8.58 gals benzine	3.47 gals	5	7.57	11.86
Avery 80 HP. With eight-furrow Cockshutt plough . .	2	31	4.94	»	10.62 gals benzine 0.44 lbs oil	2.15 gals	3	6.16	19.64
Big Four 55-60 HP. With six-furrow John Deere plough	3	11	6.03	»	0.92 gals benzine 23.69 gals Atlantic petrol 2.64 lbs. oil	0.15 gals benzine 3.94 gals petrol	3	1.38	18.94
Case 40 HP. With six-furrow plough, but only three shares working	4	5	3.46	»	13.11 gals Atlantic petrol 3.41 gals benzine 1.81 lb. oil	3.79 gals petrol 0.97 gals benzine	4	8.00	8.44
Caterpillar 60 HP. With eight-furrow Deere plough, only six shares working.	4	20	6.67	»	22.44 gals Atlantic petrol 2.40 gals benzine 4.95 lb. oil	3.36 gals petrol 0.36 gals benzine	3	3.85	15.39
Mogul 60 HP. With six shares in two independent frames.	4	32	7.14	»	33.5 gals Atlantic petrol 24.2 lbs oil	4.70 gals petrol	3	9.45	15.74
Ransomes 35-40 HP. With four-furrow Ransomes gang plough	5	7	5.41	»	17.59 gals Adriatic petrol 1.98 lbs oil	3.26 gals petrol	2	5.25	10.58
Rumely 30 HP. With four-furrow plough	4	8	4.72	»	22.13 gals Adriatic petrol 0.34 gals benzine 2.86 lbs. oil	4.65 gals petrol 0.34 gals benzine	3	6.16	11.42
Titan 45 HP. With plough with four independent shares	4	0	4.03	»	19.28 gals Adriatic petrol 11 lbs. oil	5.0 gals petrol	3	9.06	9.63
Portable engines with windlasses:									
Franco-Hungarian (16-20 HP) water-gas engines with Rud. Sack five-furrow plough	2	36	2.00	9.84	115.76 lbs charcoal 26.00 gals. water	57.88 lbs charcoal 13 gals water	1	5.48	7.71
do. do. wiht a one-share Bajac plough	2	37	0.56	19.29	117.97 lbs charcoal 31.17 gals water	210.67 lbs charcoal 53.66 gals water	5	3.73	1.97
Motor ploughs:									
Moto-aratrice 16-20 HP. (Pavesi and Tolotti) with three shares fixed in front	4	14	3.04	7.87	9.28 gals benzine 1.1 lb oil	3.04 gals benzine	4	1.197	7.16
D. K. motor plough, 80-105 HP with three shares . .	2	22	5.68	»	11.48 gals benzine 6.98 lbs oil	2.00 gals benzine	3	3.27	23.98
Stock, motor plough, 42-50 HP	2	36	6.52	»	11.33 gals benzine	1.74 gals benzine	2	10.07	24.70
Rotary tillage machines:									
Charmes, pulveriser, 26 HP	8	52	3.38	9.84	22.02 gals benzine	6.51 gals benzine	10	7.45	3.82
Meyenburg's motor cultivator, 30 HP	1	5	0.62	7.08	3.52 gals benzine	5.69 gals benzine	9	3.29	5.68
do do. second trial	4	41	1.85	7.87	13.64 gals benzine	8.01 gals benzine	13	1.88	3.95

(1) Owing to an accident the tractor America was not able to take part in the trials with the other machines, but was tried at the farm of the Colonial School of Agriculture.

(2) The cost of the fuel has been calculated: Benzine 1*s.* 7.46 *d* per gal., Atlantic petrol 9.73*d* per gal., Adriatic petrol 9.0 *d* per gal. and charcoal 2*s* 9. 87*d* per cwt.

The land was situated in the extensive plain of Chaouat. The soil was very homogeneous, compact and dry, so that the heaviest machines sank but little into it.

Most of the trials as to consumption of fuel were carried out on strips 3493 feet long by 98 wide.

The accompanying table (opposite) summarizes the results of the trials. Only the cost of the fuel used is given, as the total cost of the work depends upon several variable factors, the chief of which is the amortizement, which in its turn varies considerably with the amount of work done in the course of the year, the quality of the materials used, etc.

As already stated several dynamometer trials were also made, the results of which are given in the Report. The depth of work was regulated so as to require a fairly constant traction together with a maxium effect of the tractor, without diminishing too much the number of revolutions of the motor.

The average effort ranged from 1015 to 1624 lbs. per square foot. In a soil requiring an effort of 1421 lbs., a furrow about 8 inches deep by 12 wide demands a team of eight mules or 12 native oxen.

1040 – **The Reaper-Thresher.** — SHAW, J. W., in *The Agricultural Gazette of New South Wales*, Vol. XXV, Part 5, p. 376. Sydney, May 2, 1914.

The Reaper-Thresher, more commonly known as the "header", is a comparatively new machine and is becoming more popular from year to year.

One great difference between these machines and a harvester is that the heads instead of being stripped or combed off are cut off by a knife which is worked at the rear of the comb. The straw is drawn through the comb until the heads, assisted by the reel, come in contact with the knife. The fact of the heads being cut greatly lessens the draught. Should the ground be soft or the straw weak, the wheat is not pulled up by the roots and choked in the comb, nor is there any choking when the crop is dirty with thistles or other weeds.

When the heads are cut they are carried by means of the reel on to the canvas conveyors at the rear of the comb, which then carry them to the feeder of the threshing drum; this drum is very large and by means of pinions its speed may be varied to meet varying conditions. A second drum is placed at the rear of the machine to re-thresh any broken heads which may have escaped the first threshing.

The straw is thrown out at the side at the rear of the wheels. The grain is fed evenly on to the riddles, where it is winnowed, and is then carried by elevators into the grain box, which has a capacity of five bags.

The machine takes an eight-foot cut, and with two average teams of five horses each, in a fair crop, from 15 to 20 acres may be harvested in a day. There is very little waste of grain as compared with some other harvesters, and the lightness of draught and its power to deal with a weedy crop make the header a most valuable addition to the wheat grower's plant.

1041 – **Straw Press Binder with Two Pincer-like Groups of Arms working together.** — *Maschinen Zeitung*, Year 12, No. 8, pp. 92-93. Berlin, April 15, 1914.

A new straw press for tying straw into bundles as it issues from the threshing machine has been devised by Messrs. Volkenborn of Langenberg, and patented in Germany under No. 270 841.

It consists of two pincer-like groups of arms, which are moved towards each other by the action of one hand lever.

The press is shown open in fig. 1, half closed in fig. 2, and closed in fig. 3.

It consists of a frame a_1 a_2 and a cross piece *b*, on which the arms *c* and *d* are fixed to the pivots *f* and *g*. The arm *d* is connected by the bar *h*, hinged in *i* to the hand-lever *m*, the fulcrum of which is in *k* on the cross-piece *b*.

The other press arm *c* is worked by the bar *o*, which rests on the bolt *p* and is joined to the hand-lever *m* in *n*. This bar carries a roller *q* which runs along the bottom of the lower branch *r* of the arm *c*.

The lever is so arranged that the pressure increases towards the end of the operation and that when the press is in its closed position (fig. 3) the lever is pressed against the bolt *s* and kept there.

Thus, by a simple movement of the lever *m*, not requiring any great exertion, the straw is pressed and kept so until tied.

In order to prevent fresh straw from the threshing machine sliding down the inclined plane *y* onto the binder, the arm *c* carries a kneed piece *t* which raises the straw fender *x* and keeps it there till the press is again opened.

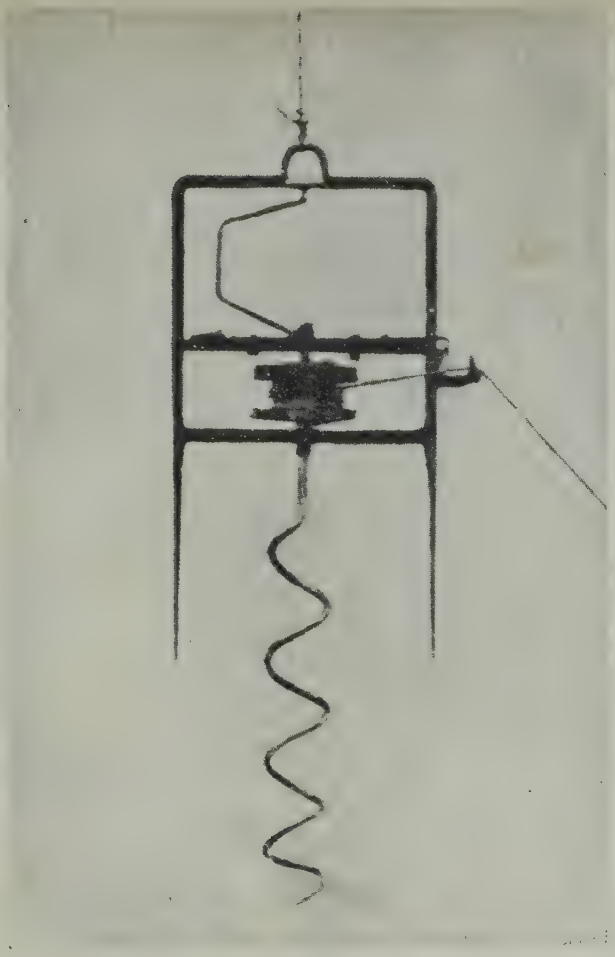
1042 – **Swift's New Hay Elevator Fork.** — *The Implement and Machinery Review*, Vol. 40, No. 473, p. 682. London, September 1, 1914.

The accompanying illustration shows the new hay fork elevator for the building of haystacks, devised by Mr. A. J. Swift of Eccleston, Lancashire. The spiral stem and the two side spikes are, by four or five turns of the crank in the upper part of the fork, pressed down into the hay, and grip a load. When the load is elevated to the desired height the operator simply pulls a rope gently, causing the spiral to unwind, when the hay falls off into several different places on the stack instead of being dumped in one heap.

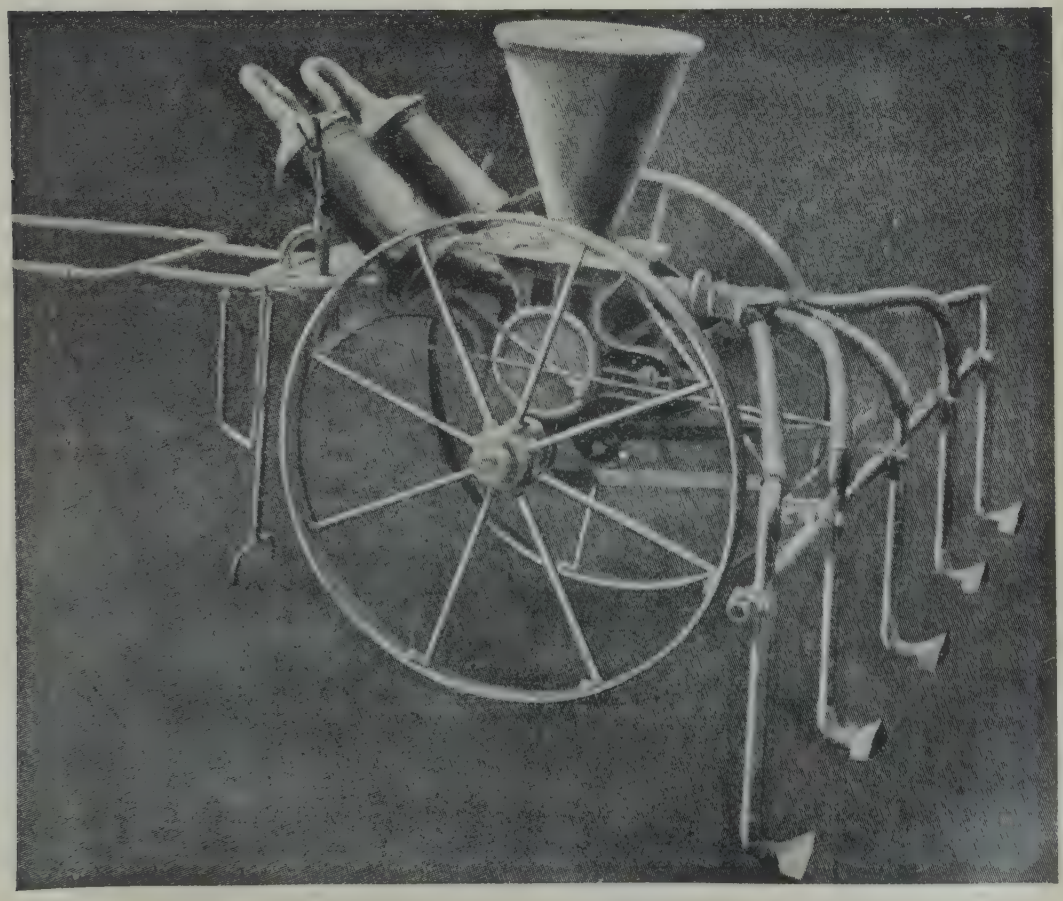
1043 – **Machine for Pickling Seed Wheat.** — ARVAY, ERNST, in *Wiener Landwirtschaftliche Zeitung*, Year 64, No. 15-4916, p. 135. Vienna, March 14, 1914.

It often happens in practice that smut appears on the crop notwithstanding the pickling given to the seed. This is due to the careless way in which the pickling is usually conducted, and which often consists in rapidly dipping baskets containing the seed into fungicide solutions. Besides being unreliable, this process is also costly as it requires much labour.

In order to avoid these drawbacks the writer devised and constructed a pickling machine which consists of a trough made of pure copper, to contain a solution of copper sulphate, in which a horizontal drum pierced



Swift's Hay Elevator Fork.



Randell's Dry Sprayer.

Fig. 1

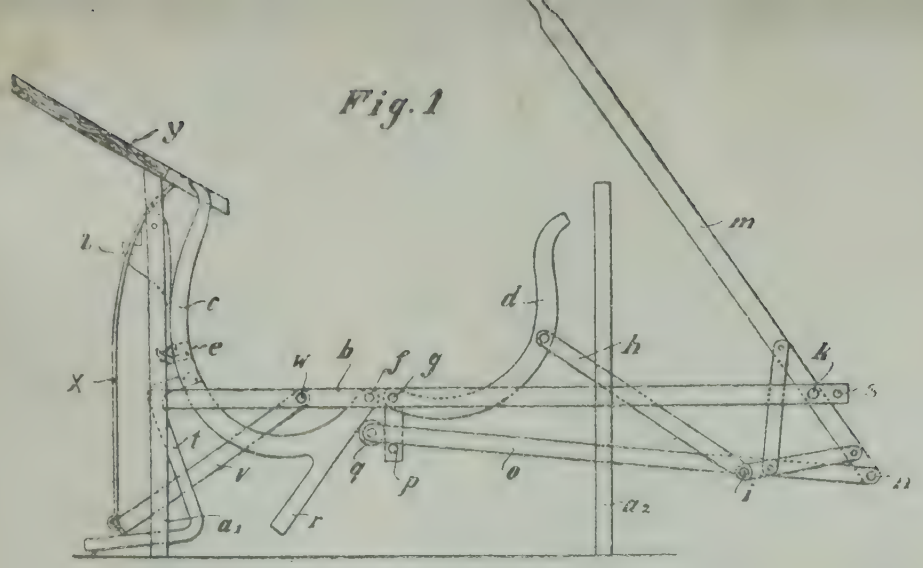


Fig. 2

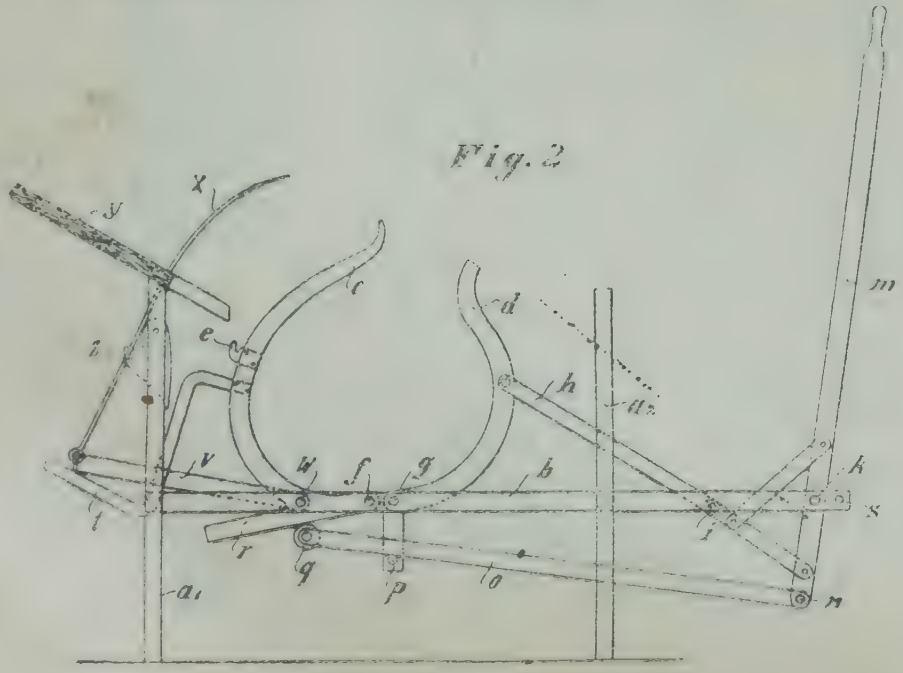

Fig. 3

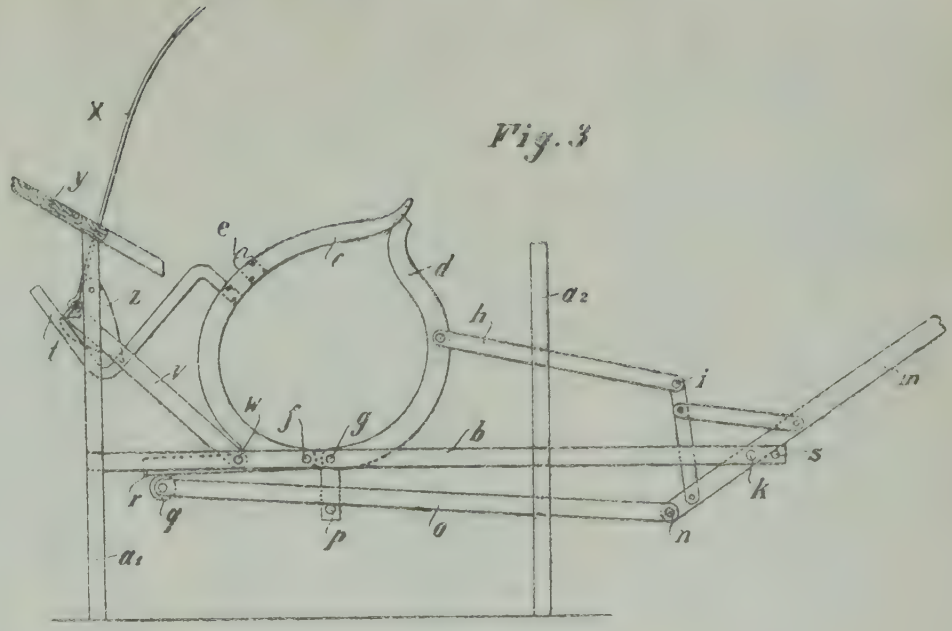

STRAW PRESS BINDER.

Fig. 1. — Open.
Fig. 2. — Half closed.
Fig. 3. — Closed.

with minute holes revolves. The seed is poured into a hopper, the outlet of which can be closed by a slide, whence it falls into a channel leading into the drum. In this an endless screw pushes the wheat along slowly so that it stays from three to five minutes in the solution, every grain being wetted by it. At the other end of the drum another screw ejects the pickled grain.

With this simple machine a saving of about three-quarters of the labour required by the primitive method is effected and the work is done thoroughly.

1044 – **Randell's Dry Sprayer.** — *The Implement and Machinery Review*, Vol. 40, No. 472, p. 559. London, August 1, 1914.

Among the machines exhibited at the Royal Agricultural Society's Show at Shrewsbury in July of this year there were two entirely new machines for dry spraying built by Messrs. F. Randall and called the " Simply Perfect ". One was fitted with five nozzles, as in the accompanying illustrations, for spraying as many rows of potatoes, for large farms, the other with two nozzles for small holdings. The blast is not produced by a fan but by two cylinders and pistons, which run at much less speed, giving a continuous blast and requiring less power to drive, a small pony being sufficient.

An agitator is provided and the feed is so arranged that any quantity of powder can be sprayed. Roller bearings are used throughout. The price of the larger machine is £30 and of the smaller one £15.

1045 – **Wallace's Portable Milking Machine.** — *The Implement and Machinery Review*. Vol. 40, No. 473, p. 672. London, September 1914.

Now that the importance of the purity of milk is universally recognized, out of door milking is advocated as a means of ensuring greater cleanliness than indoor work. In order to facilitate milking in the open, Messrs J. and R. Wallace of Castle Douglas, Scotland, have devised a portable milking machine. This plant consists of a portable house and a portable wooden framework to which the cows can be tied. The house contains a 3 ½ HP. Capelpetrol-paraffin engine connected to a vacuum pump and a vacuum storage tank. An iron pipe is fixed along the portable frame just above the cows' heads and this is connected to the vacuum tank and pump by a flexible steel tube. The framework provides accommodation to twelve cows, the animals being held during milking by a sliding bar which grips them behind the head. Six cows are milked at once and directly one is finished another takes its place. Each day the plant is moved to a different part of the field so that the cows always stand on clean grass.

1046 – **Review of Patents.**

RURAL ECONOMICS.

1047 – **The Influence of Machines and Implements upon the Profitableness of Farms of Different Sizes.** — *Deutsche Landwirtschaftliche Presse*, Year XXXXI, No. 10, pp. 740-742 ; and No. 61, pp. 749-750. Berlin, July 29 and August 1, 1914.

The present paper is a résumé of the discussions and considerations contained in the recent work of Dr. Lichtenberger on the influence of agricultural machinery on the organization and profitableness of farms of different sizes, and which may be summarized as follows :

1. In farms grouped according to size, the relative profitableness of one class as compared with that of other classes is the result of a number of factors among which are included the use of machines and implements together with other economic and natural conditions.

2. Agricultural machinery has proved useful in increasing the profits of farms of all classes of sizes provided natural and economic conditions allowed machines to be used.

3. When farms of different classes of sizes compete with each other under equal conditions, the farm in which natural and economic conditions allow the greatest intensity of farming, will draw the greatest profit from the use of machinery.

4. As a rule, large farms are in the most favourable condition to make profitable use of machines and implements. The relative profitableness of such farms is influenced in the highest degree by the use of machinery.

Medium-sized farms occupy in all respects the most difficult position : they require machines just as much as the others but must pay a higher price for their work. Nevertheless these farms also, especially of late, find their profitableness increased by the use of machinery.

In small farms the number of implements and machines that can be profitably employed is limited. This fact, however, does not place small farms in a condition of inferiority to medium and large farms, as the former have no absolute need of machines and implements. On the other hand implements and machines, in so far as they are applicable in the small farm, are of decided assistance in increasing its capacity of competition and its relative profitableness. For this class of farms cooperation in the use of machines is most beneficial.

5. Without entering into the question of comparing absolute conditions, but only examining how far the recent development of machines and implements has altered the relative profitableness of the different classes of farms, it will be found that the use of machinery at first gave large farms a great advantage over the smaller ones ; this advantage in respect of medium-sized farms has gradually diminished in consequence of the recent development of machinery and of the steadily increasing intensity of farming. This process has especially been accelerated by the progress of electrical appliances. It is electricity that provides medium and especially small farms with the most suitable motive power. To a great extent also the so-called universal machines (namely those that by means of various attachments can be altered so as to perform different kinds of work) assist in spreading the use ofmachines to the smallest farms.

6. For the calculation of the cost of the work of machines Dr. Lichtenberger considers the figures proposed by Fischer and Lang for amortization and repairs as the most suitable and those which best meet the conditions of small farms. According to them the rate consists of a fixed portion of 8 per cent. per annum of the purchase price and a variable one per day. The former represents interest at 4 per cent. and 4 per cent. for amortization. The variable portion is determined in each case by the kind of machine and the number of days in the course of the year in which the machine is used, and varies, according to Fischer, between 0.09 and 0.5 per cent. per day's work. Through the lesser use of machines in small farms a compensation within certain limits is obtained between

large and small farms ; otherwise on account of the greater purchase cost per unit of performance the amortization and repairs would be absolutely a larger item in small farms than in larger ones. The cost of teamwork should also be reckoned at lower rates in small and medium farms. If, further, the cooperative use of machines and the use of universal machines be considered, the conclusion can be drawn that the cost of machine work limits only to a very moderate degree the relative profitableness of small and medium farms.

1048 – **The Agricultural Labourers Required on Farms under 100 Hectares (247 Acres) in Extent.** — GERLACH, OTTO, in *Archiv für exakte Wirtschaftsforschung*, 15th Complementary Part, pp. 1-13. Jena, 1914.

The Chamber of Agriculture for the Province of East Prussia organized an enquiry in 1901 and 1902 on the conditions of agricultural labour; this was extended also to peasant farms. The writer discusses the results of this enquiry on the amount of labour required, and on the way in which this want was met, in 4600 farms occupying a total area of 197 600 acres. These results are collected in the following table :

Size of farm in acres	Average requirement of				Want of permanent labourers' families	Labour of owner and of his wife	
	Permanent labourers		Temporary labourers				
	Number	Days' work	Number	Days' work			
18 to 25	1	300	1	17-20	—	Both work always in all the farms	
37	2-3	600-900	1-2	40	not yet felt	» » »	
74 to 87	5	1300-1500	2-3	54-60	already felt (in 54 out of 138 farms)	Both generally work	
123	7-9	1550-2500	3	110-115	almost everywhere	The owner works only temporarily.	The owner's wife works only in the household
185	8-10	1600-2900	2-5	110-115	is common	The owner works only temporarily and seldom	» » »

The usual limit of the size of farms worked by the owner and his wife alone is from 12 to 15 acres. In the above table the data refer to the amount of labour required beyond that of the owner and his wife.

The influence of the distance from the village to the market or to the nearest railway station on the want of labour, could not be determined. A greater influence seems to be exerted by the state of the field roads and the extent of pastures.

On the supply of labour in 1288 farms of all classes of sizes between 10 and 250 acres covering an area of 108 700 acres the following figures afford information :

	On the 1288 farms		
	were required	were available	were wanting
Members of the family	1 464	1 464	0
Permanently occupied labourers' families	870	668	202
Farm servants	3 178	2 193	985

The number of permanent adult labourers required was 5512; of this number:

26.6 per cent. was supplied by members of the owner's family.
36.4 per cent. by farm servants.
16.2 per cent. by married helps.
20.8 per cent. was wanting.

The lack of permanent labour is greatest on farms between 50 and 70 acres in extent, being 29 per cent.; it is 28 per cent. on farms between 35 and 50 acres; it ranges from 18 to 22 per cent. on large peasant farms, while on smaller ones it is much less (16 and 12.5 per cent.) and it disappears altogether in the smallest farms. The unfavourable position in this respect of farms between 35 and 70 acres is explained by the fact that the collaboration of the members of the owners' families diminishes considerably, while they are unprovided with housing for labourers' families and consequently have to put up with unmarried farm hands, who are the most difficult to get.

1049 – **Influence of Economic Conditions on the Methods of Farming.** — AEREBOE, FRIEDERICH. Special reprint from *Jahrbuch der Deutschen Landwirtschafts-Gesellschaft.* Berlin, 1914.

The total process of development of public economy reacts upon agriculture chiefly by the difference between the prices of production on one hand, and the prices of the means of production on the other, and then also by the reciprocal relations of the prices of the individual agricultural products and of the several agricultural means of production. In a low stage of development of agriculture the prices of agricultural produce are low considered absolutely, and especially so in comparison with wages and with the prices of the purchasable means of production. Consequently the aim of the farmer must consist in cultivating large areas of soil with the employment of small quantities of labour and capital so as to ensure for these two factors a large harvest to compensate for its low price. At a higher stage of development, with higher prices for agricultural produce and comparatively low prices for the means of production, it becomes advantageous to increase the employment of labour and of live and dead stock per unit of area, so long as a surplus of production can be obtained.

Between these two extremes there are, however, innumerable stages which are characterized in the whole public economy by a progressive saving of the soil following upon its heightened utilization. In agriculture this sav-

ing of the soil and increased utilization is attained by the successive prefe rence given to such forms of utilization of the soil as require, it is true, greater outlay on labour and live and dead stock, but which yield a muc larger quantity of produce per unit of area, and also by concentrating th crops on the old cultivated areas and extending the utilization of the so to always poorer areas or such as are always more difficult to improve.

This evolution is naturlly accompanied by the creation of always nev systems of farming which differ from each other especially in the followin characters:

1. In the ratio between the different types of cultivation, especially in the ratio between woods and pastures on the one hand, and arable land on the other.

2. In the proportion of fallow to arable land.

3. In the proportions of the various crops, especially of hoed crops.

4. In the kind and extent of the crop grown for green manuring and especially in the proportion of catch crops.

The evolution of the systems of farming and the degree of its intensity thus depend chiefly upon the variations of the above conditions. With the general organization of the farm the importance and extent of the individual crops and cultural methods vary also and with them the tillage of the soil, the manures applied, the kind and quantity of seed, the harvesting, etc.

The writer considers the different degrees of development of a number of cultural methods in general and of their application to several plants. He distinguishes also as regards manuring the following regions of intensity or degrees of intensity in the use of farmyard manure, artificials and green manures, starting from the lowest or most unfavourable economic condition:

A. *Regions where farmyard manure and artificials are used:*

1. Regions in which the plant food diminishes.
2. Regions in which it is replaced.
3. Regions in which it is increased.

or

1. Regions that are not manured.
2. Regions in which only farmyard manure is used.
3. Regions in which farmyard manure and artificials are used
   - *a*) artificials chiefly containing nitrogen;
   - *b*) artificials chiefly containing phosphates;
   - *c*) artificials chiefly containing potash.

B. *Regions in which green manuring is practised:*

1. Regions without green manures.
2. Regions in which green manures are the chief crop.
3. Regions in which plants for green manures are sown among cereals.
4. Regions with plants for green manures sown among cereals or after harvest.

With the increasing prosperity of economic conditions the intensity of manuring increases also, with regard to outlay of both labour and capital. The same holds good, especially in the amount of labour, in the regions where weeds are controlled, of which the writer distinguishes ten :

1. Destruction of weeds only by changing arable land into pasture.
2. Do. by fallowing and ploughing between the principal crops.
3. Do. by surface ploughing, cultivating, harrowing, etc., but always by means of team work between the harvest and the preparation of the soil for the chief crops.
4. Do. by horse hoeing during the growth of the crops. Hand hoeing only in gardens.
5. Hand hoeing in field hoed crops.
6. Hand hoeing of wheat; possible through extension of hoed crops.
7. Hand hoeing of oats also, thanks to the still greater extension of hoed crops.
8. Hand hoeing of barley also.
9. Cultivation of rye in spring with Zehetmayr's roller harrow.
10. Destruction of weeds and plant diseases by means of different sprays.

From the above it will be clearly seen that all means of controlling weeds which entail labour are avoided in the lower stages of development, while in the higher ones those which demand extent of soil are abandoned.

The whole change in the development of the measures for the destruction of weeds consists in expending labour in order to save soil, which is also effected by concentrating the crops.

In the culture of rye three different regions are distinguished according to the density of sowing, as the quantity of seed diminishes inversely with the intensity of farming.

In the division of the regions of beet growing, the writer considers most of all their position in the rotation while with mangolds he gives greater importance to the methods of culture.

A. *Regions in which beets are grown.*

1. Beets only in small inner rotation, which through the frequent cultivation of hoed crops are kept fairly free from weeds.
2. Beets in the main rotation and for several successive years, in order to facilitate the destruction of weeds at least in the second and third years.
3. Beets in the main rotation in regular alternation with cereals.

B. *Regions in which mangolds are grown :*

1. Only seedlings planted out immediately after ploughing.
2. Only seedlings planted in levelled and half loosened soil.
3. Partly seedlings and partly sown mangolds.
4. Only sown mangolds.

This table also shows that the object of the farmer must be to get most returns from the outlay on labour in the lower stages, and in the higher ones greater returns from the soil area. The same conclusion may be drawn also from the succession of the potato regions:

1. Planting the potatoes after ploughing, earthing them up after repeated harrowing. Deep sowing is indispensable.

2. Planting potatoes in well loosened soil, alternately earthing up and carefully harrowing; sowing not so deep.

3. Alternate earthing up and hoeing with a horse-hoe lengthwise between the rows.

4. As No. 3, but hoeing crosswise.

5. No harrowing. The destruction of weeds effected only by hoes and chain harrow; in some cases a second hoeing by hand. Superficial sowing.

In this way areas of cultivation for all the other cultivated plants according to the methods of more extensive or more intensive cultivation and corresponding to the more or less advanced stage of economic conditions might be outlined. It is easy to understand that in different stages of development different demands are made upon cultivated plants and that consequently the aims of plant breeding must be different according as the plants are bred for localities of extensive or intensive farming. In order to illustrate this the writer draws up a table in which he compares the two extremes of wheat breeding, namely for extensively and for intensively farmed localities.

A. In the lower stages of farming or in localities situated in unfavourable economic situations, the returns per unit of area are secondary considerations, while the returns obtained by labour and capital are the principal ones; consequently the aims of breeding are:

1. Slight demands as to labour.

2. Slight need of manures.

3. High power of competing with weeds and the like.

4. Easy harvesting by machinery even should the quality of the product suffer.

5. Quantity and quality of straw secondary considerations.

B. In a higher stage of farming or for localities in economically favourable situation, the yields per unit of area are the chief considerations, while the yield per day's labour and per unit of capital are secondary matters; consequently the aims of breeding are:

1. High capacity of utilizing the labour spent upon it by high yields per unit area.

2. High capacity for absorbing fertilizers, even if accompanied by loss of thriftiness.

3. The increased care of the plants allows of their possessing a lower degree of resistance to weeds and the like.

4. High quality of the harvested grain, even if it should entail a greater consumption of labour.

5. High selling value of the straw and large quantities of it, increasing considerably the money value of the harvest.

According as these objects are more or less completely attained by breeding, the importance and the position of the individual cultivated plants change in the course of development. Those plants which by a great increase of harvest best repay the intense care and manuring bestowed

upon them will acquire most importance. In this connection the writer compares rye and oats. With oats the work of improvement was begun in Germany earlier than with rye and has obtained superior results. Consequently for many years oats have been given an always better position in rotations. From the lowest position it occupied in rotation, it has risen now to the second place, and where hoed crops cannot follow a green manure crop, oats occupy the first place. Only the later brilliant successes of rye breeding have retarded this development, but recently it has received a new impulse from the selection of Lochow's Yellow oats, which possesses all the desired qualities in a measure which had never been attained before.

1050 – **The Influence of the Prices of Agricultural Produce upon the Farming Conditions in Switzerland.** — LAUR, E. Reprint from *Schweizerischen landwirtschaftlichen Zeitschrift*, Year 1914, Nos. 26, 27, 28.

Swiss agriculture realized in the period from 1906 to 1913 about 22 per cent. more than in the period between 1901 and 1905 for the same amount of yearly production. In the same time the prices of farms, and especially of separate pieces of land, have increased considerably. That this rise in the prices of land does not always signify an increase of the value of the bare soil is proved by the following figures which show the changes in the values of farms and of the bare soil per acre of cultivable land between the period 1901-05, and that from 1906 to 1912, according to the book-keeping results obtained by the Swiss Peasants Secretariat.

Results of all the yearly balances from the investigations into profitableness.

Per acre of cultivable area	1901-05			1906-12			Increase			
Capital in:	£	*s*	*d*	£	*s*	*d*	£	*s*	*d*	per cent.
Farm	70	11	11	72	10	5	1	18	6	2.80
Soil	37	4	1	37	10	11		6	5	0.86
Buildings, improvements and plantations	33	7	5	34	19	6	1	12	1	4.80

If in the corresponding years only the farms that in those years began to have their accounts audited are considered, the results are as follows:

Per acre of cultivable area	1901-05			1906-12			+ Increase — Decrease			
Capital in:	£	*s*	*d*	£	*s*	*d*	£	*s*	*d*	per cent.
Farm	72	15	3	77	4	1	+ 4	8	11	+ 6.10
Soil	39	19	0	39	7	6	—	11	7	— 1.45
Buildings, etc.	32	16	3	37	16	8	+ 5	0	5	+ 15.30

From the above figures it appears that on average of all the farms examined the capital in soil per acre has remained very nearly the same and that the increased price of farms is mostly due to the greater value of buildings, improvements and plantations.

The greater receipts from farming are used in the first place to cover the growing cost of production. According to the observations of the Swiss Peasants' Secretariat, the cost of production of crops, not including the interest on capital amounted:

in the period 1901-05 to	£7 4*s* 5*d*	per acre
» » 1906-12 »	£8 8*s* 6*d*	»
thus increasing by	£1 4*s* 1*d*	or 17 per cent.

In the year 1912 the cost of production reached £9 4*s* 2*d*, or a third more than in the perlod 1901-05.

The share in the cost of production due to the interest on the capital in soil is mostly much overvalued. Thus, for instance, the average cost of production of milk in Switzerland during recent years was about 7.98*d* per gallon; of this less than 0.86*d* is due to the interest on the land, and from 1.29 to 1.73*d* to the interest of the other capital invested in farming. An increase in the cost of production caused by the interest on the soil cannot be recognized from the results of the examination of the accounts kept.

On the other hand the outlay on interest, amortization and repairs of buildings has increased, and amounts now to 10.8*d*. The greater demands of labour have much increased the cost of production. Labour alone claims 3.24*d* per gallon of milk. Wages have increased by 22 per cent., while, thanks to the use of labour-saving appliances, the average amount of labour per acre is only 13 per cent. more than formerly. Further, the higher prices of concentrated foods and artificial manures, the greater consumption of which have favoured the greater intensity of farming, have contributed to raise the cost of production. Only through higher prices is it possible for farming to stand this increase in the cost of production.

Under the influence of better-prices for his produce, the farmer has been able to attain better living. In farms which did not employ outside labour the cost of living per man-day in 1901-05 was 11.12*d* and in 1906-12 12.5*d*, or an increase of 1.38*d* or 12 per cent.

In the year 1912 it amounted to 13.25*d*.

In farms employing outside labour the cost of living has increased to a greater extent, being 14.25*d*. But as in this period the cost of articles of food has also risen, the nourishment has problably not changed much. On the other hand the other items of personal expenses have considerably improved per man unit and year. They amounted to £6 14*s* 10*d* in the period 1901-05, to £8 12*s* 1*d* between 1906 and 1912, increasing by £1 17*s* 3*d* or 27.7 per cent. In 1912 they reached £9 18*s* 3*d*.

Lastly, the higher incomes have allowed farmers to save more. On an average the savings per farm were £44 3*s* 4*d* between 1901 and 1905 £64 10*s* 11*d* between 1906 and 1911, an increase of £20 7*s* 7*d* or 46.1 per cent. and in 1912 they reached £80 1*s* 9*d*.

Only a very small part of these savings was invested in new capital proper, a certain amount was used for the paying off of debts, but more especially they were devoted to new installations in the farms, to the building of new outhouses, to the purchase of new machines and implements, to the increase of the live stock.

From the above it will be seen that the increased incomes of farmers, due to the higher prices of produce, benefited to a great extent other trades also, and that on the other hand a fall in the prices of produce with the usual cost of production would spell ruin to the farmers. If the whole debt of the agriculture of Switzerland, which amounts to about £150 000 000 were paid off, a fall in prices of one quarter would be enough to balance this advantage.

The gross produce of agriculture in Switzerland amounts at present to £37 670 000; three quarters of this, or in round numbers £28 000 000, are sold. The debt requires, at 4.5 per cent., about £6 700 000 for interest. The fall in prices would thus somewhat exceed the saving of interest.

With prices of produce lowered below the cost of production, the position of the peasants who had debts would not be improved but would be rendered worse, because the question of indebtednes is not so much a question of the price of land, which it is hoped to reduce by the introduction of lower prices of produce, as chiefly a question of the ratio between income and the rate of interest. So long as the agricultural net returns yield a higher rate of interest on capital than the interest that the peasant has to pay on his debts to the banks, the peasant with scanty capital can work in his farm with borrowed capital and still make a profit. On the other hand, when the low prices of produce cause the net returns from farming to sink below the rate of interest on loans, the peasant without sufficient capital or burthened with debts must end in ruin.

The most efficient method of solving the problem of indebtedness consists, according to the writer, in adopting in all transactions with farms, especially in the division of inherited land, their revenue as the basis of all valuation.

AGRICULTURAL INDUSTRIES.

INDUSTRIES DEPENDING ON PLANT PRODUCTS

1051 – **Vinification by means of Ferments other than Wine Yeasts.** — MARTINAND, V., in *Revue de Viticulture*, Vol. XLII, No. 1073, pp. 29-34. Paris, July 9, 1914.

From 1889 to 1901 the writer had studied the specific ferments of fine wines and of the grapes producing them, in collaboration with M. Rietsch; he has now isolated all the cellular ferments present on the ripe grapes of a celebrated wine. Among them are several micro-organisms which are not yeasts and which yield very little alcohol, but which impart a very agreeable fruity flavour absent from wines fermented only by the elliptical ferments.

To determine whether the Burgundy vineyards contain more of the elliptical ferments than those of the South of France, the writer repeated

Pasteur's experiments in a vineyard near the Romanée-Conti property. Of 60 grapes, only one was found to contain elliptical yeasts; four apicular yeasts, two torulae, one fungal yeast (having the characters of both *Mycoderma vini* and a yeast) and six ferments causing turbulence in must, but capable of liquefying gelatine, were also found; the remaining micro-organisms were moulds, *Botrytis cinerea* and *Penicillium glaucum* being dominant; two tubes contained no micro-organisms capable of developing in must. The bacteria were not investigated in these experiments.

The fact that the true elliptical wine yeasts occurred on only one grape is in conformity with their general rarity in the vintage.

The organisms other than the elliptical yeasts produce little alcohol, but it does not follow that they are not able to utilise grape sugar. The evolution of carbon dioxide is not a sufficient index of the activity of the ferments of the grapes. Further, these organisms possess in different degrees the power of secreting diastases which dissociate albuminoid matter more actively than the yeasts. They are also able to free the must and wine more or less rapidly from any free sulphurous acid which they contain.

The following means of utilising these ferments in vinification is distinct from the use of selected yeasts and enables sulphurous compounds to be used when desired. Cultures of the selected ferments are made separately or mixed in must containing grape sugar, and they are supplied to vine-growers at the same time as the alcoholic yeasts. They are used as follows: a starter is prepared by cultivating the ferments in must and 20 litres of the must are used for every 100 h.litres of the wine; this must is allowed an incubation period of 24 hours. The starter is then added gradually as the must is put into the vat; the culture of elliptical ferments is added at the same time, without previous incubation. Twenty-four hours after the vat is full, a considerable quantity of must is drawn off from below and added above. Fermentation proceeds very rapidly and it is advisable to cool the floating grape-skins by spraying each morning with must from the bottom of the vat.

A culture of selected ferments other than those belonging to *Saccharomyces ellipsoides* has been employed; it does not produce more than 6 per cent. of alcohol. Another culture of alcoholic yeasts has been applied either to the starter of pure yeasts or direct to the vintage.

Sulphurous compounds, if used, should be applied only during the initial racking off and not on the grapes during fermentation. The amount should be less than in ordinary vinification, and it should only be used in the later racking if the temperature of fermentation rises too high, viz. above 35° C. (87° F.).

The writer considers that the selected ferments are used in large quantities in order to dominate the microflora, and the alcoholic yeasts added in less quantity are only able to complete the fermentation of the sugar to form alcohol. The micro-organisms of the selected cultures promote the activity of the alcoholic yeasts. The rapidity of fermentation prevents the growth of disease germs. Thus sulphurous compounds are unnecessary and are only added when the fermentation diminishes. Sulphurous acid gives

the wine considerable quality and by means of numerous comparative experiments it will be possible to limit or extend its use.

The writer points out the advantages to be derived from the use of selected ferments in connection with pure yeasts. The fresh fruity wines of the Beaujolais, as well as the Aramon wines from the South of France, much liked for this reason, will improve considerably when prepared by this method. The yeasts possessing a characteristic bouquet, like those of champagne, retain their quality in the presence of these selected ferments. The danger from a later fermentation in the bottle as in the case of sulphited wines, does not exist with wines prepared by this method of fermentation.

1052 – **Physico-Chemical Volumetric Estimation of Potash and Magnesia and its Application to Wines.** — DUBOUX, M., in *Comptes Rendus hebdomadaires des Séances de l'Académie des Sciences*, Vol. 159, No. 4, pp. 320-323. Paris, July 27, 1914.

M. Duboux proposes to extend the application of the electrical conductivity method (1) to the estimation of potash and magnesia, which had not yet been studied.

The potash is estimated in neutral solution after the addition of 18 times its volume of 95 per cent. alcohol by determining the conductivities after successive additions of platinic chloride. Magnesium is determined by the changes of conductivity of the solution to which 0.02 per cent. of ammonia and 0.06 per cent. of ammonium chloride have been added, induced by successive additions of a semi-normal solution of phosphoric acid. In estimating these substances in wines the organic matter must be previously removed.

The volumetric method gives results sufficiently consistent with those obtained by the customary gravimetric method, but generally about 0.01 gm. per litre below them.

1053 – **The Influence of Radioctive Emanations on Yeasts and Alcoholic Fermentation.** — JACQUEMIN, G., and GIUREL, G., in *La Vie Agricole et Rurale*, Year III, No. 35, p. 232. Paris, August 1, 1914.

Radioactive emanations have a marked action on alcoholic fermentation and yeasts, exerting a stimulating action from the moment of inoculation of the medium and the growth of the elliptical yeasts until the final stages. The transformation of sugar is more complete and the yield of alcohol is greater by several tenths of a degree in most radioactive media. A radioactivity of ½ to 1 unit per litre exerts a beneficial action on yeasts and accelerates the breaking-down of saccharine organic compounds, just as in the case of the mineralization of nitrogen by nitrifying organisms.

The increased activity and alcohol-yielding capacity of radioactivated yeasts is of great advantage in many fermentation industries and notably in vinification.

(1) See article by P. DUTOIT and M. DUBOUX: "Analysis of Wines by a Physico-Chemical Volumetric Method". — *B.* Dec. 1912, pp. 2562-2569. Also, No. 947, *B.* Oct. 1914. (*Ed.*).

1054 – **Some Products of the Banana.** — *Queensland Agricultural Journal*, Vol II, Part 1, pp. 40-41; Part 2, pp. 150-152. Brisbane, July and August 1914.

It has been calculated that in all exporting countries there are probably 8 000 000 bunches of bananas that annually fail to come up to the standard required by shippers. These 8 000 000 bunches, at 6 *d* each, amount to £200 000 per annum. This shows the importance of the problem of their industrial utilization.

The writer describes the methods of preparing dried bananas, or " banana figs ", banana meal, banana wine (obtained by the spontaneous fermentation of the fruit mixed with water, but which keeps only a short time), and banana alcohol or whisky. Bananas analysed by Corenwinde showed that they contain as much as 22 per cent. of sugar, 16 per cent. of which is crystallizable; hence the conclusion that they might produce an excellent alcohol. At the Central Laboratory of Guatemala experiments were conducted which led to the production of a good spirit something like whisky. Samples of this spirit that had been only six months in the barrel were sent to the St. Louis Exhibition where they were much appreciated. The cost of manufacture is said to be much less than that of ordinary whisky. The yield may be estimated at about 1 gallon per bunch of bananas. The cost of a plant capable of producing 150 casks of whisky daily is estimated at about £34 500. This estimate includes buildings, machinery, apparatus, fuel, labour, administration, general expenses for two years, cases and bottles for one year and raw material for manufacture for two years, namely 270 000 bunches at 7 ½*d* each.

1055 – **Studies on the Extraction of Olive Oil.** — VENTRE, JULES (Ecole Nationale d'Agriculture de Montpellier) in *Annales de l'Ecole Nationale d'Agriculture de Montpellier*, New Series, Vol. XIII, Part IV, pp. 249-269. Montpellier, April 1914.

I. — *Formation of the oil in the olive and its relation to the time of harvest and storage.* — Experiments were conducted to determine how far it is true that the yield of oil is increased by delaying the harvest of the fruits. The results are set forth in Table I and show that the increased yield of oil after maturity is only apparent, being due largely to loss of water by evaporation.

TABLE I. — *Composition of olives at various stages of maturity.*

	Date of gathering			
	November 15 unripe, skin of a yellow rose colour	December 3rd skin reddish	December 21 ripe and black not wrinkled	January 10 end of season fruit shrivelled
Weight of one olive . . . gms.	1.685	1.650	1.615	1.512
No. of olives per litre	350	392	420	458
Weight of 1 hl. . . . . kg.	58.975	64.680	67.830	69.250
Water in fresh olives . . . %	40.85	38.92	36.74	30.93
Oil in fresh olives . . . . %	17.2	20.85	24.16	25.63

In order to determine whether continued maturation on the tree influences the formation of oil, batches of fruits were stored in a dry atmosphere from the 15th of November to the 10th of Jannary. The percentage of oil was determined at three different periods during this time and the results compared with the analyses of similar fruits gathered fresh from the trees at the same times as those taken from storage. The results are given in Table II.

TABLE II. — *Comparison between the oil-content of fresh olives and stored olives at different stages of maturity.*

Date of gathering or removal from storage	Stored olives			Fresh olives		
	Moisture % of fresh olives	% of oil in		Moisture % of fresh olives	% of oil in	
		fresh olives	dried at 105°		fresh olives	dried at 105°
November 15	—	—	—	40.85	17.2	29.1
December 3.	33.23	22.64	33.92	38.90	20.85	35.15
December 21	23.6	28.42	37.20	36.65	24.16	37.60
January 10.	20.62	30.48	38.40	30.92	25.63	37.12

It is seen that the proportion of oil to dry matter is sensibly the same in stored and freshly gathered fruits. On the 15th of November the olives contained 40.85 per cent. of water and on the 10th of January only 20.62 per cent. ; by calculation from the 17.2 per cent. in the dry matter on Nov. 15, the stored fruits should contain 23.32 per cent. on Jan. 10, while the actual result obtained by analysis was 30.48, thus showing an increase of 7.16 per cent.

These results also show that harvesting the fruit too late diminishes the yield of oil. Olives may therefore be safely stored for a certain time provided they are placed in layers not exceeding 16 inches in thickness and the storeroom is kept ventilated.

Heated olives give a higher yield of oil. The best temperature is beteween 35 and 40° C. (95 and 105° F.) and is obtained by natural fermentation at the end of 6 to 8 days after storing according to the above conditions. Should spontaneous fermentation proceed too far, or if mouldiness appear, the oil will be acid and very inferior.

From these results the writer draws the following conclusions :

1. The yield of oil from olives increases from the beginning to the end of maturity, chiefly owing to the loss of moisture by evaporation and the consequent increase in the proportion of the other constituents.

2. The olive contains a sufficient quantity of reserve material to be transformed into oil during storage, and ripening may continue after harvesting the fruits as in the case of other fruits.

3. The best time for harvest is during the second and third periods of maturity, when the skin is red or black and without wrinkles.

4. Storage under rational conditions in no way endangers the quality and maturation of the fruit for industrial purposes.

II. — *Comparisons of mechanical and hydraulic presses.*

The results of experiments with the hydraulic press are given in Table III. Treatment A consisted in subjecting the paste of olives ground for half an hour on a small mill stone, to a maximum pressure of 260 000 lbs maintained for 80 minutes, The oil thus obtained was of superior quality.

Treatment B consisted in subjecting the paste to a preliminary pressure of 150 000 lbs. for 25 minutes, after which the baskets were emptied and the paste placed in the finishing press, taking care to add 2 litres of warm water at 80-85° C. to each basket. The pressure was then raised to 260 000 lbs. for 55 minutes. The liquid of the different pressures was collected separately ; the first was of fine quality, the second had a less agreeable dry taste.

Treatment C was exactly similar to the preceding, with the difference that the water used was at a temperature of 15° C. The separation of the watery layer was more rapid than in the preceding case and the second oil extraction was considerably improved; it was considered advisable to mix the two qualities of oil and obtain a unique product of superior quality. Treatment D differed from B and C in omitting the addition of any water to the pressed paste. The quality of the oil obtained at both pressures was superior to that obtained by treatment B.

Treatment E was like treatment B, but the duration of the pressure was doubled, 40 minutes in the preliminary press and 80 minutes in the final press. The product obtained in this case was inferior to all the preceding.

Table III shows that the yields were almost equal by each method, excepting the slight increases when water was added.

The use of cold water, which does not injure the product, should not be neglected in large factories.

The experiments of which the results are summarised in Table IV were conducted in a mechanical lever press, with a pressure of about 167 000 lbs. The proceedure was analogous to that of the preceding experiments ; in A the pressure was maintained for 100 minutes, in E each pressure was applied for 1 hour.

Comparing Tables III and IV it is seen that the yield of oil from the first operation is greater with mechanical presses than with hydraulic, but the total yield of oil is greater from the latter.

The residues of the two series of experiments were analysed. The Table shows that the residues of the first series (hydraulic presses) contain in the average of the treatments 10.16 per cent. of oil (in terms of dry matter), whilst the residues of the second series (mechanical presses) contain 11.59 per cent.

It was observed during these experiments that the degree of grinding

Residue, % of fresh olives		59.9	54.4	57.1	54.3	53.4

has no essential importance with respect to yield of oil, and that if it is too extreme the yield is actually diminished.

The conclusions drawn from these experiments are:

1) Hydraulic presses are always capable of excellent returns, with regard to both yield and economy of time.

2) Mechanical presses, when well made, can yield almost as good results as hydraulic presses under certain conditions.

3) Hydraulic presses should be employed in large installations where the increased yield will compensate for their heavy expenditure.

4) Apart from the pressure, the addition of hot or cold water results in an increased yield.

5) As a general rule the yields obtained by the use of cold water are about equal to those obtained by hot water.

1056 – **Some Data on Peanut Butter** (1). — UTT, C. A. A. (Kansas State Agricultural College, Manhattan) in *The Journal of Industrial and Engineering Chemistry*, Vol. 6, No. 9, pp. 746-747. Easton, Pa., September 1914.

The writer analysed 23 samples of peanut butter bought on the Kansas market and found that the percentage of oil varied between 46.44 and 53.64. The refractive index at 25° C. ranged from 1.4680 to 1.4707 and the iodine value from 88.76 to 94.36. He further prepared three samples of roasted peanuts reduced to butter-like consistency and found their characters to be within the above limits. Another sample was prepared by roasting peanuts brown in olive oil and then grinding them as finely as possible. It was found to contain 55.48 per cent. of oil and its refractive index was 1.4620.

According to BEATTIE some fresh peanuts may contain as much as 50 per cent. of oil ; after roasting the oil content would be higher owing to a corresponding loss of water. The writer concludes that finding more than 50 per cent. of oil in peanut butter does not warrant its being declared adulterated by the addition of other oil. That added oil can be detected is seen in the lowering of the refractive index by the use of olive oil.

1057 – **The Japanese Seaweed "Tosaka Nori."** — COTTON, A. D., in *Royal Botanic Gardens, Kew, Bulletin of Miscellaneous Information*, No. 6, pp. 219-222. London, 1914.

Professors Cotton and Yendo have identified and named *Eucheuma papulosa* the edible Japanese alga known in Japan as "tosaka nori", and which had been described under several other names. It is found in the Red Sea, and in the seas near Somaliland, Formosa, Japan, Guadeloupe and the Sandwich Islands. In Japan it is much esteemed. It is often collected by divers in a depth of 10-12 fathoms along open coasts in the middle and southern parts of the country. Large quantities of the plant are, however, obtained by picking up the floating fronds with scoop nets after rough weather in early spring. The weed is dried in the sun and sold in the markets. It is prepared into isinglass and is used as food. A certain amount is also exported annually to China, where it is known as "hong-tsay" (crimson weed).

(1) See No. 65, *B.* Jan. 1913. (*Ed.*).

058 – **Bacteriological Enquiry on Sterile Milk Sold in Brussels.** — KUFFERATH, H., in *Annales de Gembloux*, Year 24, Bk.8, pp. 417 424. Brussels, August 1914.

From the results of 17 samples the writer draws certain conclusions oncerning milk sold as "aseptic" in Brussels. Comparing the results obtain-d by the use of aseptic milking with those already published on the rdinary milk delivered in the city of Brussels, the progress made by dairy-nen becomes apparent. The writer had found that the ordinary milk ontained on an average 1 388 430 germs per cc., whilst in the 17 samples bove mentioned only 17 263 germs per cc. were found. These results how the importance of the establishment of official bacteriological control or milk supplies and the value of such a service to the public.

Of the 17 samples examined, two were found to contain *coli* bacilli. Sterile milk should be such that it may be safely consumed without boiling. It is therefore evident that the greatest care should be taken to observe strictly all regulations.

The Belgian Permanent Milk Commission asked the writer to determine a maximum limit for the number of germs allowable in sterile milk. This standard should be about 50 000 germs per cc., estimated by counts on gelatine plates kept for 3 days at a temperature of 38° C. At the same time no injurious bacilli such as *coli* and tuberculosis germs must be allowed.

1059 – **Payment for Milk and Cream Supplies.** — CUDDIE, in *The Journal of Agriculture.* Vol. VIII, No. 3, pp. 295-299. Wellington, N. Z., March 1914.

While the purity of milk (that is the lowest possible content of micro-organisms) is of the greatest importance for making cheese and butter of the very best quality, milk supplied to dairies continues to be paid for according to fat content alone. As all the lots of milk are mixed and worked up together the least pure lots reduce the best to a lower common standard, and the injury caused only by the least careful dairy farmers is felt equally by all.

The official inspection of milking sheds, yards, etc., has only a partial success in raising the standard of purity in factory supplies. The writer therefore proposes that a reduced price per pound of butter-fat be paid for those quantities of raw material which can yield produce of only indifferent quality, and a premium be given for those deliveries which possess a high degree of purity.

In order to introduce such a scheme it would, of course, be necessary to have the milk and cream from each farm classified by a competent and independent officer, who would visit the factory for the purpose, not less frequently than once a week. The date of his visit should not be known to the suppliers.

A sample representative of the day's supply should be taken on the day of the officer's visit and submitted to the "curd test".

This test has been tried over a long period of years and has been found to be thoroughly reliable as an indicator of the purity of the milk, although it does not appear to have ever been applied to the grading of milk for payment purposes.

The samples submitted to the grading officer for examination need bear only a number and not the name of the owner. The grader would record his decision and hand a copy of his results to the secretary of the company concerned, who would credit each supplier with the grade recorded for that particular period. The number of days covered by this test might be made coincident with the period covered by the test for butter fat, which would simplify the work.

The men selected to undertake the grading should be appointed by Government. If the work were properly organized, in most districts several neighbouring factories might agree to have the same inspector, which would make the expense to each very moderate.

The writer is convinced that the adoption of the scheme outlined above would eventually raise the value of New Zealand butter and cheese by at least 3*s* or 4*s* per hundredweight. In fact the best New Zealand cheese exhibited at the last Dunedin Winter Show and then sent to London, where it was placed on exhibition, was sold 4 to 5 *s* per cwt. more than New Zealand cheese was bringing on the market at the time.

1060 – **The Influence of Foot-and-Mouth Disease on the Composition of Milk and Butter.** — Bordas, F., and De Raczkovski, S., in *Annales des Falsifications*, Year 7, No. 68, pp. 271-292. Paris, June 1914.

After giving a résumé of the question which has interested the chemists and magistrates appointed for the suppression of frauds (1), the writers furnish additional information for the solution of this problem. The researches were made with samples of milk taken with all possible care in the presence of the local veterinary surgeon in places where foot-and-mouth disease had been reported. The results of the analyses of diseased and healthy milk from the same cowsheds have been compared with the average obtained the same day from milk collected throughout the district.

The changes in the composition of the milk and butter due to this disease are as follows:

1) *Milk.* — A notable increase in the proportions of fat and mineral salts, especially chlorides, and a decrease in the percentage of casein. There is apparently no change in the percentage of lactose, except that in the case of milks from cows in the height of fever and of those with abnormally high fat content there is a decrease in lactose accompanied by a corresponding increase in ash. The percentage of organic phosphorus and the acidity remain unchanged. Milks in which solids-not-fat fall below 86 gms. per litre are rare.

2) *Butter.* — Examination of butter from a single badly diseased cow might lead one to suspect addition of about 25 per cent. of margarine, whilst that from a herd of cows more or less infected would be suspected of an addition of 5 to 6 per cent. The conclusions of the writers confirm those put forward by French Analysts.

Thus, though it is true that the milk from a single cow or a small number of cows in the same shed, or that the butter obtained from a small quantity

(1) See No. 2783, *B.* Aug.-Sept.-Oct. 1911; No. 954, *B.* Aug. 1913. (*Ed.*)

of infected milk may show an abnormal composition, the collected milk or the butter centrifugalised from it never show any defects such as would make them unsaleable.

1061 – **New Observations on the Origin of the Taste of Swedes in Butter.** — WEIGMANN and WOLFF, in *Landwirtschaftliche Jahrbücher*, Vol. 46, Part 3, pp. 343-365. Berlin, May 15, 1914.

In the 37th volume of *Landwirtschaftliche Jahrbücher* one of the writers demonstrated that the taste of swedes in butter it to be attributed, for the most part, to bacterial action and only for the very least part to a somewhat stronger smell and taste of the cow than is found in ordinary milk. He further recognized that the bacteria which caused this secondary flavour are not new and special ones, but those which are generally found in milk, especially *Bacterium coli*, lactic acid bacteria, *Actinomyces odorifer*, besides some mycelia rarely found in milk.

Since the above publications the writers studied further cases of the taste of swedes in samples of milk and butter. It was first established that the swede flavour was due to strains of *B. coli* together with other species, among which is to be mentioned *Bacterium fluorescens liquefaciens*, which possesses to a great degree the power of producing the taste of swedes and of carrots in milk. The observations on the latter taste were made on the occasion of investigating a milk which was designated as " bitter " and subject to " premature curdling ", in which this bacterium was prevalent together with members of the *coli-aerogenes* group, short alkaline bacilli and cocci. The glass plates on which the milk was laid smelt distinctly and strongly of carrots, and the milk inoculated with the isolated bacteria took after 24 hours the same strong taste and smell.

The taste of swedes caused by *Bacterium fluorescens liquefaciens* is exceedingly acute and strong, and could be studied in a number of cases. In several occasions, when the above bacterium was present, instead of the swede taste a fine pineapple or strawberry flavour could be detected. In other instances the *Bacterium fluorescens* did not produce the swede taste when alone but only in the presence of other bacteria, especially of lactic acid bacteria. The latter alone may even be the cause of the defective taste of the milk, from which it follows that they also are capable of giving the swede taste to butter. This is perhaps rather more a taste of " fodder ", which becomes stronger and more distinctly swede-like as soon as other bacteria or fungi possessing similar properties are present.

In all the cases mentioned the writers have found bacteria which possess the power of producing such tastes and odours. It may thus be inferred that the substances giving these tastes and odours are due to properties of the bacteria acquired during their evolution, which properties the writers attribute chiefly to the nutritive medium or to the medium in which the bacteria live.

The experiments made, show that these odorous substances of the nutritive medium are partly directly transmitted and are partly due to the production of substances which do not exist in the nutritive medium but are formed from the components of the medium. It may be admitted

as certain that every group and species of bacteria has its specific action as to taste. Whether the same nutritive medium under the action of different bacteria gives rise to the same taste remains to be investigated.

1062 – **The Odessa Cattle and Meat Supply.** — *Daily Consular and Trade Reports Issued by the Bureau of Foreign and Domestic Commerce*, Year 17, No. 196, pp. 1004-1005. Washington, August 21, 1914.

The Russian cattle industry is continuously declining and the meat producing centres are gradually receding to the outskirts of the country; nevertheless there is no scarcity of forage and the breeds are improving considerably, as has been shown by the recent livestock exhibition at Petrograd. There were no oxen weighing less than 542 lbs. and some weigheed as much as 1264 lbs.

During the last three years the following animals were slaughtered at the Odessa abattoir :

	1911	1912	1913
Cattle	132 566	119 397	125 474
Calves	26 522	25 412	26 343
Sheep	68 963	84 911	88 114
Lambs	46 935	43 159	53 398
Swine	41 825	53 924	61 797

Cattle and other animals intended for consumption must be killed and prepared at the city abattoir. Only such animals as have been inspected by its veterinary surgeons are allowed to be killed, and after slaughter the meat is again inspected as well as all prepared meat brought into the city. All meat intended for exportation must also be accompanied by a certificate from the veterinary of the National Government. A small quantity of meat is sent from Odessa to other Russian ports on the Black Sea.

The Odessa cattle market, the largest in South Russia, supplies many neighbouring towns and determines the prices of meat animals for a wide radius. In 1913 the following animals were brought to the Odessa market : oxen 39 965 ; cows, 48 286; heifers 76 464; calves 1556. Most of the cattle and meat supply of the city is brought from within a radius of 200 to 300 miles.

The following table shows the average wholesale prices per 100 pounds of various meats during the last three years :

Years	Beef	Veal	Mutton	Pork
1911	$ 7.75	$ 15.00	$ 6.80	$ 8.30
1912	8.00	15.75	8.55	8.90
1913	7.80	15.00	7.50	8.50

The retail price of beef has risen during the last seven years from 7.2 cents per lb to 11.1 cents.

In considering these prices it must be remembered that the animals are not of improved breeds and that the method of cutting up provides the buyer with much waste.

Much attention is given to the treatment of by-products at the city abattoir. The blood is mostly dried and powdered. The entrails are used chiefly for feeding swine and fowls. The intestines are worked up locally into sausage casings and musical instrument strings, and occasionally small quantities are salted for export. Most of the fat is used in the local industries, especially that of soap making, partly also in the manufacture of margarine. Some mutton fat is exported to Turkey. Hoofs and horns are for the most part worked up by factories in Central Russia. Almost all the hides go to local tanneries. The contents of stomachs are desiccated and carted to the Odessa irrigation fields, where they are ploughed into the poorest soils, which are a mixture of brackish sea sand and clay carried down by the rains.

When amply manured, treated with the city's waste waters and cleared of salt, the ground is good for kitchen-garden produce.

1063 – **The Wool Clip in Australasia in the Year 1913-1914.** (1) — *The Agricultural Gazette of Tasmania*, Vol. XXII, No. 7, p. 254. Hobart, July 1914.

The number of sheep estimated to have been shorn in the Commonwealth and New Zealand in the season 1913-14 was 109 692 264 head, including lambs, and they produced 7.87 lbs. per fleece as against 7 lbs. for the previous season. An average monetary return of 6*s* 4*d* per head was realized, the total value of the wool clip being £34 957 463. The oversea exports of wool, plus the quantity retained for manufacturing purposes, give a total of 2 639 280 bales. The average sale price per bale was £13 4*s* 11*d* and the total amount of all the wool sold in Australia and New Zealand was 1 968 578 bales, while 10 years ago only 837 497 bales were sold. The increase in the value of the wool clip sold in Australasia in 10 years amounts to no less than 160 per cent.

PLANT DISEASES

GENERAL INFORMATION.

LEGISLATIVE AND ADMINISTRATIVE MEASURES

1064 – **Decree of the Governor of the Colony of Eritrea, dated 13 July 1914, (No. 2026), concerning the Protection of Plants.** — *Bullettino ufficiale della Colonia Eritrea*, Year XXIII, No. 29, pp. 221-222. Asmara, July 16, 1914.

Art. 1. - Proprietors and directors of horticultural establishments and nurseries in Eritrea producing plants, parts of plants and seeds, or engaged in their sale, are required to declare this to the regional commissioner.

The Colonisation Department has the right to inspect crops and vegetable products wherever they may be stored, and, if they are considered infected, to prevent their sale or order their disinfection.

Art. 2. — Officers acting under the instructions of the Director of the Colonisation Department have the right of entry into all properties, irrespective of the crop or use of the land, to ascertain whether diseases are present, and according to the provisions of this decree and special enactments, they have the power to take the necessary steps for the disinfection and care of infected plants.

Art. 3. — The introduction of agricultural, forest and ornamental plants and parts of plants or seeds from Italy is forbidden, unless they are accompanied by a certificate indicating their origin and declaring them to be free from plant diseases liable to endanger the production of crops or useful wild plants in the Colony.

Art. 4. — The certificates referred to in the preceding article should be signed by the Directors of the State Phytopathological or Entomological Stations or Laboratories, or by the Directors of State Institutes or Experiment Stations authorised to grant such certificates.

Art. 5. — The importation of plants, parts of plants and seeds from foreign countries is in general forbidden. In exceptional circumstances the Colonisation Department will be able to grant special permission for the introduction of plants, parts of plants and seeds from foreign countries when certified to be free from dangerous diseases by competent persons appointed by the Department itself.

Art. 6. — Plants not considered free from diseases dangerous to the cultivation of crops or economic plants in the Colony will be destroyed without any compensation being allowed to the owner. The destruction of plants is placed under the charge of the Director of the Customs Office.

Art. 7. — Contraventions of this decree or of regulations to be published for the execution of the decree are punished by a fine of from 8*s* to £ 4, without excluding more serious penalties for violations of provisions of the Italian Penal Code. Contraventions of the prohibition of importation and conveyance shall be liable to a penalty not less than 8*s* and not exceeding £ 12, without excluding more serious penalties for contraband.

Art. 8. — On the proposal of the Director of Colonisation, special dispositions concerning the following matters may be published :

a) destruction of stubble and crop refuse liable to endanger the cultivation of other crops in the Colony;

b) prohibition of growing certain crops or of certain methods of cultivation liable to cause damage to cultivated or wild plants of economic value to the Colony;

c) prohibiting cultivators from allowing plantations of trees to be neglected if they are attacked by injurious parasites ;

d) enforcing definite treatment for the disinfection of plants, parts of plants and seeds introduced into the Colony ;

e) enforcing the use of remedies and the means of control against plant diseases, injurious insects and other plant pests, in cases in which the efficacy of the above measures depends upon the cooperation of all interested, and in cases of neglect to observe these orders, the carrying out of the necessary treatment at the expense of the defaulters.

Art. 9. — Special decrees will be introduced concerning the publication of provisions which may be required for the control of specially injurious pests or for the more effective protection of special crops.

DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN.

1065 – **The Contortion and Breaking of Wheat Straw.** — Darnell-Smith, G. P., in *The Agricultural Gazette of New South Wales*, Vol. XVI, Part 5, pp. 377-378, 1 fig. Sydney, 1914.

In several districts of New South Wales, especially at Nyngan, Wagga and Cowra, it has been observed that wheat is subject to a malformation or twist of the stem as though its normal development had been restrained. The stem is thus weakened and is liable to be broken by the wind when the grain is ripe. In some cases this is so common that the crop appears to have been trampled under foot.

The natural strength of the straw does not appear to have any considerable influence on the prevalence of this phenomenon. In explanation it has been suggested as being caused by insect attacks and also by disproportionate growth of the stems.

Similar cases were also recorded at Carrathool and Deniliquin in 1900, and in the former place it was said to be caused by the bites of aphides during the early stage of growth.

Examination of the diseased straws in 1912-13 did not show the presence of any insect or fungus disease, nor were aphides found on the wheat at Nyngan, Wagga or Cowra in 1914.

According to Maiden, the Government Botanist, who examined several stems, the centre of the disturbance is situated near the lower nodes of the stem. He also remarks that a similar phenomenon has been described as " contortion " by Masters and according to him it is generally produced by retarded growth in certain directions or abnormal growth in others.

Unfortunately, neither attacks of aphides nor abnormal growth due to irregular rainfall admit of the application of remedial measures.

BACTERIAL AND FUNGOID DISEASES.

GENERALITIES

1066 – **Parasitic Fungi collected in the Straits Settlements and Fiji Islands.** — *Royal Botanic Gardens, Kew, Bulletin of Miscellaneous Information*, 1914, No. 4, pp. 156-159. London, 1914.

Among the 11 species enumerated, the following described by Massee as new to Science are worthy of mention from a phytopathological point of view: 1) *Cyphella Hcveae* collected in Province Wellesley on the bark of *Hevea brasiliensis* and undoubtedly parasitic on this plant; it is allied to *C. villosa* Karst.; 2) *Botrytis necans* observed in the Botanic Gardens at Singapore on the larvae of *Brachastona catoxantha* (Lepidoptera), which is effectively kept in check thereby; 3) *Cercospora Musae* parasitic on the leaves of bananas in the island of Viti Levu (Fiji). It is considered to be the cause of a serious disease in estates in the Sigatoka district. Infected leaves fall early: generally the lowest leaves are attacked first and the disease spreads upwards.

FUNGI

1067 – **The Presence of the Hybernating Mycelium of *Macrosporium Solani* in Tomato Seed.** — MASSEE, I., in *Royal Botanic Gardens, Kew, Bulletin of Miscellaneous Information*, 1914, No. 4, pp. 145-146, 1 plate. London, 1914.

It has long been suspected that the spores of " black rot " of tomatoes (*Macrosporium Solani* Cke.) were contained in the seeds, but the actual presence of the fungus had not yet been demonstrated. When the fruits are attacked by the fungus the seeds show black spots on their surface. In 1906 G. Massee showed that the plants derived from such infected seeds were often attacked by " black stripe " disease of the stem due to *M. Solani*. Microtome sections of these spotted seeds show the presence of the mycelium of the fungus.

In a healthy tomato seed, the external integument is in intimate contact with the endosperm, whilst in an infected seed there is a thick layer of hyphae between the two.

In the case of badly damaged fruits the mycelium extends below the diseased zone and in many cases the placentas are completely invaded by a thick web of mycelium, which renders them quite black. The seeds attached to these placentas are often attacked by the mycelium, which penetrates the micropyle. The web of mycelium sometimes forms a uniform layer round the endosperm; in other cases it is of variable thickness or only represented by local patches. The hyphae extend from the periphery to the endosperm and also to the embryo, probably dissolving the thin cell-walls by means of a ferment. When the end of a hypha comes in contact with a cell-wall, it flattens and swells, a small portion of the centre then penetrates the cell-wall and swells out on the other side to its normal size. In other cases the penetration of the hyphae is effected without the flattening and swelling out. No haustoria are found.

On the germination of infected seeds, the embryo is destroyed almost immediately by the mycelium if it is present in quantity, or the mycelium continues to grow in the tissues of the young plant where it may easily be found. Infected plants show the "black stripe" disease before they are two months old, if grown under favourable conditions for the growth of the fungus. Sections of diseased seeds which had been kept dry for several months became surrounded by a mass of mycelium when placed on damp filter paper in a Petri dish, thus showing that the mycelium retains its vitality for a considerable time inside the seed. In numerous cases when the seed from a diseased fruit does not contain mycelium in its interior, it is surrounded on the exterior by a web of mycelium which cannot be removed by the ordinary processes of cleaning, since it is held in position by the thick layer of hairs on the seed-coat.

This external mycelium is therefore a source of danger. The only certain means of avoiding the disease is by rejecting all seeds produced by diseased fruits, even those which do not show black spots.

1068 – **The Resistance of Different Varieties of Gooseberries to American Gooseberry Mildew *(Sphaerotheca mors-uvae)* and the Effect of Treatment with Sulphur.** (1) — KÖCK, G., in *Zeitschrift für das Landwirtschaftliche Versuchswesen in Oesterreich*, Year XVII, Part 6-7, pp. 634-637. Vienna, 1914. RESISTANT PLANTS

During 1913 the writer had the opportunity of studying the resistance to American gooseberry mildew (*Sphaerotheca mors-uvae*) of some hundred varieties of gooseberries, at Eisgrub (Bohemia). The effect of sulphuring (with "Ventilato") was also observed.

This rich collection of goseberries was examined on July 15th and it was found that of the red varieties the following were attacked by the disease: Chain Red, Drum Major, Guido Red, Overall, Raspberry and Roaring Lion (or Rote Preisbeere); on the occasion of a second visit on August 5th, Monstrueuse (or Rote Preisbeere) was found to be diseased. Of the green varieties the following were infested on July 15th: Duke of Bedford, Green Walnut, Keepsake, Plain Long Green, Smiling Beauty

(1) See also No. 884, *B.* July 1913; No. 1301, *B.* Nov. 1913; No. 183, *B.* Feb. 1914. (*Ed.*).

(Hellgrüne Samtbeere). The following yellow varieties were found diseased on July 15th: Globe Yellow (or Runde Gelbe) and Rockwood, whilst Yellow Lion was found diseased on August 15th. The only white variety attacked was Queen Mary.

Sulphuring caused leaf-fall in the following 56 varieties:

Aaron, Alexander, Antagonist, Apo lo, Britannia Red, Chain Red, Champagne Yellow, Companion, Conquering, Hero, Drum Major, Duckwing, Fleur de Lys, Frühe Weisse, Früheste von Neuwied, Green River, Grosse Rauhe Rote, Guido Red, Husbandman, Industry (or Rote Triumphbeere), Jaune Rouge, Jolly Miner, Jolly Printer, Keen's Seedling, Large Hairy, Leveller, Liberator, Migolez (or Red Walnut), Minima, Monstrueuse, Mount Pleasant, Oakmere, Overseer, Pitmaston Green, Plattrunde Himbeerstachelbeere, Pride, Prince of Orange, Prince Regent, Printer, Queen Caroline, Raspberry, Roaring Lion, Rockwood, Rose of Sharon, Rough Red, Sämling von Maurer, Sämling von Pausner, Sampson, Shannon, Smiling Beauty, Smith's Improved, Smooth Yellow, Teazer, Twigem, White Champagne, Yellow Eagle, Yellow Lion.

The following varieties resisted infection:

1) *Red:* Alicant, Alexander, Britannia, Bloodhound, Companion, Forester, Grosse Rauhe Rote, Industry, Jaune Rouge, Jolly Miner, Jolly Printer, Keen's Seedling, London, Migolez, Octavius Brown (Dans Mistake), Plattrunde Himbeerstachelbeere, Rough Red, Rose of Sharon, Sämling von Maurer, Twigem, Wonderful (Braunrote Riesenbeere), Ironmonger.

2) *Green:* Balloon, Aaron, Bumper (Rockwood), Emerald (Smaragdbeere), Früheste von Neuwied, Green Willow (Grüne Flaschenbeere), Green Yellow Seedling (Golden Lion), Green River, Independent, Jolly Angler (Grüne Riesenbeere), Lovely Anne, Lofty (Grüne Riesenbeere), Nettle Green (Dünnschalige), Pitmaston Greengage, Smith's Improved, Thumper, Frühe Weisse Hebbun, Green Prolific, Lady Delamere.

3) *Yellow:* Britannia, Catherina, Conquering Hero, Champagne Yellow, Duckwing, Golden Yellow (Marmorierte Goldkugel), Höning's Früheste (Früheste Gelbe), Husbandman, James Dawson Yellow, Liberator, Leveller, Lord Rancliffe, Minima, Prince of Orange, Printer, Rumbullion, Reveller, Smooth Yellow, Sampson, Triumphant, Two-to-one, Teazer, Yellow Eagle, Mount Pleasant, Stella.

4) *White:* Antagonist, Apollo, Date, Eagle, Fleur de Lys, Large Hairy, Primrose, Queen Caroline, Sämling von Pausner, Shannon, White Lion, White Champagne, Whitesmith.

The following showed no leaf-fall after treatment with sulphur:

1) *Red:* Alicant, Bloodhound, Forester, Over-all, Octavius Brown, Ironmonger.

2) *Green:* Balloon, Bumper, Emerald, Green Willow, Green Yellow Seedling, Green Walnut, Independent, Jolly Angler, Keepsake, Lovely Anne, Lofty, Nettle Green, Plain Long Green, Thumper, Duke of Bedford, Green Prolific, Lady Delamere.

3) *Yellow:* Britannia, Catherina, Globe Yellow, Golden Yellow, Höning's Früheste, James Dawson Yellow, Lord Rancliffe, Rumbullion, Reveller, Triumphant, Two-to-one, Stella.

4) *White:* Date, Eagle, Primrose, Queen Mary, White Lion, Whitesmith.

The observations concerning the disease resistance of each variety and the action of sulphur on the leaves will be continued.

1060 - **On the Composition of Alkaline Bordeaux Mixtures and their Soluble-Copper Content.** — VERMOREL, V., and DANTONY, E., in *Comptes rendus hebdomadaires des séances de l'Académie des Sciences*, 1914, 2nd Half-year, Vol. 159, No. 3, pp. 266-268. Paris, 1914

MEANS OF PREVENTION AND CONTROL

According to some authorities, the insoluble copper exists in Bordeaux mixture in the form of hydrate: according to others it is also present in the form of basic sulphates and double sulphates of calcium and copper. This work was carried out to determine the conditions of formation of these different compounds and to determine whether alkaline mixtures are free from soluble copper.

It was found that acid mixtures, apart from the free copper sulphate, consist almost entirely of the basic sulphates of copper of green colour to the exclusion of the hydrates of copper, whatever their mode of preparation. The precipitate has no immediate action on neutral solutions of ferrous sulphate.

Further, experimenting with exactly determined equal proportions of copper sulphate and lime, it is possible to produce two alkaline mixtures absolutely different, one being blue and the other green. On adding an excess of lime to a solution of copper, the blue hydrates or green basic sulphates of copper are produced according to the rapidity whith which the lime is poured in. When hydrates are formed, they consist chiefly of the stable hydrate of Péligot.

The quantity of copper in solution in blue alkaline mixtures, valued as sulphate, may reach 23 gms. per hl., but it diminishes on keeping. Besides the copper thrown out of solution, green alkaline mixtures contain both lime and copper compounds in solution; the proportion of copper valued as sulphate reaches 41 gms. per hl. but diminishes on keeping.

It follows that alkaline mixtures, contrary to the general opinion, always contain some copper in soluble form; and this amounts to about 2000 to 4000 times the amount required to prevent the germination of the spores of *Plasmopara viticola*. Consequently the objections to this mixture are unjustifiable.

1070 - **Potato Diseases in Victoria, Australia.** — BRITTLEBANK, C. C., in *The Journal of the Department of Agriculture of Victoria, Australia*, Vol. XII, Part 7, pp. 400-403. Melbourne, 1914.

BACTERIAL AND FUNGOID DISEASES OF VARIOUS CROPS

Since 1911, Victoria has, so far, been fortunate in not having to record any of the more serious diseases affecting potatoes in Europe and other countries. The only new disease, and one possibly of minor importance, is that commonly known as " dry scab " (*Spondylocladium atrovirens* Harz). Neither the " corky or powdery scab " (*Spongospora subterranea* [Wallr.] Johnson) nor " black wart disease " (*Synchytrium endobioticum* Percival) has yet made its appearance in this country. The former has, however, been detected in two separate shipments of potatoes from Europe, both being confiscated and destroyed.

From the serious nature of these diseases it would be as well, before too late, to prohibit totally and absolutely the importation of potatoes into Victoria from countries beyond the Commonwealth. Varieties suitable to the climate could be raised within the State, from seed either im-

ported from abroad or raised here. By adopting this course the danger of introducing either of the above diseases would be minimised.

During the past three years, examination of the consignments of potatoes from various countries, revealed the universally diseased condition of the tubers. Not a single consignment was free from disease. The following diseases were found to occur in one shipment alone: *Spongospora subterranea* (Wallr.) Johnson, *Phytopthora infestans* De Bary, *Rhizoctonia Solani* Kühn, *Spondylocladium atro-virens* Harz, *Fusarium oxysporum* Schlecht., *Oospora Scabies* Thaxt., *Bacillus Solanacearum* E. F. Smith.

1071 – **Fungus Diseases of Hevea in the Belgian Congo.** — VERMOESEN, in *Bulletin agricole du Congo belge*, Vol V, No. 2, pp. 312-321. Brussels, 1914.

During a stay at Bakusu, Coquilhatville, in the Belgian Congo, in January 1914, the writer examined the Hevea plantations for fungus diseases.

Only a single case of root-disease was found; probably the freedom from disease of the roots was due to the plantations being on a deep, well drained, sandy soil, as well as to the fact that the land was almost wholly cleared of trunks and stumps, which favour the spread of *Fomes semitostus* and other root parasites: it should be noted that this *Fomes* was found on two stumps.

The "die-back" disease of branches and trunk is very widespread at Bakusu. In the nurseries the damage is slight, only the tips of the branches being attacked generally, though in exceptional cases the main stem may be killed. The worst damage is just after planting out, when many trees succumb. In older plantations it is chiefly the younger branches which are attacked, the result being weakening of the tree.

The disease normally appears at the tips of the green branches, from which it works its way towards the base of the stem. On the bark appears a pale brown patch bounded by a sharp line, while the wood turns blackish grey. The infection often stops when it reaches the junction with a larger branch and almost always at the trunk. On old branches the disease is recognized by the loss of the leaves, in conjunction with the change of colour of the wood. The fruiting-bodies of the fungus causing the disease also appear: it is probably referable to *Diplodia cacaoicola*, which attacks Hevea, cacao, etc., in various tropical countries.

A few other parasites of no practical importance were noted, *viz.* a fungus near *Hypocrella* and an alga (*Cephaleuros*) on the leaves, and *Glocosporium* sp. and a fungus belonging to the Hysteriaceae on the twigs.

Root-disease should be combated by burning all wood infected by *Fomes semitostus*, as well as stumps and dead branches Care should be taken not to spread infected earth about, and after an infected tree has been removed the earth should be turned over to expose it well to the sun; lime may be added if obtainable; in any case fresh trees should not be planted for five or six months.

"Die-back" may be dealt with by spraying the young trees in the nursery with Bordeaux mixture; infected twigs or trees should at once be burnt. Older plantations should be gone over at least every two months to cut out infected wood. Vegetable tar should be applied to all wounds.

1072 – **Fungus Diseases of Cacao in the Mayumbe, Belgian Congo.** — VERMOESEN in *Bulletin agricole du Congo Belge*, Vol. V, No. 1, pp. 186-202, figs. Brussels, 1914.

These diseases are divided into four groups :

a). *Root diseases.* — They are very rare, only two or three very doubtful cases having been observed. This may be attributed to the resistance to root-diseases possessed by cacao and the fact that the first cacao plantaitons in the Mayumbe have been made on partially cleared forest land in which the trees were not all cut down, so that the soil is not covered with numerous trunks and dead stumps which favour the development of root parasites.

b). *Trunk disease.* — The chief external symptoms are a yellowing and sudden and simultaneous drying of all the leaves and twigs of the bush. Very often the disease spreads to the roots. On removing the bark of a diseased tree large blackish spots are seen ; these extend irregularly, but chiefly in a longitudinal direction and on the death of the tree more or less completely surround the trunk. The diseased condition of the wood extends inwards to a variable depth (up to 1 ½ inches). It does not necessarily extend completely round the trunk at a given height, but extends for the whole length of the tree in the form of irregular spots which collectively extend round the circumference of the trunk. Further examination of the surface of a stripped tree during the early stages of the attack (*i.e.* on the yellowing of the leaves) shows the presence of small galleries produced by insects and corresponding to the position of the spots. These insects attack healthy vigorous trees independently of the fungus, and they are always present on diseased cacao plants, even during the last stages of the disease.

If a diseased tree is left in a damp shady place for a few days the characteristic spores of a *Diplodia*, probably *D. cacaoicola*, appear in large quantities on the trunk and branches. Microscopical sections of the black spots show the presence of myriads of hyphae of a brown mycelium to which the black discoloration of the diseased areas is due.

It is more than probable that the above-mentioned insects become infected with the viscid *Diplodia* spores which are so abundant on the dead branches, decomposing fruits and especially refuse pods, and introduce them into their galleries in the bark of the tree, thus causing infection.

To control this disease the writer recommends in the first place that all diseased trees should be cut to the surface of the ground without delay, on the appearance of the first symptoms of the disease ; then the cut surfaces should be coated with a layer of vegetable tar. Attention should be given to the clearing up of all rubbish, such as dead or useless trees in the plantations. Where it is not practicable to burn the empty cocoa pods they should be buried with lime.

c). *Diseases of the branches.* — Canker disease is caused by the punctures of *Sahlbergella singularis* (Hemiptera). " Red rust " is due to an alga, *Cephaleuros virescens*, which causes the premature fall of most of the leaves, and is especially prevalent in situations exposed to the sun. There are also other less serious diseases of the branches and leaves.

d). *Diseases of the fruits.* — There are several different kinds of rot caused by *Phytophthora Faberi*, *Diplodia cacaoicola*, or an undetermined *Colletotrichum* : the latter fungus develops more rapidly on fruits attacked by *Sahlbergella singularis*.

1073 – **Damage caused by *Marssonia Rosae*, in the Roseries near Lyons.** — CHIFFLOT, in *Comptes Rendus hebdomadaires des Séances de l'Académie des Sciences*, 1914, 2nd Half-year, Vol. 159, No. 4, pp. 336-338. Paris, 1914.

As a result of observations of rose gardens in the Lyons district, valuable contributions to our knowledge of *Marssonia Rosae* (Bon.) Br. et Cav. (Melanconiaceae) have been obtained, and it has been realised that this fungus is a more serious pest than was formerly believed.

Not only is the leaf-blade liable to attack as early as June, but also the petiole, stipules and stem are liable to be attacked by the fungus. Further, the disease appears towards the end of September on the flowers, beginning at the base of the sepals, petals and stamens. Although formerly regarded as a leaf-parasite, this fungus may attack all the aerial organs of the plant, especially in certain less resistant varieties. Further, the mycelium, though generally considered as subcuticular, may penetrate into the parenchyma of the leaves and the woody tissues of the stem. It appears that the mycelium is persistent and that it is possible that budding from infected trees will spread the disease.

Although the fungus is difficult to destroy, it is not impossibe to prevent the attack. Infected leaves should be removed and burnt with all fallen leaves. After pruning, the soil and the branches should be sprayed with either Burgundy or Bordeaux mixture or copper acetate, the latter in the proportion of $^3/_4$ lb. to 1 lb. in 10 gallons of water. The addition of 1 oz. of gelatin previously dissolved in 1 quart of warm water improves the adhesive power of the solution. This treatment has given excellent results near Lyons ; the prevention of defoliation thus obtained is favourable to the ripening of the wood and the formation of fruits.

1074 – **Field Studies on the *Endothia* Canker of Chestnut in New York State.** — RANKIN, W. H., in *Phytopathology*, Vol. 4, No. 4, pp. 233-260, figs. 1-2, plate IX. Baltimore, Md., 1914.

These experiments were conducted in temporary field laboratories located at Highland, New York and Napanoch during 1911-13.

In 1911 the disease was abundantly widespread east of the Hudson river as far north as Albany and made the greatest ravages along the state line between New York and Connecticut. West of the Hudson River the disease had not advanced as far north. In Albany County the disease was only general in the southern part. A few spot infections were found in southern Delaware County along the Delaware and Susquehanna Rivers. One spot infection was found at Masonville, Delaware County, and was destroyed. No infections were known west of this region in 1911.

In 1913 the strip along the Delaware River was found to be abundantly affected where previously only isolated spots were found. The disease does not appear to be spreading as rapidly north as west and no infections were found in Otsego County.

In the inoculation of lenticels, glass rings were fixed to the branches with grafting wax so as to maintain a proper humidity for spore germination on the bark. The enclosed bark was then sprayed with a suspension of ascospores in water and the ring sealed with a coverglass. Eleven such inoculations were made and in no case was infection accomplished, whilst every case of wound inoculation produced cankers.

Attempts to obtain inoculation through natural cracks in the bark were also unsuccessful. It is therefore reasonable to conclude that the fungus is not able to penetrate healthy tissue as single hyphae, but when sufficient dead tissue is present to afford the fungus a chance to form the mycelial fans it invades the living tissues.

Mycelium from pure cultures, bits of affected bark, conidial sporehorns, pycnidia from wood, and conidia and ascospores suspended in water, were all capable of producing infection when introduced into open wounds in the bark.

The fact that infection cannot be obtained in old wounds such as insect tunnels is unexplained as yet. Possibly partial callus development and suberisation of the exposed tissue accounts for it.

As a general rule the primary infection of healthy trees takes place in the smaller branches and usually in limbs towards the top or outside of the crown where they are more or less exposed.

Numerous inoculation experiments have shown that two and three year old branches remain susceptible to the disease throughout their growing period, whilst first year shoots are immune during the spring and are only exposed to infection during the summer.

No infection is possible through the midribs of the leaves. No difference in susceptibility between young and old bark was noticeable, except in the case of the present year's growth during the spring, nor was any seasonal variation observed in the degree of suceptibility. Cessation of the growth of the mycelium in the bark during winter, as well as negative results of inoculation at this time of the year, is explained purely on the basis that the temperature is too low for the vegetative activity of the fungus. The healthiest and most vigorous trees are as susceptible as the slow growing, half-dead or otherwise injured trees. Drought and cold do not appear to affect the tree's resistance to the disease and there does not appear to be any relation between the water content of the bark and the rate of growth of the mycelium. Such variations as occur may be explained by other environmental factors, mainly temperature.

Of morphological interest is the development of a form of pycnidium without stroma which is often found on the wood beneath the loosened bark and on the cut ends of stumps and logs.

Other morphological characters of the fungus and the ejection of spores are also dealt with.

1075 – **Two New Wood-destroying Fungi: *Fomes putearius* and *Trametes setosus*.** — WEIR, JAMES R., in *Journal of Agricultural Research*, Vol. II, No. 2, pp. 163-167, plates IX-X. Washington, D. C., 1914.

The writers gives the systematic description of two new Polyporaceae *Fomes putearius* and *Trametes setosus*. The former is closely related to *Fomes conchatus* (Pers.), which is always found on the wood of deciduous trees, especially oaks and willows (*Salix* spp.), and which has not yet been reported on wood of conifers nor been collected in the West. Several collections at hand from southern Germany are all on the wood of broad leaved trees. *Fomes putearius*, on the other hand, always occurs on coniferous wood: *Pinus ponderosa*, *Pseudotsuga taxifolia*, *Picea Engelmanni* with a preference for larch (*Larix* spp.). The rot produced is one of the most conspicuous found in the northwestern forests and is similar to that produced by *Trametes pini* Fries., but the reduction of lignin is on a much greater scale. The fungus was first collected in the Kaniksu National Forest, near Priest River, Idaho. It is distributed throughout the Northwest and is most abundant in the white pine zone.

Trametes setosus is chiefly parasitic on *Pinus monticola* and occurs occasionally on the wood of other trees, but always on conifers. *Polyporus gilvus* Fr., which seems to be the nearest relative and is usually found on the wood of deciduous trees, has not been collected in the West. *T. setosus*, on account of its abundance, causes serious damage to fallen merchantable timber in forest-fire areas. The chemical action of the mycelium on the wood is to reduce the lignin principally in the spring wood, leaving a cellulose ring alternating with sound autumn wood, which causes the annual rings to separate. It was also first obtained in the above-mentioned forest of Idaho and it is distributed throughout the white pine (*Pinus monticola*) belt of the Northwest; specimens have been collected in all the principal forest areas from Vancouver, B. C., to Montana.

INSECT PESTS.

GENERALITIES

1076 – **The Life Cycle of *Sitona lineata* in Germany.** — MOLZ, E., and SCHRÖDER, D., in *Zeitschrift für wissenschaftliche Insektenbiologie*, Vol. X, Part 8-9, pp. 273-275. Berlin-Schöneberg, 1914.

The pea-weevil (*Sitona lineata* L.), which is recorded as particularly injurious in England, should also be classed among the dangerous insects in Germany.

During 1913 the Experimental Station for plant diseases at Halle received notification of 14 occurrences of the insect causing damage by devouring the edges of leaves of leguminous crops; seven outbreaks were on peas, two on beans, two on lucerne, and one each on haricot beans, vetches and clover. One case was also recorded on chicory.

The writers have observed the larvae towards the end of April and the adults towards the end of May. In the open, according to information received, the adults appear in April and May as well as in July and August.

t appears therefore that the beetle is double-brooded in Germany as in England.

In order to reduce the damage in the larval stage which occurs on chicory and beets in April, it is advisable to sow later in districts liable to attacks. Since the larvae begin to pupate at the end of April and beginning of May the larval stage will be almost completed before the plants appear. It is also desirable to make a thicker seeding in the infested areas.

1077 – **The Preparation of Lime-Sulphur Solution.** — *The Agricultural Gazette of Tasmania*, Vol. XXII, No. 7, pp. 255-257. Hobart, 1914.

The Sub-Committee on Fruit-Culture of the Department of Agriculture of Tasmania, after careful examination, recommends the following formula for concentrated lime-sulphur solution (in parts by weight): 50 pure lime, 100 pure sulphur, 500 water. (1) They also recommend dilutions of 1 in 7 (about 14 per cent.) for winter spraying of fruit-trees, 1 in 28 (about 3½ per cent.) for summer spraying of deciduous trees, and 1 in 20 (5 per cent.) for citrus trees (2).

MEANS OF PREVENTION AND CONTROL

1078 – **The Practical Efficiency of Food Traps in the Control of Vine Moths (*Conchylis ambiguella* and *Polychrosis botrana*), and the Presence of the Vine Pyralid (*Oenophthira pilleriana*) in Piedmont.** (3) — Topi, M., in *Rendiconti delle sedute della Reale Accademia dei Lincei, Classe di scienze fisiche, matematiche e naturali*, 1914, 2nd Half-year, Vol. XXIII, Part I, pp. 15-18. Rome, 1914.

Attempts to catch the moths of *Conchylis* and *Polychrosis* in the spring time by means of vessels containing a fermenting sugary liquid made at Alice Bel Colle (prov. Alessandria), had met with little success. The writer therefore repeated his experiments in the summer from July 9 to August 5, placing earthenware vessels containing fermenting liquids at each of the four corners of a vineyard of about an acre in area surrounded by other vineyards; water was added every few days to the pots to make up the loss from evaporation.

At the end of this period 10 *Conchylis*, 73 *Polychrosis* and many other insects, including 2 *Oenophthira*, were caught in the liquid. This method does not appear to be favourable to trapping the last-named moth, which would probably be more attracted by lamp-traps.

From July 18 to August 11 F. Monticelli experimented with two vessels, one containing strong vinegar diluted with water and the other sweet wine equally diluted; he placed them beside a large vine growing on the espalier system against a wall in the town. All the moths captured belonged to *Polychrosis*; 7 were caught in the vinegar and 20 in the sweet wine. A large number of Hymenoptera were drowned in the liquids, most being in the vinegar.

(1) This is the same as the formula recommended by the Citrus-growing Station of Acireale (Sicily): see No. 753, *B.* April 1912. (*Ed.*).

(2) Cf. No. 753, *B.* April 1912; No. 1245, *B.* Aug. 1912; and No. 317, *B.* April 1913.

(3) See also No. 969, *B.* Oct. 1914. (*Ed.*).

This and recent experiments made in France show that liquids with alcoholic fermentation are the most suitable for the capture of the moths. Considering the small number of insects captured in a district with a large area under vines and the large number of food traps and the expense required to carry out the method effectively, as well as the fact that good results can only be obtained by cooperation of all the growers, the writer does not recommend this as a practical means of control. It is, however, valuable as an indicator of the most suitable time to commence operations with insecticides against the larvae.

In studying the development of the broods, thin active larvae of *Polychrosis* 8 to 9 mm. long and stumpy lazy larvae of *Conchylis* of the same length were found during the beginning of June. The vine was in full flower in the middle of June. As is well known the summer pupation takes place in the most diverse places; the pupae are however, rarely found in the places preferred as a winter refuge, but more frequently in the bunches and in leaves spun up by *Oenophthira*. At the beginning of July, the first adults of the second brood are on the wing; all the adults collected, belonging chiefly to *Polychrosis*, were males; it is therefore certain that in this species the males appear before the females.

Large numbers of larvae of *Oenophthira* were noticed in certain places near Alice Bel Colle, though the damage up to the present has not been very important. This is attributed to the abundance of parasites, especially Tachinids, but it is possible that the moth may become very injurious in certain years.

INSECTS INJURIOUS TO VARIOUS CROPS

1079 – ***Euxesta chavannei* and its Relation to the Sugar Cane Disease caused by *Bacillus Sacchari*, in the Province of Tucuman, Argentine.** — BRÈTHES, JEAN, in *Bulletin de la Société entomologique de France*, 1914, No. 2, pp. 87-88, 1 fig. Paris, 1914.

This article contains a description of the new species *Euxesta chavannei* (Diptera), which, according to the collector M. JEAN CHAVANNE, causes the decomposition of the young shoots of the sugar cane and prepares the way for the entrance of the disease known as " polvillo " caused by *Bacillus Sacchari* Speg.

This species is allied to *E. acuta* Hend. and *E. argentina* Brèthes.

1080 – ***Sahlbergella singularis* and other Pests on Cacao in the Mayumbe, Belgian Congo.** (1) — MAYNÉ, R., and VERMOESEN in *Bulletin Agricole du Congo Belge*, Vol. V, No. 2, pp. 261-281, figs. 110-116. Brussels, 1914.

Sahlbergella singularis Hagl. is the most active and most dangerous pest in cacao plantations in the Mayumbe. It appears in abundance twice a year, *viz.* at the beginning of the rainy season (October-November) and towards the end of this period (April-May). There are also other less numerous broods throughout the rainy season.

This insect is most active at night and the effects of its punctures vary according to the organ attacked. In the case of fruits a small vitreous-look-

(1) See also No. 1072, *B.* Nov. 1914. (*Ed.*).

ing dark green spot appears immediately after the insect has made the puncture ; this spot then becomes surrounded by an opaque border of a brownish red colour, which gradually spreads over the spot ; the surface then becomes depressed, and as the spot develops the edges take on a pale orange colour, while the centre turns black.

The damaged tissues grow more slowly than the surrounding healthy tissue, producing cracks, which are soon invaded by fungi or insects, which may produce complete rotting of the fruit or cankers.

On the green branches the spots are at first like those on the fruits ; in general they are elongated and much depressed ; frequently the tip of the shoot dies.

On the lignified branches the punctures develop into longitudinal fissures, which become more numerous as the branch grows and expose the woody vessels. These wounds may soon heal of themselves, or they may extend round the branch owing to successive attacks of the insect or to the intervention of other insects or fungi.

If the attack is serious, the trees gradually lose their leaves and also the greater part of their lateral branches. Sometimes even the larger branches dry up completely.

Other Hemiptera causing similar cankers are : *Helopeltis* sp. (on the fruits and rarely on the twigs) ; *Atelocera serrata* Westw. (common on the twigs) and two undetermined species (rarely on the fruits).

The fungi which cause the rotting of wounded fruits are : *Phytophthora Faberi* Maubl. (at present rare), *Colletotrichum incarnatum* Zimm. and *Diplodia cacaoicola* ; on decomposing fruits two species of *Nectria* have also been observed, one allied to *N. Bainii* Massee, with *Fusarium* sp., etc. The following have been found on the branches: *Diplodia, Colletotrichum* sp., various undetermined Ascomycetes, and besides *Fusarium* sp. other Hyphomycetes, one of which probably belongs to the genus *Tubercularia*.

A combined wash of Bordeaux mixture and petroleum emulsion is recommended for the control of *Sahlbergella* and the other insects and fungi. The wounds should be dressed with vegetable tar, since coal-tar causes a prolonged sterility of the branches. Burning of twigs, branches and dead bushes lying in the plantations is also recommended.

1081 – **Insects injurious to Tobacco in Hawaii.** — Fullaway, D. T., in *Hawaii Agricultural Experiment Station, Bulletin* No. 34, pp. 20 + 9 figs. Washington, 1914.

An account of the principal insect pests of tobacco in Hawaii with reference to their distribution, biology, habits, means of control, natural and artificial, etc.

I. Insects attacking the plant.

a) Caradrina reclusa is the most common of the " cutworms " in these islands and is known locally as " peelua ". This moth was probably introduced a short time ago from Fiji and is now one of the most injurious pests. It is often necessary to replant the crop six or seven times, in spite of the general distribution of poisoned baits and hand picking. Much of the difficulty of the control of the insect is due to the rocky nature of the soil, making it difficult to work. After thorough cultivation of

the soil, the best artificial means of control consists in the spread of poisoned baits amongst the plants (white arsenic or Paris green mixed with moistened and sweetened bran, flour, or middlings). The edges of fields adjacent to uncultivated land are often trenched, so as to present a steep surface on the exposed side which the cutworm cannot climb. Handpicking is sometimes resorted to, but is altogether too slow and expensive. Amongst their natural parasites are : *Frontina archippivora, Chaetogaedia monticola, Ichneumon koebelei, Trichogramma pretiosa* (1) and several birds, which should be protected and increased in number by importation.

b) *Phthorimaea operculella* (2) , or common Gelechiid moth, was first noticed in Hawaii in 1892. The grub (tobacco splitworm) mines the leaves of its host plants, making a broad, flat track through the mesophyll between the upper and lower epidermis, which often becomes badly split and shattered when dry.

It is most injurious to seed-bed plants and considerably retards their growth, so that sturdy seedlings for transplanting are difficult to obtain. This trouble is partly overcome by seeding the beds very thinly and protecting them with cotton netting. The damage on well-conducted plantations is generally confined to the two or three poor soiled lower leaves. In neglected plantations however the disease becomes general.

The grubs can be destroyed by dusting arsenate of lead on the plants in the seed-bed when they are emerging through the epidermis to form new burrows. The arsenic may also be applied as a spray combined with Bordeaux mixture. Under field conditions this treatment is of little value and very expensive. As a precaution against general infestation no solanaceous plants should be grown near the tobacco fields and all solanaceous weeds in the immediate vicinity should be periodically destroyed. The most common parasites of this pest are *Chelonus blackburni* and *Limnerium blackburni.*

c) *Heliothis obsolcta* (3), the tobacco pod-borer, or cotton boll-worm, injures the tobacco plant chiefly by boring the seed pods and to some extent devouring the foliage. In Hawaii it is never found on either corn or cotton and is not generally considered a serious pest of tobacco. It is held in check by topping the plants as soon as the flowers appear, and when seed is desired the flower stalks are enclosed in a bag. Neglected fields always show signs of the borer and if for any reason a field of standing tobacco is abandoned, the plants should be ploughed up and destroyed to avoid a general infestation. The eggs of this moth are probably parasitised by *Trichogramma pretiosa*, though it is not recorded as being actually bred from *Heliothis* eggs in Hawaii. It is possible that it is also attacked by the common tachinid parasites.

d) *Phlegethontius quinquemaculata* (4), or hornworm, is extremely

(1) See also No. 438, *B.* April 1913.

(2) See also No. 1117, *B.* July 1912.

(3) See also No. 2584, *B.* Aug.-Sept.-Oct. 1911 ; No. 627, *B.* June 1913 and No. 1117, *B.* Sept. 1913. (*Ed.*).

(4) See also No. 1118, *B.* Sept. 1913. (*Ed.*).

uncommon and has never been seen by the writer on cultivated tobacco. It is sometimes found near Honolulu on the wild tobacco (*Nicotiana glauca*), which it soon defoliates.

If it were to appear in tobacco fields it could be checked by spraying with lead arsenate (3 lbs. to 100 gallons of water), to which the young larvae are very susceptible. Large worms should be hand picked, as it is difficult to kill them with a stomach poison. Its natural enemies are not known, but there is probably an egg parasite.

e) *Epitrix parvula*, or tobacco flea-beetle, is of recent introduction into Hawaii. Both larvae and adults cause damage, especially the latter, by piercing holes and breaking up the margins of the leaves. It is more common and injurious in neglected plantations, especially in the neighbourhood of other solanaceous plants.

In growing tobacco commercially it is necessary to exercise care and allow no plants to remain after the tobacco has been picked. Other solanaceous crops and weeds in the neighbourhood should be periodically destroyed. When the insect causes damage the affected plants may be sprayed with arsenate of lead, 1 lb. to 20 gallons of water, or half this strength if the arsenate is in paste form.

f) *Minor pests :* the larvae of *Plusia chalcites* and *Amorbia emigratella ; Pseudococcus citri* and *P. virgatus ; Siphanta acuta* and *Pulvinaria psidii ; Elimaea appendiculata* and *Xiphidium varipenne ; Nysius delectus* and *Xyleborus* sp.

II. Insects affecting the stored product.

Lasioderma serricorne, or cigarette beetle, is very injurious and was first observed in Hawaii in 1885. It is generally destroyed by fumigation with carbon disulphide or hydrocyanic-acid gas. This method gives admirable success where the infestation is only incidental and local and the infested material can be placed in a tight compartment so that the full strength of the gases can be utilised. When the infestation becomes general, as in warehouses in which stored products are being continually handled, it is exceedingly difficult to control the beetle. The only means is a systematic fumigation of the whole warehouse from time to time, or different parts of it which can be rendered tight against the diffusion of the gas. It is sometimes a distinct advantage to spray the walls and floors with benzine or kerosene. Manufactured goods are often kept in cold storage to prevent beetle injury, and if not removed too soon the danger of injury after withdrawal is greatly reduced. It has, however, been shown that even low temperatures continued for long periods are not sufficient to destroy the vitality of the eggs. A species of *Pteromalus* has been obtained as a natural parasite of this beetle.

1082 – **Peach Tip Moth injurious to Peaches and other Fruit Trees in New South Wales.** — FROGGATT, WALTER W., in *The Agricultural Gazette of New South Wales*, Vol. XXV, Part 5, pp. 413-414, 3 plates. Sydney, 1914.

Four or five years ago it was noticed in the suburban gardens and in many orchards between Sydney and the mountainous region, that the ends of young branches of peaches and nectarines were attacked by certain small

larvae which pierced one side of the shoots and bored a cavity inside towards the base, causing the drying up of the leaves and the exudation of gum at the tip of the damaged shoot. Sometimes all the branches of the tree were damaged in this manner and an otherwise healthy tree would show tufts of dead leaves at the ends of its branches.

Later developments showed large quantities of the fruits with numerous pustules covered with a gummy secretion under which insects had destroyed the epidermis.

Examination of a few specimens showed the damage to be due to a larva of a small *Tortrix*, which has not yet been identified, but which resembles the codlin moth (*Carpocapsa pomonella*) in its larval and adult forms. The damage to the surface of the fruit is more serious than that to the branches, since large scars are formed on the unripe fruits, which then become unfit for sale.

After describing the life-history, the writer mentions that the larvae cause considerable damage in the neighbourhood of Sydney, not only to peaches, but also to other fruits such as apples and quinces.

As a protection, the peaches should be thoroughly sprayed with arsenate of lead at the beginning of summer and after the appearance of the first damage. In gardens and small orchards straw-banding the trees is recommended.

1083 – **The "Leaf Case Moth" (*Hyalarcta hübneri*) injurious to Fruit Trees in Victoria.** — FRENCH, C. (Junr.), in *The Journal of the Department of Agriculture of Victoria, Australia*, Vol. XII, Part 5, pp. 294-297. Melbourne, 1914.

The "Leaf-Case Moth" has recently been recorded as doing considerable damage to apples, quinces, vines, etc.

The larva has the habit of detaching portions from different fruits, thus rendering a large quantity unserviceable. It also eats the epidermis of the leaves, giving the tree a scorched appearance. The grubs appear to have a distinct preference for the young buds, and since as many as 50 may be present on one tree the damage is considerable. Native trees such as the "tea tree" (*Leptospermum*), eucalyptus and even imported plants (pines and cypress) are attacked with avidity by the pest, though it appears to prefer fruit trees.

The larvae adorn their exterior protective sheath with portions of the leaves upon which they are feeding. If a half-grown larva is transferred to another tree it changes its old covering of leaves for the new leaves.

Another closely allied species, *H. nigrescens* Doubl. (ribbed case or bag moth) causes damage to eucalyptus, but it has not yet been found on fruit trees.

H. hübneri is easily destroyed by means of spraying with arsenate of lead.

1084 – **Insect Pests of Citrus in Ceylon.** — RUTHERFORD, A., in *The Tropical Agriculturist*, Vol. XLIII, No. 1, pp. 49-50. Colombo, July 1914.

The leaf-miner (*Phyllocnistis citrella*) is described in detail. The caterpillar of this Tineid moth mines underneath the upper or the lower epi-

dermis of the young leaves, thus causing them to curl up. The mines also occur underneath the epidermis of the young twigs. The mine often begins near the midrib, runs towards the base of the leaf, where it takes one or two turns, runs alongside the margin and takes one or two turns and then approaches close to where it began. The course of the mine is marked out by a narrow band of brownish frass and the mine itself has a silvery appearance. Not infrequently 4 or 5 caterpillars may be present in a single leaf.

The caterpillars are subject to the attack of small, black Chalcids, which, however, are unable to keep them in check. Were the attack noticed early enough a spraying with tobaco extract might do some good. But it is usually finished before the casual observer's attention is drawn to it. The citrus grower should make himself acquainted with the first symptoms and be on the look out for them.

Sometimes the folded leaves are subsequently tenanted by mealy bugs (*Pseudococcus* sp.), which continue the injury ; but these are less injurious in Ceylon than in many other countries. Here, they are attacked by various enemies, the two chief being the caterpillar of the Lycoenid, *Spalgis epius* West., and a Cecidomyiid (*Diadiplosis coccidivora* Felt.).

A moth very similar to that of the leaf-miner was reared by the writer from leaves of *Melia Azedarach*, but the pupa showed several points of difference.

Other insects that have been observed or recorded recently as doing more or less damage to citrus trees in Ceylon are :

1) *Walkeriana* sp. This large coccid encrusts the stem and branches and is heavily parasitised by an Agromyzid, *Cryptochaetum curtipenne* Knab. The scale is attended by a species of *Cremastogaster*, but the ants do not succeed in deterring the *Cryptochaetum*. 2) *Coccus viridis* Green, or " green bug ". 3) *Lepidosaphes beckii* Newm. infests the fruits and leaves, causing the latter to crumple. 4) *Toxoptera* sp.. an aphis found occasionally on young shoots, but not sufficiently numerous to cause damage. 5) *Tetranychus mytilaspidis* Riley ; a mite closely resembling this occurs on the leaves, causing them to become yellow. 6) *Apogonia comosa* Kav., Melolonthid beetle reported as eating the leaves.

Occasionally, from fruit that has fallen prematurely, small bright-eyed flies emerge. These are Drosophilids, whose habit is to lay their eggs in fermenting material. The fruit falls from some other cause and the flies probably infest it as it lies on the ground.

1085 – ***Otiorrhyncus sulcatus* attacking Vines in the Ile d'Oléron, France.** — RIGOTARD, MARCEL, in *Journal d'Agriculture pratique*, 1914, Vol. II, No. 29, p. 94. Paris, 1914.

The vines in the Ile d'Oléron have been attacked by *Otiorrhynchus sulcatus* F., which appeared for the first time in 1913. The centre of infection is in the communes of Saint-Pierre, Saint-Georges, Dolus and Le Château.

The adult weevil devours the buds and shoots of the vines and the larva feeds on the roots of this and other plants (strawberry, raspberry,

peach, etc.). The damaged roots may succumb to their injuries, and the shoots whose tips are repeatedly damaged are short and knotty and cannot be pruned properly.

Of the various methods of control, the simplest and most efficacious consists in collecting the adults in traps consisting of tufts of grass, moss or dried leaves, exposed at the base of the vines and inspected daily. A local syndicate collected as many as 90 lbs. of insects in two weeks by this method, and it requires about 7 000 insects to weigh 1 lb.

The Forests of Chile.

by

FEDERICO ALBERT,

Inspector General of Forests, Hunting and Fisheries, Santiago.

Of the 185 939 400 acres which constitute the whole area of Chile, 38 907 750 acres are covered with forest. The distribution of the forests is very irregular and is made clearer by dividing them into the following six forest regions:

Region I. — From the northern frontier of the Republic as far as Taltal, including the provinces Tacna, Tarapaca and Antofagasta, of which only from 0.01 to 0.03 per cent of the area (in all 52 000 acres) is wooded. The forests are composed of *Prosopis Tamarugo, Cordia decandra* and other less important species.

Region II. — From Taltal to the river Choapa; this includes the provinces Atacama and Coquimbo, of which only from 0.3 to 2.5 per cent (in all 226 600 acres) consists of forests. The trees here are *Gourliea decorticans, Caesalpinia brevifolia, Porlieria hygrometrica*, etc.

Region III. — From the river Choapa and to the south as far as the Maule. This district includes the provinces Aconcagua, Valparaiso, Santiago, O'Higgins, Colchagua, Curico and Taltal, with a total of 1 732 000 acres of forest; in the first four the forest area does not exceed 5 to 8.5 per cent, while in the last three it may amount to 12 or even 17 per cent. The forests of the first group of provinces contain only *Acacia Cavenia, Bellota Miersii, Quillaja saponaria, Maytenus Boaria, Litrea caustica, Boldoa fragrans, Cryptocarpa Peumus, Drimys Winteri, Prosopis Siliquastrum* and other secondary species, while in those of the three last we already encounter *Nothofagus macrocarpa, N. obliqua* and *N. Dombeyi, Gevuina Avellana, Kageneckia oblonga* and *Libocedrus chilensis*, with other less important species.

Region IV. — From the river Maule to the river Valdivia, including the provinces Linares, Maule, Ñuble, Concepcion, Arauco, Bio-Bio, Malleco, Cautin and a large portion of Valdivia, with a total of 5 700 000 acres of forest ; the percentage reaches from 17.5 to 35.5. The abundance of forests increases in the following order : Valdivia, Bio-Bio, Malleco, Ñuble. As far as the river Bio-Bio, the exploitable timber is furnished by the following species : *Acacia Cavenia, Quillaja saponaria, Maytenus Boaria, Litrea caustica, Boldoa fragrans, Cryptocarpa Peumus, Drimys Winteri, Nothofagus obliqua, N. Dombeyi, Gevuina Avellana, Persea Lingue;* in the south of Bio-Bio, *Acacia Cavenia* and *Quillaja saponaria* are absent, while in addition are found : *Lomatia dentata, Myrceugenia apiculata, Podocarpus andina, Prumnopitys elegans, Araucaria imbricata, Nothofagus procera, Laurelia aromatica, Myrceugenia Luma, Nothofagus Pumilio, Libocedrus tetragona, Myrceugenia Temu, Myrceugenia multiflora,* and other less important species.

Region V. — This extends from the river Valdivia to the peninsula Taitao, including the provinces Valdivia (southern part), Chiloé and Llanguihue, with a total of 11 145 000 acres of forest (40 per cent of the whole area of the region). This region is already outside the range of *Araucaria imbricata, Nothofagus procera* and *Laurelia aromatica,* while *Nothofagus obliqua, Maytenus Boaria, Libocedrus chilensis, Nothofagus Dombeyi, Persea Lingue* and *Podocarpus andina* are not found beyond the Chacao canal ; on the other hand the following begin : *Embothrium coccineum, Caldcluvia paniculata, Weinmannia trichosperma, Sophora tetraptera, Myrceugenia Meli, M. planipes, Tepualia stipularis, Maytenus magellanica, Nothofagus nitida, N. betuloides, Libocedrus tetragona, Fitzroya patagonica, Lauretia serrata, Eucryphia cordifolia, Podocarpus chilina, Lomatia ferruginea* and other species in small numbers,

Region VI. — This comprises all the territory of Magellan as far as Tierra del Fuego, and has some 20 million acres of forest, or about 30 per cent of its area. These forests consist of the trees mentioned as occurring south of the Chacao canal, with the exception of *Nothofagus nitida* and *Lomatia dentata,* but gradually the number of all the trees decreases till there remain only *Nothofagus betuloides* and *Maytenus magellanica* and some species of *Myrceugenia* as stunted shrubs.

From the area of 38 million acres classed as forest, must be deducted : 8 908 200 acres used as pasture, 18 576 950 acres which produce firewood only, and 6 092 180 acres which only supply stakes and small wood ; there therefore remain only 5 002 110 acres which can be exploited for large timber.

A very important fact which merits consideration also is that of these 38 million acres covered with forest, 20 million acres are upon agricultural land, about 7 ½ million acres are under forest that is beginning to grow, or are pasture, or of uncertain classification and only 11 400 000 acres are on true forest land. On the other hand, nearly 10 million acres of true forest land which were formerly wooded are now completely cleared, the greater part being eroded and worn into gullies by rain, so that it will

soon come under the category of waste land. The immoderate deforestation practised for the purpose of obtaining fuel, and the irrational system of cultivating steep slopes liable to slip under the influence of heavy rains, explain the present existence of 153 000 acres of dunes and the want of water for irrigation, drinking purposes, etc., which prevails in the spring and autumn.

The exploitation of the existing forests requires means of transport, *viz.* alteration of river courses, construction of roads and a thorough system of railways. Only concerns with abundance of capital (which latter is lacking in our country) could undertake such operations, all the more as the State does not possess the necessary funds to carry out the work at its own expense. Wealthy foreign capitalists are therefore required in Chile, where they will find an extensive and lucrative field for the development of their trade.

Generally wood in Chile is sold green as soon as it has been felled; it is badly worked, or hastily piled up, so that it arrives on the market warped, cracked and out of shape.

There are only a few firms which have drying apparatus and it is necessary to encourage and increase such plant, in order that the wood may be exported in the best condition possible. The consumption of the country is not sufficient to absorb the enormous amount which should be produced by the forests in the next few years. The export of wood should be based upon transport by sailing ships, which is more economical than transport by steamers, all the more, seeing that at present there are no means of lowering steam freights, which are very high, amounting to from 30 to 35 shillings per cubic metre (35 cu. ft.) from Chile to Europe.

The two first forest regions were exclusively engaged in importing, but they are now beginning to export pods of *Prosopis Siliquastrum*, which contain from 35 to 50 per cent. of tannin; they give a tawny yellow colour to leather and render it supple. *Cordia decandra*, already rather a rare tree, yields a yellowish brown wood with pretty black markings and is used for ornamental veneering. The wood of *Porlieria hygrometrica* can be used for engraving.

The third forest region also has to import wood; it furnishes the bark of *Quillaja saponaria*, which contains from 15 to 25 per cent of saponin and is largely exported. For furniture making are used the wood of *Bellota Miersii*, *Maytenus Boaria* and *Drymis Winteri*, while the wood of *Prosopis Siliquastrum* is used by the cabinet-maker and enlayer; it resembles that of *Cordia decandra*, but is already very rare. *Acacia Cavenia* might be used for ornamental purposes, but is generally burnt for charcoal or used as firewood or by the wheelwright; the same applies to the wood of *Litrea caustica* and *Prosopis Siliquastrum*. The leaves of *Boldoa fragrans*, and its extract, the well-known *boldoina*, a remedy for diseases of the liver, the urinal and digestive systems and also for internal parasites, should be important articles of export. The present stock of *Nothofagus obliqua*, *N. macrocarpa* and *Libocedrus* no longer suffices for the most pressing needs of the district.

The fourth forest region, in its part to the north of the river Bio-Bio, only exports *Quillaja saponaria* bark, for it does not produce sufficient wood for cabinet-making even to supply its own requirements, and is obliged to obtain it from the provinces south of this river. These, which are usually called " La Frontera ", possess the richest forests of the Republic.

In the first place we may mention as growing there : *Nothofagus obliqua*, yielding a dark red wood, hard and heavy, which lasts for 25 years and more in the ground, and is more resistant than that of most pines and is much used for beams, planks, wharves and piles.

Nothofagus Dombeyi, when its heartwood is of a dark red colour, shot with pale reddish or greenish hues, is as durable as *N. obliqua* and a little harder ; in the trade the two timbers are confused. The pink *Nothofagus Dombeyi* does not last long, while the white form, which covers large tracts of country, could, owing to its low price, be used advantageously in the chemical manufacture of cellulose, but its lack of durability renders it of doubtful value in the mechanical process where cylinders are used.

The wood of *Nothofagus procera*, which is dark red with a slight violet reflection, is a little less hard than that of *N. obliqua* ; it is durable, easy to work and polish, does not break and is the material most used in the interiors of houses. On account of its good qualities, it is difficult to find a substitute. Doors, furniture and windows of this wood last indefinitely; it is also much used for small casks for ordinary wines and in cooperage generally. It is perhaps the best wood for the above-mentioned purposes.

The wood of *Laurelia aromatica* is of an ashy yellow colour, sometimes with dark spots or lines ; it warps and is not very durable in damp, but is much used, and with good results, for the interiors of houses and for furniture.

Persea Lingue wood is reddish, pinkish, or yellowish, sometimes with pretty dark rays. It is heavy, hard, elastic and fibrous and adapted to all purposes. As it retains dyes well, this product is used in the imitation of " nogal ", " caoba ", etc., and is with good reason much appreciated in the country.

The wood of *Podocarpus andina* is of a lemon-yellow colour, less hard and more supple than the preceding products, and is used in the interior of houses both by the joiner and the carpenter. It is not very plentiful.

Libocedrus wood is yellowish white with pale brown rays, a little reddish in the centre ; it is supple, elastic, fibrous, perfumed, does not decay and is used for all kinds of building, furniture, carpentry, beams, posts, props, etc. It is much appreciated in the country, but difficult to exploit, because it grows on slopes far from all means of transport.

Myrceugenia Luma yields a dark red, heavy, very hard, elastic wood, which does not decay and is most suitable for wheelwright's and carpenter's work, especially in the making of poles, wheel spokes, stakes, etc.

The wood of *Araucaria imbricata* is whitish, a little yellowish, supple, hard and durable ; it is employed for all kinds of structures, furniture, posts, and even beams, but as the tree grows on the summits of distant

mountains it has only lately begun to be exploited. The seeds of this tree serve as an article of food for the peasantry during much of the year.

The following would be very valuable woods for furniture, veneers, flooring, etc., both in Chile and abroad: *Gevuina Avellana*, *Lomatia dentata*, *Prumnopitys elegans* and *Drimys Winteri*; but, on account of the fashion of using foreign products, these will not be appreciated at home as they should, until the appreciation of the exported timber shows that we have not rightly valued our national riches.

The barks of *Persea Lingue* and of *Drimys Winteri* are decidedly important, and might be even more so; these are richest in tannin (15 to 30 per cent) when they are thinnest, and are stripped from the trees at the end of winter or in early spring. This bark is the best adapted for tanning leather for soles.

The fifth forest region, in spite of its abundant forests, imports some timber of *Nothofagus obliqua*, *N. procera* and *Persea Lingue* from the fourth region, as well as *Weinmannia trichosperma*, *Caldcluvia paniculata*, *Sophora tetraptera*, *Myrceugenia Meli*, *Tepualia stipularis*, *Eucryphia cordifolia* and *Laurelia*. The other species are not yet well enough studied and known, and are of less industrial importance.

The wood of *Fitzroya patagonica* is light red or reddish brown; it is very elastic and soft, but firm, fibrous and almost without knots; it does not decay, is easy to cut, and does not warp or split. It is used for all kinds of work: furniture-making, carpentry, cooperage, musical instruments, packing-cases, and especially for building in the south, as well as for sheds, partitions and roofs; it is also exported abroad, This wood is much appreciated, but cannot be sufficiently exploited on account of the difficulties of transporting the giant trees from their habitat in the high mountains.

Libocedrus tetragona and *Podocarpus andina* of the south replace by the quality of their wood the similar species which are found further north.

Nothofagus nitidus and *N. betuloides* cannot in the same way replace *N. obliqua* of La Frontera, with which they have nothing in common but their popular name, for their wood rots, splits, warps and spoils. In the same way, *Laurelia serrata* cannot replace the Frontera "laurel", for, in addition to other defects, it is less durable and has a strong smell.

The wood of *Eucryphia cordifolia* is dark reddish, hard, heavy, resistant, does not decay in water, but rots when in contact with the soil. It is used in houses for carpentry, joinery, cabinet-making; also, with varying results, for the piles of quays and for props, stakes, wheelwright's work, etc. The bark of this tree gives a hard leather and contains as much tannic acid as that of *Persea Lingue*, or more.

For flooring and high-class furniture the following woods can be used: *Lomatia ferruginea*, *Embothrium*, *Sophora*, *Tepualia*; as well as others which have been mentioned above, such as *Gevuina*, *Lomatia dentata*, *Drimys*.

Good beams can be made from the wood of *Caldcluvia* and *Weinmannia*, and posts from the latter as well as from *Sophora*, *Myrceugenia Meli* and *Tepualia*; while *Prumnopitys*, *Gevuina*, *Embothrium*, *Myrceugenia*

planipes, M. multiflora and *Maytenus* are used in carpentry, and *Myrce*
genia Meli, Persea and *Sophora* for carts and wheelwright's work; the ra
"curam" more or less replaces *Nothofagus procera* for these purpose
Good charcoal can be obtained from *Myrceugenia Luma, Caldcluvia, Wei*
mannia, Sophora, Myrceugenia Meli, Tepualia and *Eucryphia*; the tw
latter are used by preference for building timber.

All this would be very satisfactory, were it not that the least usef
species are the most plentiful and grow largest, while the most useful a
the rarest and smallest, with the exception of *Myrceugenia Luma* an
M. Meli: these are fairly plentiful and form from 6 to 9 per cent of th
forest trees, while the other species only amount to 0.5 or at most 2 pe
cent of the whole.

The sixth forest region already imports much more timber of *Noth*
fagus obliqua, N. procera and *Persea* than the fifth region, although it figure
as possessing half the forests of the Republic; it also takes from the fift
forest region small quantities of the wood of *Libocedrus, Fitzroya, Wei*
mannia, Caldcluvia, Myrceugenia Meli, Tepualia and other trees, though
possesses the same species; this is owing to the want of means of commun
cation, and to the fact that the trees decrease in size and become mor
irregular as they approach the south and gradually disappear.

There is a large field for exploitation and trade in the native timber tree
which make up about 40 per cent of the forests in Magellan, but it mus
be borne in mind that lack of means of transport, the steepness of the land
the many new species unknown in the wood trade, and the present an
future high freights necessitate that the exploitation of these nationa
riches should be undertaken by large firms.

The study of Chilian timbers shows that there are very few soft, suppl
kinds like *Fitzroya* and *Libocedrus*, but that, on the contrary, hard heav
species abound; further, there is no substitute for oak for making cask
for fine wines. This accounts for the importation, in 1912, of 1 ½ millio
cubic feet of pine wood (chiefly Oregon pine, *Pinus taxifolia*) to the tota
value of £ 160 000, of which 91 per cent came from the United State
and only 9 per cent from Europe. The same thing occurs in the cas
of oak staves, of which 1500 tons, worth £ 8000, are imported, while th
value of the exported wood is only £ 23 000. With good managemen
and administration, the value of these exports might amount to nearly
million sterling, and be a source of considerable revenue to the country

Attempts are being made to supply the want of soft wood in Chile b
planting rows of poplars, but their wood will never adequately repla
deal for general use.

Plantations of pines on a large scale have only been made by son
coal-mine proprietors, as at Lota and Curanilahue, while small plantin
have been made by some of the more progressive landowners. The tre
planted by the State on the dunes of Chanco are a mere drop in the bucke
as far as the present needs of the country are concerned and afford n
adequate provision for future requirements. Nearly all the plantation
consist of poplars (usually *Populus nigra*), *Pinus insignis* or *Eucalypt*

obulus, as rapid production is preferred to quality, to the exclusion of rees yielding good wood such as: *Pinus canariensis* and *P. maritima*, *ucalyptus diversicolor* and *E. resinifera*, *Cupressus macrocarpa* and *C. to-ulosa*, *Acacia melanoxylon*, *Quercus pedunculata*, *Picea excelsa*, *Pinus onderosa* and *P. mitis*, *Abies*, *Picea*, *Larix*, etc. It would be well worth hile to organise also in Chile syndicates, and national and foreign societies ell provided with capital, which could turn their attention to the pre-ervation, good exploitation and re-planting of the forest land of the Re-ublic, taking as a basis the best native species, and at the same time plant-ng such exotic trees as are acclimatised and grow even better in Chile han in their original habitat.

The want of foresight as regards the preservation, exploitation and lantation of forests is such, that any firm undertaking this work on a erious basis, can be assured of the future of its industry, all the more, s no one in the country thinks of future needs, and scarcely even considers resent necessities.

List of the trees mentioned above with their local names.

Acacia Cavenia	espino comun.
Araucaria imbricata	araucaria, piñon.
Bellota Miersii	belloto.
Boldoa fragrans	boldo.
Caesalpina brevifolia	algarrobo.
Caldcluvia paniculata	tiaca.
Cordia decandra	carbon.
Cryptocarya Peumus	peumo.
Drimys Winteri	canelo.
Embothrium coccineum	ciruelillo.
Eucryphia cordifolia	ulmo, muermo.
Fitzroya patagonica	alerce.
Gevuina Avellana	avellano.
Gourliea decorticans	chañar.
Kageneckia obliqua	bollen.
Laurelia aromatica	laurela.
„ *serrata*	huahuan, laurela.
Libocedrus chilensis	cipres.
„ *tetragona*	cipres de Guaitecas.
Litrea caustica	litre
Lomatia dentata	radal.
„ *ferruginea*	huinque.
Maytenus Boaria	maiten.
„ *magellanica*	m. de Magellanes.
Myrceugenia apiculata	arrayan.
„ *Luma*	luma.
„ *Meli*	melí.
„ *multiflora*	pitra.
„ *planipes*	peta.
„ *Temu*	temu.
Nothofagus betuloides	roble de Magellanes.
„ *Dombeyi*	coihue.
„ *macrocarpa*	roble de Colchagua.
„ *nitida*	r. de Chiloé.
„ *obliqua*	roble pellin.
„ *procera*	rauli.
„ *Pumilio*	nirre.
Persea Lingue	lingue.
Podocarpus andina	mañiu.
„ *chilina*	mañiu.
Porlieria hygrometrica	guayacan.
Prosopis Siliquastrum	algarrobo.
„ *Tamarugo*	tamarugo.
Prumnopsitys elegans	lleugue.
Quillaja saponaria	quillai.
Sophora tetraptera	pelù.
Tepualia stipularis	tepù.
Weimannia trichosperma	teñiu.

The Development of the Dairy Industry in Hungary (1).

by

Dr. ISTVÁN KOERFER,

Chief of the Dairying Section of the Hungarian Ministry of Agriculture, Budapest.

Of late years the Hungarian dairy industry has altered its aims. Formerly it dealt chiefly with the various methods of utilizing the milk that was produced, whilst at present, without giving up its old principles, it seeks to increase the yield of milk itself.

According to the last census, Hungary possessed 2 800 000 cows which yielded about 808 million gallons of milk; at a price of 5.9 *d* per gallon, this represents a value of £ 19 867 700. For this estimate we have taken as basis the average yield of each of the breeds as shown in Table I.

TABLE I. — *Average yearly yield of the various breeds.*

Breeds	Head	Average yearly yield	
		Per cow, gals.	Total, gals.
Hungarian	630 000	198	124 740 00
Red spotted:			
Simmental & Pinzgau	1 700 000	330	561 000 00
Gray Alpine	90 000	396	35 640 00
Other breeds	290 000	242	70 400 00
Buffaloes	90 000	176	15 840 00
Total	2 800 000	—	807 620 00

In 1913 the value of the exports was as follows :

	£
Milk	443 034
Butter	206 571
Cheese	88 390
Total	797 995

The milk and its products were exported to the following countries: Austria, Bosnia-Herzegovina, Germany, Switzerland, Italy, Netherlands, Rumania, Serbia, Bulgaria, Albania, Greece, Turkey in Europe and in Asia, Egypt, United Kingdom, Russia and United States.

(1) See No. 678, *B.* July 1914 (*Ed.*).

The total exportation of milk, butter, cheese and condensed milk corresponds to 36 029 532 gallons of milk. Comparing these figures with the 807 620 000 gallons of milk produced and mentioned above, it will be seen that our exportation of milk represents 4.46 per cent of the total production.

During the closing years of the nineteenth century there were still many communes in Hungary in which milk could not be disposed of at anything like profitable prices. This fact induced the Ministry of Agriculture to favour the institution of cooperative rural dairies. These were at first rather collecting centres than real dairies, the cream being taken to the central dairies and the skimmed milk sent back to the members. Created by two joint stock companies, the central dairies are under the control of the State, which subventions them. They produce butter of the highest quality, much appreciated at home and abroad. The first central dairy was opened at Temesvár in 1899 and the next year others were founded at Dombrovár, Veszprém and Szabadka.

Three or four years after the organisation of these dairies, a certain number of the cooperative creameries, especially the larger ones, were no longer satisfied with the sale of milk but started the manufacture of butter on their own account. At first this new departure proved very remunerative, especially when, owing to the foot-and-mouth disease and the lack of fodder, the yield of milk diminished considerably, both in Hungary and in the neighbouring countries. Nevertheless the foot-and-mouth disease which raged in 1912 revealed clearly that the recent efforts of the cooperative dairies had not yielded good results.

Since 1906 it has been a constant struggle, every year in one part or another of the country, sometimes against the drought and the shortage of fodder, at other times agaist floods or foot-and-mouth disease. It was natural that these adverse circumstances should lead to an increase in the prices of milk and butter, which in its turn caused the butter from the Hungarian dairies, which until then had been for the most part in demand on the Austrian markets, to be gradually ousted by Danish butter, which was preferred for both its price and its quality. The cooperative dairies suffered great losses and at present a number of them have given up making butter and limit their activity to the collecting and carrying of cream. They have thus led to the creation of three new central butter dairies in three counties. The management of these butter dairies has recognized that in order to improve the quality of Hungarian butter it was necessary to adopt all the measures suggested by the progress in science and technique, and since then the cream has been pasteurized and pure culture starters have been used.

Cooperative dairies do not develop to the extent that would be desirable for the progress of the Hungarian dairy interest. This is to be attributed to the fact that in some parts of the country the small farmer is not convinced of the utility of cooperative dairies. More than once it has happened that small farmers have abandoned the cooperative dairy if in the same commune some dealer has paid a fraction of a penny more for their milk. Still, the commercial spirit of our small farmers is awakening,

and I hope that the principle of cooperation will gradually gain ground among the producers of milk.

As for the production of our cooperative dairies, the following data are available. Since 1897 cooperative dairies have been founded in greater numbers; in that year 34 cooperative dairies with 5937 shares produced 420 759 lbs. of butter; their receipts amounted to £ 22 470. At the end of 1913, 573 cooperative dairies were in full activity; they turned out 4 730 000 lbs. of butter and their total trade amounted to £ 418 150.

The new tendency is to increase the milk yield of our cows, which has been judged insufficient. The average yearly yield of the country corresponds to 308 gals. per cow. Comparing these figures with the results obtained in the States of Western Europe, it must be recognized that there is still much margin for improvement in the production of milk in Hungary. The returns of the dairy industry in the States of Western and Northern Europe are twice as great, in Holland even two and a half times as great, as in our country.

With a view to increasing the production, milk record associations have been organized. The field of their activity is in the county agricultural societies, where they act as sections for cattle breeding or milk recording.

At present milk recording is carried out in 17 societies, in 36 districts, in which 17 000 cows belonging to 635 owners are submitted to methodical control. In one district to which the neighbouring herds are admitted, one inspector records the performance of about 500 cows. The inspectors follow a three months course of instruction in milk control, which is held in one of the dairy schools and to which only pupils who have attended a dairy school of the country and who are aquainted with the practice of dairying are admitted. In each county agricultural society, the section of milk records registers the controlled animals in a local herdbook, and the cows whose yield attains at least 660 gals. during one lactation are also admitted to entry in the national herdbook. In order to defray part of the expenses entailed by the milk control, as well as the salary of the inspector, etc., the societies or control sections receive in the course of three years, a subvention of 2000 crowns (£ 83 6*s* 8*d*) per annum from the Government. The work of the record societies is under the supervision of the Ministry of Agriculture, whose dairy section revises the results sent in by the milk inspectors. The milk record societies held last year their first national conference, at which a proposal was made to found a central milk recording station as soon as milk recording has been instituted in fifty districts. The duty of this station will be to control the work of the sections.

The record associations are very important in Hungary from the point of view of the increase of the production of milk. The experience gained in the country and abroad shows that the average yield of each cow subjected to record increases by 44 gals. during the very first year. Thus, if only 5 per cent of the stock of cows, or 140 000 head, be submitted to systematic control, the surplus of milk will be about 6 173 000 gals., worth £ 151 667. Besides the increase of milk yield systematic and economic

feeding and the keeping of pedigree books, the artificial feeding of calves is also aimed at (1).

Owing to the constantly increasing importation of cheese, efforts have also been made to start cheese factories. Nevertheless as the lack of fodder and the foot-and-mouth disease often hinder the increase of the production of milk, cheese dairying has not yet made much progress. Besides, this branch of the milk industry requires much more experience and technical knowledge and is more risky, than butter making, in which progress is clearly noticeable. The recent increase in the consumption of butter is due to the high prices of lard.

The kinds of cheese made in Hungary are especially Hungarian Emmental, Trappist, Romadour and Magyaróvár, the latter resembling the Tilsit cheese made in the north of Germany. This industry was introduced into Hungary by Swiss cheese-makers who have established themselves in the mountainous parts of the country and make handsome profits. Lately these cheese-makers have established their factories by preference in the western parts of Hungary, because in the South the demand for milk has increased, its price has gone up and turning it into cheese is not remunerative. The Emmental and Gruyère cheeses are for the most part made in the dairies at Répcelak, Bánóc and Nagyszécsény ; the soft dessert cheeses are made at Sárvár, Pusztadör and Kisbér, and most of the Magyaróvár cheese at the cooperative dairies of Moson county.

The number of milk ewes is about three million. (In 1913 the total number of sheep was 6 600 000). Calculating on an average yearly production of 8.8 gals. per ewe, the total yield may be estimated at 26 400 000 gals., which, at 5.45 *d* per gal., are worth £ 600 000. The ewes' milk is used in the manufacture of Brindza or Liptó cheese (2), much esteemed abroad. In 1913, Hungary exported 55 486 cwt., of it, of the value of £ 126 873.

During the last ten years our exportation of milk and milk products has not kept pace with the increase of the production of milk, and this must be due to the increased home consumption of these articles. Only a short time ago, butter, especially in the provincial towns, was used only at dessert, whereas now it has become a popular article of diet.

The greatest consumer of milk is Budapest ; its 900 000 inhabitants consume daily 66 000 gals., or about 0.6 pint per head. In the capital two great firms supply 33 000 gals. per diem ; one, which delivers 26 400 gals., is organised on a cooperative basis; the other, which sells 6 600 gals., is a joint stock company. The farmers send their milk to one of the Budapest railway stations and sell it at 9 *d* and 9 ½ *d* per gal. The public pays 1*s* 2 ½ *d* per gal. for the best milk in bottles delivered at the consumer's house, and 1*s* or 1*s* 1*d* for milk in caus.

For the last three or four years, among the other large cities of Hungary, Temesvár and Nagyvárad have also started municipal dairies ; but as the

(1) See No. 1029, *B.* Nov. 1914. (*Ed.*)
(2) See No. 1669, *B.* Dec. 1912. (*Ed.*)

initial difficulties are not yet overcome, we cannot give exact data on their results.

In Hungary the consumption of milk has considerably increased, especially owing to the anti-alcohol campaign. The daily consumption per inhabitant may be estimated at a little over half a pint ; thus, taking the population of Hungary at 18 ½ millions, the yearly consumption of milk is 446 million gallons, or 55 per cent. of the total amount of cow's milk produced.

Basing our calculations on the available data and taking into consideration the prices of concentrated foods, we have been able to determine the cost of production of milk in this country, which is set forth in the following table :

Cost of production of 1 *gallon of milk.*

Daily yield gals	Corresponding cost d
0.88	9.9
1.10	7.9
1.32	6.6
1.54	5.7
1.76	4.9
1.98	4.4
2.20	5.9
2.42	4.4
2.64	4.9
3.30	4.4

The Control of Plant Diseases in Sweden

by

Prof. JAKOB ERIKSSON, *Stockholm.*

A. — INTRODUCTION.

Many years have elapsed since Sweden began to take measures for the control of plant diseases. The first step in this direction was made in 1876 by the appointment of a Botanist at the Experiment Station for Agricultural Chemistry attached to the Royal Academy of Agriculture and situated at Experimentalfältet near Stockholm. For the appointment of the Botanist the Swedish Riksdag had voted a sum in 1875, and this was renewed for a series of years. The Botanist had the duty of making, during the summer, botanical investigations connected with the experiments carried out by the Station of Chemistry. On December 17, 1876, the writer was named Botanist.

In 1886 a special Botanical Institute, that is to say the Experiment Station for Plant Physiology (Växtfysiologiska Försöksanstalten) was

founded by the side of the Chemical Station. In 1885 the Riksdag had voted the necessary yearly funds for it. The Botanist became the chief of the new station and was entrusted with the drawing up of the detailed regulations and instructions for the 16 State Seed Control Stations, which were approved, the former in 1886, the latter in 1888. The duties of the chief included also the inspection of these Stations during the years 1888 and 1889.

In 1889 there was a disastrous attack of rust on the oats in Sweden: the total crop of the whole country was about 160 000 tons below the average of the preceding ten years. According to a proposal of the chief of the Station, the Academy of Agriculture presented to the Government on January 20, 1890, the request that a sum of £ 550 be voted for new, thorough and extensive investigations into this rust during the years 1890 to 1892. On February 14 the Government granted the sum demanded and the work began immediately. As assistant for this investigation Dr. G. J. Henning was attached to the Station up to April 1894.

On June 22, 1905, the American gooseberry mildew (*Sphaerotheca mors-uvae*) was observed for the first time in a Swedish garden (at Blekinge in the south of Sweden). In a short time the disease spread to several other localities. In investigating the matter it was found that the disease had been introduced by means of gooseberry bushes which had been sent direct some years previously from a Danish nursery. A leaflet was immediately distributed to put farmers on their guard against the parasite. On September 22 the Government enacted a provisional law against the importation of gooseberry plants and fresh gooseberries into Sweden. At the same time the chief of the Station addressed to the Governments of all the countries of Europe in which gooseberries are cultivated, an appeal to put themselves on the defensive against the approach of the enemy. In the course of the following year (1906), the disease having invaded the neighbourhood of Stockholm, further measures were taken. The Government allocated a sum of £ 55 for the control of the fungus. On September 10 of the same year the Government prohibited, until further orders, the transport within the country of gooseberry plants or parts of plants, with the exception of the fruit. By means of articles in a great number of Swedish newspapers the public was warned of the danger that threatened this important crop. The most rapid and efficient measures were recommended for the eradication of the pest. Unfortunately this appeal remained without effect. During the succeeding years the disease spread more and more; at present it is frequent in most of the Swedish gardens. The laws against the importation and transport of gooseberry bushes were repealed in April 1910.

Since 1907 the Botanical Station has formed part of the Central Agricultural Experiment Station (Centralanstalten för försöksväsendet på jordbruksområdet) as Division of Agricultural Botany (Afdelningen för landtbruksbotanik). In 1907 also some changes were made as to the buildings, etc., of the Station. A new piece of land for experiments and a new building were placed at its disposal. Since 1914 the Division

disposes of an annual budget of £ 973 10s. Out of this sum the chief gets £ 410, with a periodical increase of £ 33 for seniority. The assistant receives £ 165, and the laboratory help £ 38 10s. For the experiments £ 357 10 s. are set apart.

On October 2, 1912, potato canker (*Synchytrium endobioticum* or *Chrysophlyctis endobiotica*) was observed in Sweden. Efficient measures were immediately taken to eradicate the disease, and apparently with happy results (1).

On October 1, 1913, I retired, having reached the age limit fixed by the law, and on April 24, 1914, my post was occupied by Mr. E. J. Henning, professor at the Ultuna College of Agriculture. Mr. C. T. V. Hammarlund is at present attached to the Division as assistant.

B. — Work of the Botanical Station at Experimentalfaltet.

a) *Various work.* — During the first years, several experiments of cultures in solutions were made with the object of investigating the influence of certain mineral salts, considered poisonous, on certain plants. But even as early as that some research on plant diseases was made.

At the same period popular pamphlets on various diseases were issued; such were papers on *Nectria ditissima*, on *Exoascus Pruni*, etc.; they were followed by the publication of special studies, for instance in 1879 on *Typhula graminum*, in 1880 on *Sclerotinia Trifolium*, in 1883 on *Cladosporium herbarum*, in 1884 on *Phytophthora infestans*, and in 1885 on *Scolecotrichum graminis*, *Phragmidium subcorticium*, *Sphaerotheca pannosa*, *Uncinula Aceris* and *U. Tulasnii*, *Asteroma radiosum*, *Fusicladium dendriticum* and *F. pirinum*, *Morthiera Mespili* and others. In 1890 a summary of observations made in the course of several years on a great number of the diseases of various plants was published under the title of " Some diseases of cultivated plants and the means of controlling them ".

Since 1890, the presence of parasitic fungi in the samples sent to the Station has been determined, and information as to the nature of the diseases and on the corresponding treatment is forwarded to the senders of the samples. Whilst the number of such samples rarely reached 100 before 1902, it has often been 300 and 400 during recent years. The highest figure was reached in 1907 when the number of reporters was 464 and the number of specimens and questions was 537.

Besides the above work, the officials of the Station have visited the various infected localities of the country to make investigations on the spot and to give farmers information and advice.

b) *Research on the rust of cereals.* — In 1894 and 1895 the first preliminary publications on certain results obtained during the years 1890-1893 appeared. In 1894 : " Principal Results of New Investigations into the Rust of Cereals " (2), and in 1895 : " On the Specialization of Para-

(1) See *B.* July 1913, p. 1006, and No. 18, *B.* Feb. 1914.

(2) According to the wish of the author, the titles of articles published in Swedish are here translated. (*Ed.*).

sitism in Cereal Rusts", "Favourable Influence of Cold on the Germination of the Spores of Certain Fungi", "Is the Rust-resistance of the Various Varieties of Wheat Constant or not?" were published.

A detailed account of the results obtained between the years 1890 and 1893 was published in June 1896 under the title "Die Getreideroste, ihre Geschichte und Natur, sowie Massregeln gegen dieselben". The 1894 Report and the detailed account of 1896 were written by the chief and the assistant of the Station together.

In a series of more or less ample works published successively, after new research, and written by the chief of the station, many subjects connected with the rust of cereals were examined in detail. Among these publications may be mentioned the following: in 1896, "Which are the Grasses which can communicate Rust to Barberries?", "New Research on the Specialisation, Propagation and Origin of Black Rust", and "Barberries Bearing and Propagating Rust"; in 1897, "Further Observations on the Specialisation of Black Rust", "New Observations on the Nature and Propagation of Crowned Rust", "Characteristics of the Brown Rust of Cereals", "On the Duration of the Capacity of Germination of the Winter Spores of Certain Kinds of Rust"; in 1899, "New Studies on the Brown Rust of Cereals"; in 1900 and 1901, "On the Origin and Spread of Cereal Rust by Means of the Seed"; in 1902, "Ist der Timotheengrassrost eine selbständige Rostart oder nicht?," "On the Specialisation of Cereal Black Rust in Sweden and in Other Countries"; in 1903, "On the Vegetative Parts of Yellow Cereal Rust"; in 1904 and 1905, "Ueber das vegetative Leben der Getreiderostpilze", I-IV; in 1905, "Zur Frage der Entstehung und Verbreitung der Rostkrankheiten der Pflanzen"; and in 1908, "Neue Studien über die Specialisierung der grasbewohnenden Kronenrostarten".

With the preliminary communication of 1894 mentioned above, and especially with the detailed report of 1896, the question of the rust of cereals entered upon a new phase.

From that moment it became evident that among the rusts attacking the common cereals (wheat, rye, barley and oats), six different species were to be distinguished, namely: *P. graminis*, *P. glumarum*, *P. dispersa*, *P. triticina*, *P. simplex*, and *P. coronifera*; and for the commonest grasses, the very similar rusts of which had always been regarded as identical with those of cereals, six other species: *P. Phlei-pratensis*, *P. bromina*, *P. agropyrina*, *P. holcina*, *P. Triseti* and *P. coronata*.

In the two above-mentioned publications, the principles of the specialisation of fungi were set forth and discussed. In one and the same species of fungus several different strains may be distinguished; these are distinct from each other from the biological point of view, and are called "specialised forms" (f. sp.): *P. graminis*, for instance, which attacks the four cereals and also a great number of grasses, includes among other forms the f. sp. *Avenae*, living on oats, *Dactylis*, *Alopecurus*, *Milium* and certain other grasses, but incapable of transmission to wheat, rye or barley.

In the full Report mentioned above, the whole life and cycle of evolution of the different kinds of rust, as well as the essentially different degrees of resistance of the various cereals to the various species of rusts, are described in detail.

The greatest care has been bestowed on the study of the hibernation of these fungi and the appearance of new outbreaks of disease on the following year's crop. It was believed that these two questions were completely solved by the existence of winter spores, and that these spores lived unchanged until the following spring, when they germinated and gave rise to new outbreaks of the disease. The new investigations did not, however, support this opinion generally accepted by the learned. The winter spores alone were not sufficient to solve the problem of hibernation. Numerous observations made in the course of several years led me to suspect the existence of an interior germ of the disease in the grain itself or in the young plant grown from it. These suppositions were presented to the public for the first time in the works that appeared between 1897 and 1900, and especially in the memoir " On the Origin and Spread of the Rust of Cereals by means of Seed " (1900-1901).

In these publications the hypothesis was advanced that the fungus was present in the cell of the host in a special state ; that it lived under the form of a plasma, and that it contracted a kind of simbiosis with the protoplasm of the cell. It is this association which has been called " mycoplasm ". At a certain period of development of the host plant, during a certain season, and when external conditions (heat, moisture, light, etc.), are favourable, the mycoplasm abandons its state of plasm, issues from the cell and forms a perfect spore-bearing mycelium giving origin to rust pustules.

In 1902 and 1903 this hypothesis was subjected to a scrupulous examination, in which the new methods of cytological preparation were applied. Dr. G. Tischler, lecturer at the Heidelberg University, took part in these investigations as collaborator during both summers. The results of this cytological investigation were published in a series of memoirs under the title " Ueber das vegetative Leben der Getreiderostpilze ", I-IV (1904-05), in which the phases of the vegetative life of these fungi are described.

It was easy to foresee that a new theory as subversive as this would meet with opposition. This opposition led to answers on my part, published in the memoirs of 1904 and 1905, as well as in several special pamphlets, including the following: in 1903, " The Researches of Professor H. Marshall Ward on the Brown Rust of the Bromes and the Mycoplasm Hypothesis " ; in 1910, " Ueber die Mycoplasmatheorie, ihre Geschichte und ihren Tagestand " ; " F. Zach's cytologische Untersuchungen über die Rostflecken des Getreides und die Mycoplasmatheorie " ; in 1912, " Rostige Getreidekörner und die Ueberwinterung der Pilzspecies " ; and in 1914, " On the Appearance of Rust Spores and Mycelium in the Seeds of Cereals ".

c) *Studies on other kinds of rusts.* — In 1898 a note entitled " Study on *Puccinia Ribis* ", containing the history of the development of this fungus, was published.

In 1896 appeared a pamphlet: "Some Observations on the Vesicular Rust of Weymouth Pine". In this it is shown that the relationship existing between *Peridermium Strobi* and *Cronartium ribicola* is not always sufficient to explain the occurrence of this rust. On both kinds of host plants (*Pinus* and *Ribes*) the fungus can live from one year to another when one of the hosts is absent, or when the distance between them is 20 or 30 miles.

Hollyhock rust (*Puccinia Malvacearum*) has for a length of time been the object of very extensive research; the results are published in two Reports, one of 1911 under the title "Der Malvenrost, seine Verbreitung, Natur und Entwickelungsgeschichte", the other of 1914 bearing the title "Experiments of Immunisation of the Hollyhock against Rust". It appears from the first work that the reappearance of the disease on the new growth cannot be sufficiently explained by the fungus spores. Two forms of spores have been recognized, similar to each other morphologically but having a different way of infecting. The second work shows that the vitality of the fungus living in the latent state in the inside of plants, may be arrested or weakened by introducing a liquid fungicide into the roots of the host plant or by watering the soil in which the hosts live with a weak solution of sulphate of copper.

d) *Studies on other plant diseases.* — During the years 1898-1902 and 1911, a disease attacking several root crops and known under the name of *Rhizoctonia violacea* was studied. The results of these investigations were published in 1903: "Some Studies on *Rhizoctonia violacea* on Carrots", and in 1913: "Studies on the Disease caused by *Rhizoctonia violacea*" (1).

Since 1905 extensive research has been carried out on the American gooseberry mildew (*Sphaerotheca mors-uvae*). The results of these investigations are published in about thirty papers, among which we quote the following: in 1905, "The American Gooseberry Mildew in Sweden", "American Gooseberry Mildew, its Nature, its Propagation, and the Means of Controlling it"; in 1908, "Stachelbeermehltau und Stachelbeerkultur"; in 1909, "Einige Versuche das Winterstadium des amerikanischen Stachelbeermehltaues mit Fungiciden zu töten", "Die verschiedene Empfänglichkeit der Stachelbeersorten im Kampfe gegen den Amerikanischen Stachelbeermehltau".

Two of the most destructive diseases of fruit trees, *Monilia fructigena* and *M. cinerea*, have been the object of continued research (2). We may mention here the publication: "Zur Kenntniss der durch *Monilia*-Pilze hervorgerufenen Blüten- und Zweigdürre unserer Obstbäume".

On another equally destructive enemy of fruit trees, the apple mildew (*Podosphaera leucotricha*), a communication was made in 1908 in the paper: "Der Apfelmehltau und seine Bekämpfung".

A new disease which until then had not been observed, caused by

(1) See No. 426, *B.* April 1913; and *B.* July 1913, p. 1007. (*Ed.*).

(2) See *B.* July 1913, p. 1007. (*Ed.*).

Exosporium Ulmi, was the object of minute investigation during the years 1905 and 1906. The result was published in 1912 in a paper " Ueber *Exosporium Ulmi* n. sp. ".

During recent years several potato diseases have been studied. In 1912 the results of an examination of the felt disease of potatoes (*Hypochnus Solani, Rhizoctonia Solani*) were published in the article " Felt Disease of Potatoes " (1).

In order to ascertain the influence of a solution of formalin spread on the soil in which potatoes grew, on potato canker or black scab (*Synchytrium endobioticum* or *Chrysophlyctis endobiotica*) some special cultures in boxes were organized during the summer of 1913.

In 1912 a summary of the results of research carried out for many years on the diseases of beets was published. This work bears the title " Fungus Diseases on Swedish Beet Crops " (1). A more detailed report of one of the diseases (*Uromyces Betae*) mentioned in the said work, was given in 1914 under the title " Some Studies on Beet Rust ".

A summary of research concerning the diseases of cucumbers (1) was published in 1913 in the work " Fungus Diseases of the Swedish Cucumber Crop ".

In 1910 I published a manual bearing the title " Landtbruksväxternas Svampsjukdomar ". In 1912 an English edition, revised and somewhat enlarged, appeared under the title of " Fungoid Diseases of Agricultural Plants ". A German edition " Die Pilzkrankheiten der landwirtschaftlichen Kulturpflanzen " was published in 1913, and a French edition, " Les maladies cryptogamiques des plantes agricoles et leur traitement ", in 1914.

e) *Efforts for the establishment of international collaboration with a view to controlling the diseases of cultivated plants.* — The idea of such an international collaboration was mooted for the first time in 1890 at the International Congress of Agriculture and Forestry at Vienna. At that time I presented a proposal aiming at an international agreement for the defence against such diseases. A great number of motions all tending to the same aim have been presented since at International Congresses : Paris (1900), Rome (1903 and 1905), Vienna (1907), Rome (1907 and 1908), Montpellier (1908), Rome (1909,1910 and 1911), Paris (1912) and Rome again for the eighth time in 1913.

In view of an efficient control of plant diseases, a Bill was prepared for Sweden in June 1913, and the Swedish Government is having it examined.

But the most important diseases, those which are responsible for at least 90 per cent of the yearly losses, cannot be advantageously controlled by legislative measures. In a Report presented to the International Conference on Phytopathology (held in Rome from February 24 to March 4. 1914) and bearing the title " Phytopathological problems : the different diseases require different measures ", I called attention to this important fact.

C. — Work of Official Botanical Institutions.

At the Ultuna Agricultural College, near Upsala, prof. Henning has studied some fungi and insects injurious to crops; he has besides given advice and information as to the methods of controlling them and has published works on these subjects.

At the Alnarp College of Agriculture, near Lund, Prof. T. Hedlund has studied several parasitic fungi and especially those of root crops. He has also published reports on the results obtained by his research and he has distributed papers dealing with these subjets among farmers.

In connection with the extensive work for the improvement of seed carried out by the Svalöf Station for Seed Improvement (Sveriges Utsädesförening i Svalöf) several plant diseases have been studied. Reports upon this work have been published by officials attached to the Institution, and especially by Dr. H. Nilsson-Ehle and Dr. H. Tedin.

The State Forest Experiment Institution (Statens Skogsförsöksanstalt i Stockholm) has commenced of late years investigations in forest pathology. Memoirs concerning diseases of conifers and some other species have already been published. These publications are due to the Assistant of the Institution, Dr. G. Lagerberg.

SECOND PART.

ABSTRACTS

AGRICULTURAL INTELLIGENCE

GENERAL INFORMATION.

ORGANIZATION OF EXPERIMENTAL AND ANALYTICAL WORK

1086 – **Report of the Work of the Experiment Stations and Experiment Fields of Annam, 1913.** — DEVRAIGNE, GEORGE (Chef des Services Agricoles et Commerciaux locaux de l'Annam) in *Bulletin économique de l'Indochine*, Year 17, No. 108, pp. 348-363. Hanoi-Haiphong, May-June 1914.

I. — *Experiments with industrial plants.* — The Caravonica variety of cotton was experimented with at the station of Hué. It is a resistant variety and makes good growth, but has the disadvantage that its pods reach maturity during the rainy season. Attempts will be made to remedy this as far as possible by suitable pruning. Kapok from Venezuela was very successful, whilst that from the Malay peninsula and Cambodia was less successful. The oil-yielding *Camelia* (1) was successful at the Yên-dinh Station (north Annam), but it was not a success at the Hué station (South Annam), where the climate is very different. Amongst rubber trees *Ficus elastica* and the liana *Cryptostegia madagascariensis* have succeeded at Hué ; *Funtumia elastica* was less successful and Hevea was a failure. *Arenga saccharifera* succeeded well at Hué and in groups of three the trees resisted the most violent winds and typhoons; it is fairly abundant in the forests of Annam and the fibres are used to a small extent by the natives. Camphor grows exceedingly well at Hué, and Kola nuts, *Merremia mamosa* and *Curcuma longa* were also successful..

II. *Experiments with food plants.* — In 1912 an orchard was established at Hué with native and exotic species, including bananas, shaddock,

(1) Various species of *Camelia* such as *C. drupifera*, *C. Sasanqua*, *C. theifera*, are used for the extraction of oil from the seeds. Cf. WATT, *Dictionary of Economic Products of India*. Calcutta. (*Ed.*).

orange, mangosteen, pineapple, papaya, cacao, pepper, etc. Experiments on the cultivation and selection of rice have been in progress since 1906 at the Yên-dinh Station. The results obtained each year from 1906 to 1913 are summarised in tables by the writer. During the last year (1913, the variety "Lua Chânh", an early hill rice. yielded 1242 lbs. per acre) whilst various selected swamp rices yielded from 1242 to 2737 lbs. per acre.

III. — *Animal breeding.* — At the Hué Station the acclimatisation of a breed of Kélantan sheep from Yên-dinh was very successful. The silkworm egg-breeding stations founded by the Government continue to increase: during 913 they numbered 11 and distributed 636 293 batches of eggs.

CROPS AND CULTIVATION.

1087 – **The Climate of Ethiopia.** — EREDIA, F., and DE CASTRO, L., in *Bollettino della Reale Società Geografica*, Part VIII, pp. 845-884. Rome, 1914. AGRICULTURAL METEOROLOGY

There is little information concerning the climate of the high plateau of Abyssinia, the only data available being those of DOVE obtained in 1890 (Kulturzonen von Nord Abessinien, *Ergänzungsheft Nr. 97 zu Petermanns Mitteilungen*, Gotha, 1890), those published in the *Annales de l'Observatoire physique Central Nicolas*, Petrograd, 1898-1903; those collected by LYONS, etc. All these observations have the disadvantage of having been made during limited and irregular periods.

In October 1901 Dr. L. DE CASTRO established a meteorological station at Addis-Abeba, where he began a series of regular observations which, together with Dr. E. ODDONE, he continued until 1911. The data thus obtained have been examined by Prof. FILIPPO EREDIA and summarised in the accompanying table.

The difference between the highest and lowest mean monthly temperatures (18.7° and 14.6°) is very slight; thus the climate is mild and the mean temperature almost uniform throughout the year. The difference between the day and night temperatures, on the other hand, is very great and averages 15° C. The maximum daily temperatures during the hottest period are almost 35° C. whilst the night temperatures during the coldest months approach zero.

The rainfall shows a very distinct period of abundant rain from the last ten days of June until the second ten days of September, the highest rainfall being during the first ten days of August. This period of intense rain is followed by an interval where the rainfall is less abundant, beginning suddenly and lasting until the end of February. Extreme drought occurs in January, when no rain has ever been recorded during the first ten days. This period is followed by more abundant rains, which increase as the rainy season approaches. The rains may be divided into two classes: the less abundant and prolonged rains during the period of low rainfall and the more abundant short rains during the rainy season. The heavy rains are almost always accompanied by electrical disturbances,

which are particularly frequent in the afternoons. At the same time the wind is generally from the S or SW, whilst the storms come from the N or NE and sometimes from the E. The heavy rains should therefore be attributed to opposing currents of air, whilst light rains may be considered as entirely of orographical origin.

During the rainy season the predominant winds are N, W and NW.

Summary of the Climatological Data of Ethiopia.

(*Temperatures in deg. C., rainfall in mm.*)

Month.	Mean temperature				Extreme temperature		Rainfall		Fine days.	Relative humidity	Direction of predominant wind
	daily	max.	min.	range	max.	min.	quantity	No. of rainy days.			
January	15.5	24.2	6.8	17.4	28.0	3.0	12.5	3.8	22	53	SE
February	17.0	25.3	8.6	16.6	30.0	3.5	33.1	2.9	20	54	SE-E

Year	16.7	24.4	9.0	15.4	38.0	0.0	1 212.6	148.1	169	66	SE-

There is also a distinct daily variation; in the mornings the E and S E winds predominate, changing to the N in the evening. The end of the period of heavy rains is marked by the predominance of N E and E winds, those of the S W and S disappearing almost completely.

The seasons are described as follows:

Winter (October, November, December): low temperature; little rain; high variation daily; minimum relative humidity; large number of fine days; prevailing wind E.

Spring (January, February): mild temperature; relative lack of rainfall; high daily variation; minimum relative humidity; large number of fine days; predominant wind: S E.

Summer (March, April, May, June): high temperature; relatively abundant rain; average daily variation; average relative humidity; few fine days; predominant wind S E.

Autumn (July, August, September): mild temperature; abundant rain; minimum daily variation; high relative humidity; very few fine days; predominant winds; N and S E.

The natives divide the seasons according to their rainfall, the four seasons in the above order being known as Tebbi, Hagai, Todi and Kerempt.

1088 – **The Estimation of Phosphates in Soil Extracts.** — PRESCOTT, J. A. (Rothamsted Experimental Station) in *The Journal of Agricultural Science*, Vol. VI, Part 2, pp. 111-120. Cambridge, May 1914.

SOIL PHYSICS, CHEMISTRY AND MICROBIOLOGY

The method of estimating phosphates recommended by the United States Division of Chemistry, which consists in dissolving the phosphomolybdate precipitate in excess of standard alkali and titrating back with standard acid, was examined with regard to certain working conditions. It was shown that it is essential to avoid working at too high a temperature, 55° C. proving most favourable. The presence of silica also proved a disturbing factor and this substance should be precipitated in the preliminary phases of the estimation. Determinations made with solutions containing known amounts of phosphate yielded results 3 per cent too high when the calculations were based on the usual factor (1 cc. $^{N}/_{10}$ alkali = 0.0003088 gm. P_2O_5) and it is therefore recommended that the factor 1 cc. $^{N}/_{10}$ alkali = 0.0003004 be adopted, as it corresponds approximately to the constitution $48\,MoO_3 . 2P_2O_5 . 5\,(NH_4)_2O$ for the yellow precipitate.

Another method of estimating small quantities of phosphate was tried; it consists in converting the phospho-molybdate precipitate into lead molybdate and weighing it as such; it was found to be no more accurate than the titration method, while being less rapid.

1089 – **Azotobacter in Connection with Nitrification.** — HEADDEN, W. P. (Colorado Experiment Station) in *Science*, Vol. XL, No. 1028, pp. 379-381. Garrison, N. Y., September 11, 1914.

In certain pure cultures of *Azotobacter*, brown pigmentation was obtained; this tended to weaken and disappear in the successive generations. Where such pigmentation occurred a decided reaction was obtained with phenolsulphonic acid apparently indicating the presence of nitrates and consequently a power of nitrification on the part of *Azotobacter*. On further investigation, however, it was found that the colour reaction was due to the pigmentation and not to the presence of nitrates, thus destroying all evidence of nitrifying power on the part of *Azotobacter*.

1090 – **Overhead Watering Plant.** — DEAN, WILLIAM HARPER, in *The Country Gentleman*, Vol. LXXIX, No. 31, pp. 1309-1311. Philadelphia, August 1, 1914.

PERMANENT IMPROVEMENTS, DRAINAGE AND IRRIGATION

Among the many systems of irrigation, the overhead system presents several advantages, namely that it can be used on sloping uneven ground where surface irrigation would be difficult to apply, that it can be used to distribute liquid manures, and that sprays for the control of plant diseases and injurious insects can be applied easily, evenly and efficiently.

The writer, in company with the U. S. Government irrigation engineer in charge of irrigation investigations in the States east of the Mississippi,

visited some farms irrigated on this system and reports upon two among the most successful of them.

The first is situated in Central New Jersey. It is a farm in which 9 acres are irrigated by this system and 19 by surface irrigation; most of the land is under strawberries and orchards. The water is pumped up from a river by a 24 HP. gazoline engine. The pumping plant, pump house and connection to the mains carrying water to the fields cost $778. The rest of the irrigation plant for the first five acres cost, in 1910, $1162 distributed as follows:

Pipe materials all galvanised	$ 852
Freight on pipes and incidentals	25
Patented fittings	143
Posts for spray lines	52
Day labour at $ 1.25 per day	50
Plumber at $ 3 per day	40
	$ 1 162

The second part of the installation for the next 4 acres cost $1438.

From the pumping plant a 5-inch galvanized steel main carries water under 30 or 40 lbs. pressure to the overhead pipes. These pipe lines are 425 feet long and 50 ft. apart, supported every 40 ft. by upright steel pipes. In order to ensure the same pressure throughout, the diameter of the pipes varies from 1 ½ inch to ¾ inch.

By a slight turn of a lever the whole length of these pipes may be turned to change the angle of the tiny spray nozzles that are situated four feet apart in each pipe; roller bearings on each line make this possible. During irrigation the angle of these nozzles has to be changed seven times to get the rain evenly distributed over the space between the lines.

This system supplies 40 gals. a minute to the acre; it would put an inch of water on the land in about 12 hours.

The second farm visited is situated in Southern New Jersey; it covers 35 acres, 10 of which under overhead irrigation. The land is level and the soil a light, poor sand.

The water is pumped up from a creek by a 12 HP. gazoline engine and is distributed at 20 lbs. pressure. The overhead lines are 250 feet long and 50 ft. apart. The supports are 20 ft. wooden posts 125 ft. apart: from the tops of these poles were stretched cables from which are suspended the spray pipes by means of other wires. Twelve gallons a minute is the output through the nozzles for the first half of each spray line, and half of this for the second half, at which rate an inch of rainfall can be put on in 12 hours.

The average cost of the plant is $250 per acre. Depreciation is very low being chiefly limited to the pump and engine and to the wooden supports for the spray lines.

In this farm concentrated Bordeaux mixtures or Paris green wash pumped into the system of pipes while clear water is running through, and in 20 minutes 1 ½ acres can be sprayed. Liquid manures are applied in the same way.

1091 – **Irrigation Scheme for Sinde; The Development of Cotton.** — SUMMERS, T. (Proceedings of the East-India Association), in *The Asiatic Review*, Vol. V, No. 11, pp. 298-330. London, October 1914.

The low productivity of this large tract of the Indus Valley appears to be due to the low rainfall, which varies from 2 to an average of 6 inches. The soil of the Sind consists of alluvial silt deposited by the Indus, and in former times (about 500 B. C.) its fertility was increased by an excellent irrigation system which enabled it to support a much greater population.

At the present time, a few canals exist only on the lowest tracts, only one-fourth of the area is cultivated, the cultivators lift comparatively silt-less water on to their fields at a cost of 5 rupees or more per acre, and a population of 800 000 persons cultivates only 600 000 acres.

The writer describes a scheme, known as the Rohri Canal Project, which, if carried out, will bring into cultivation between one and two million acres of this fertile land, of which half to three-quarters of a million acres will be suitable for cotton and capable of supporting twenty or thirty cotton mills.

The cost of this scheme is estimated at about 10 millions sterling and at the present rate of assessment the net annual profit to the Government would amount to between ¼ and ½ a million sterling.

1092 – **Experiments in Tilling the Soil by Means of Explosives.** — I. SPRING. F. G. Dynamite Experiment. — *The Agricultural Bulletin of the Federated Malay States* Vol. II, No. 11, pp. 297-299. Singapore, June 1914. — II. DURHAM, HERBERT E. On the Use of Explosives in the Garden, in *The Journal of the Royal Horticultural Society*, Vol. XL, Part I, pp. 7-18. London, August 1914.

TILLAGE AND METHODS OF CULTIVATION.

I. In October, 1913, some experiments were made at the Experimental Plantation, Kuala Lampur (Federated Malay States), on the use of explosives in rubber cultivation. The land on which they were carried out is of a poor laterite nature and the rubber plants were very backward in growth. The results are those hitherto obtained from an area subjected to gelignite charges.

Three parallel rows of rubber, each containing 34 trees, were selected; on one the explosive was used, while the other two were kept as controls. The cartridges were placed at a depth of 2 ½ feet below the surface of the ground, one cartridge between two trees 12 ½ feet apart. The method of firing was by means of fuses and detonators.

The average increase of girth measured on June 9, 1914, was 2.56 inches in the dynamite row and 1.81 and 1.62 in the control rows. The cost of applying the explosive is 15 cents per charge, inclusive of labour. One charge per tree is generally allowed. The results would have been more evident if the subsoil had been of a clay nature, as is the case at Castleton Estate, where an experiment on a much larger scale is being conducted.

II. The writer wished to ascertain whether explosives can be used for loosening the subsoil on small areas, such as gardens intensively cultivated, and near buldings. He used " cheddite " cartridges with 2 oz., 1 ½ oz., 1 oz. and ½ oz., charges placed three feet apart and at a depth of three feet. One piece of the ground had recently been double dug before the exploding

and it was obvious that much of the force which would have been utilized if the ground had not been spaded was wasted.

Compared with the control plot not loosened by cheddite, the potato Crimson Beauty showed that the response to the exploisve was very marked. Thus the ½ oz. charges gave about 15 per cent. increase, the 1 oz., 43 per cent and the 2 oz. about 88 per cent. Cauliflowers and cabbages showed no appreciable difference on exploded and unexploded ground. With peas the number of plants was much smaller on the unexploded side, on which they blossomed and matured a week earlier than on the exploded ground. Carrots, onions and scorzoneras gave a greater number of plants, and germinated and developed much better on the exploded ground ; with the latter plant especially the crop was much increased by the explosive. With asparagus the shoots were not far from having been doubled in length.

As for the cost : at wholesale prices, four or five 2 oz. shots including fuse and detonators can be had for a shilling. With regard to the energy developed by cheddite, allowing 50 per cent loss of the total available energy a 2 oz. charge gives about 50 400 foot-pounds in the soil, that is quite ten times as much energy as would be put into the soil by using the spade to a depth of three feet.

MANURES AND MANURING

1093 – **The Relative Effect of Lime as Oxide and Carbonate on Certain Soils.** — HUTCHINSON, H. B., and MAC LENNAN, K., in *The Journal of Agricultural Science* Vol. VI, Part 3, pp. 302-322, plates IX-X. London, September 29, 1914.

To make a further study of the hitherto not fully known mechanism of the changes wrought by caustic lime in the soil, five soils of widely different type were taken :

1. *Rothamsted soil*, a poor stiff clay containing 7.72 per cent of organic matter (loss on ignition) and 1.94 per cent of CaO.

2. *Chelsea soil*, a black sandy soil containing 14.32 per cent of organic matter and 1.42 per cent of CaO.

3. *Craibstone soil* (Scotland), a light soil, rich in organic matter (14.5 per cent), with 0.41 of CaO.

4. *Millbrook soil* (Woburn), a very light sandy soil, poor in organic matter (4.46 per cent), with 0.26 of CaO.

5. *Woburn soil*, an open sandy loam, which has been rendered distinctly acid by annual applications of sulphate of ammonia for the last 37 years it contains 4.58 per cent of organic matter and 0.56 per cent of CaO.

Laboratory Experiments.— The soils were passed through a 3 mm. sieve and filled into bottles in lots of 900 gms. A set of bottles from each soil was set aside as control, and the others received calcium oxide in the proportion of 0.1, 0.2, 0.3, 0.4, 0.5 and 1.0 per cent, while calcium carbonate was added to another lot to the extent of 1.0 per cent, with the exception of the Craibstone soil, where applications of 0.3, 0.6 and 0.9 per cent of carbonate were made. The water content was made up by means of sterilized water to 18 per cent. A set of bottles was taken immediately after the end of this ten-day treatment, and the others were stored, provided with cotton wool plugs, at room temperature. The various soils were examined once a month: the number of bacteria was determined, as well as th

amount of ammonia and nitrates produced. Examinations for protozoa were also made.

Pot experiments — The soils were passed through a 3 mm. sieve previous to being filled into glazed earthenware pots (in which loss by drainage was prevented) at the rate of from 8 to 10 kg. of soil per pot. Lime as oxide and carbonate was applied in the same ratio as in the laboratory experiments. The surface soil was then wetted with 100 cc. of water in order to allow of efficient action of the caustic lime before it became carbonated. Ten barley seeds were sown in each pot, and after about a month the plants were thinned out to five per pot. Equal numbers of the seedlings were weighed to ascertain the initial effect of the lime on plant growth.

The results are given in numerous tables and diagrams and are summarized as follows:

Caustic lime is found to have two distinct effects on the soil:

1) A partial sterilisation effect.

1) A chemical action, decomposing some of the soil organic matter.

The amount of caustic lime necessary to induce specific changes in the flora and fauna of the soil depends very largely upon the character of the soil. The light sandy Millbrook soil, poor in organic matter and in carbonate, reacted sharply with 0.2 to 0.3 per cent. caustic lime; the Rothamsted clay soil, poor in organic matter but rich in carbonate, was found to react to 0.3 to 0.4 per cent; the acid Woburn soil required between 0.5 and 1.0 per cent, as did also the rich Chelsea garden soil, which already contained carbonate; the Craibstone soil, with a high organic and a low carbonate content, failed to react even to applications of 1.0 per cent caustic lime.

Each of these soils, as well as many others examined, appears to absorb directly a definite amount of caustic lime, and until these requirements are fully satisfied the partial sterilization phenomena do not set in. These phenomena include a sudden initial decrease and subsequent increase in the numbers of bacteria, the extinction of the larger forms of protozoa and the inhibition of nitrate production. Lower doses than those required for partial sterilisation induce a temporary suspension of nitrification, and consequent accumulation of ammonia, for periods varying with the amount of lime and the character of each soil; they also lead to a temporary increase in numbers of bacteria capable of growing on gelatine plates, but these afterwards decrease, until the level of the untreated soil is reached.

Caustic lime causes chemical breaking down of some of the organic matter of the soil, as shown by the ammonia formed during periods when soil bacteria are quiescent; when, however, bacterial growth commences, there is a large increase in the rate of ammonia production.

The return in nitrogen, as ammonia and nitrate for each increment of lime applied, varies with the character and reaction of the soil and the carbonate content. On the average, and within a period of about 250 days, it amounted approximately to 1.0 per cent by weight of the caustic lime applied. Carbonate gave less returns, apparently because of its relative inaction on soil organic matter.

The pot experiments show amounts of available nitrogen in the soils comparable with the amounts of ammonia and nitrate produced in the laboratory experiments. In some cases the amount of caustic lime applied was sufficiently large to check the growth of bacteria and to depress plant growth in the first crop, but in the case of the Chelsea soil the bacteria were active but plant growth was depressed, a phenomenon not yet satisfactorily explained.

As in other experiments, inhibition of nitrification resulting from applications of lime leads to a higher nitrogen content in the plants. This has been ascribed to the assimilation of nitrogen compounds other than nitrates, and, if occurring to any extent, involves an uneconomic utilisation of soil nitrogen. Where the amount of lime does not check nitrification, as in the case of the lighter dressings to the Craibstone soil, the nitrogen content of the plants is about the normal.

1094 – **The Duration of the Action of Manures.** — HALL, A. D., in *The Journal of the Royal Agricultural Society of England*, Vol. LXXIV, pp. 119-126. London, 1913.

A set of experiments was started at Rothamsted in 1904 in order to obtain practical information on the duration of action of manures. It took the following form : for each manure five plots were set aside ; one was a check plot which at no time received the manure under investigation ; of the other plots, one received the manure in 1904, but remained unmanured in 1905, 1906 and 1907 ; a second plot was manured in 1905, but not in 1906 and 1907 ; the third in 1906, but not in 1907 ; the fourth in 1907. Thus in 1907, by which year the experiment was in full swing, there was a plot that had been manured in that year, another that had been manured in the previous year, a third two years previously, and a fourth three years previously. In 1908 it was considered that the manure applied in 1904 to the first plot had been exhausted by the four crops grown with it, and the manure was renewed on that plot ; on the second plot it was renewed in 1909, and so on. The field was farmed on a rotation of alternating corn and roots and contained eight sets of five plots as follows :

Nitrogenous manures :

1. Dung made from roots and hay only.
2. Cake-fed dung.
3. Shoddy (wool waste).
4. Peruvian guano.
5. Rape dust.

Phosphatic manures :

6. Bone meal.
7. Superphosphate.
8. Basic slag.

Once during each rotation a dressing of superphosphate and sulphate of potash was applied equally to all the nitrogen plots ; similarly for the corn crops a dressing of sulphate of ammonia was given alike to all the phosphatic plots. The unmanured plot in each series was so placed in the line that together they formed two diagonals across the field and the mean

of the first five was used for comparison in the case of nitrogenous manures, the mean of the last three as the standard for the phosphatic plots.

The results are considered under three headings.

1. *Residual values of rich and poor dung.* (1) — In the year of application, the cake-fed dung showed a great superiority over the roots and hay dung, but this superiority was much less manifest the second year and entirely disappeared the third and fourth year, though the effect of the dung persisted in both cases, raising the yield above that of the unmanured plot. These results are due to the fact that both kinds of dung contain approximately the same amount of insoluble nitrogen, while the cake-fed dung is richer in ammonia and amides, the effect of which had completely disappeared after the second crop.

2. *Other nitrogenous manures.* — The relative total produce of the other three nitrogenous manures is given below, the unmanured plot in each case being taken as 100.

	Year of application — Mean of 9	1 year old residue — Mean of 8	2 year old residue — Mean of 7	3 year old residue — Mean of
Shoddy	139.7	125.2	116.1	106.7
Peruvian Guano	150	101	96.5	94.4
Rape dust	136.2	100.4	100	94.4

A marked contrast exists between the shoddy on the one hand and Peruvian guano and rape dust on the other. The shoddy evidently contains compounds of nitogen subject to comparatively slow decay, so that its effect in the second and succeeding years is considerable, there being a distinct increase indicated in the fourth crop grown with the manure. Indeed, the values yielded by shoddy compare very closely with those obtained with farmyard manure made from roots and hay only. It is a persistent manure that exerts in the first year of application less than one-half of its total effect. Doubtless we should include in the same category all manures made from hair, fur, skin, silk, hoofs, horns, etc ; and probably also the nitrogen compounds of bones.

Very different are the results yielded by Peruvian guano and rape dust. For both these manures the return in the first season is high ; they are well-known as active and effective nitrogenous fertilizers ; but the experiments show that they leave no residue possessing any value for succeeding crops. Owing to the limited number of experiments, too much stress cannot be laid on the actual figures obtained, but it may be concluded that the nitrogenous residue from Peruvian guano or rape cake after a crop has been taken will give less than 10 per cent. increase in the second crop, and after that

(1) See No. 15, *B.* Jan. 1914.

will be completely exhausted. (It should be noted that this statement applies to the nitrogenous part only of these manures, not to the phosphates they contain). Now the nitrogen compounds in question are, in the gnano, ammonium compounds, uric acid and its derivatives, and some proteins ; in the rape cake, almost entirely proteins ; and it is a point of great importance in this connection thus to find that proteins are as active and as temporary in their action as ammonium compounds. Such a result is indeed intelligible, for the true proteins are readily and completely digestible, are equally easily attacked by bacteria, and pass thereby into ammonia and kindred bodies with great rapidity. There is other evidence from the Rothamsted experiments that the nitrogen in rape cake is, pound for pound, very nearly as immediately effective as the nitroegn in ammonium salts. The proteins thus fall into line with nitrates, ammonia, urea, etc., as compounds which produce all their effect in the season of their application, and leave little appreciable residue behind, in contrast to the collagens (the insoluble nitrogen compounds of wool, skin, bone, etc.) and to the indigestible residues of food. With this distinction in mind, the residual value of the nitrogen in other fertilizers can be roughly estimated : in cakes and seed residues it will be present in the form of protein : in fish guanos, it wll be mainly protein ; in meat guanos, protein and collagen, the latter predominating the poorer the manure becomes and the more it approximates to bone meal. Though these conclusions are based on experiments on the Rothamsted soil alone, it is one that would usually be considered retentive of manure, being both heavy and cool, fairly supplied with rain but not waterlogged.

3. *The phosphatic fertilizers.* — The following table shows the relative total produce yielded by the three phosphatic fertilizers, the unmanured plot in each case being again taken as 100.

	Year of application — Mean of 9	1 year old residue — Mean of 8	2 year old residue — Mean of 7	3 year old residue — Mean of 6
Superphosphate	116.2	109.1	113.8	107.8
Bone meal	114.6	112.4	109.1	105.6
Basic slag	114.5	110.5	104.8	112.0

These results are significant in two directions : 1) that the phosphatic manures persist in the soil, and the residues exert an effect roughly proportional to the amount of phosphate unused ; 2) that superphosphate is as lasting a manure as either bone meal or basic slag. These conclusions are perhaps limited to a soil like that of Rothamsted reasonably well furnished with carbonate of lime, so that the compounds formed in the soil by the soluble phosphoric acid will be mainly those containing lime. With regard to the original object of these experiments, it is clear that the

compensation to be paid for a dressing of phosphatic manure must be spread over a longer period than that given for most kinds of nitrogenous fertilizers.

Phosphatic manures are usually applied in considerable quantity; with the ordinary dressings it may be assumed that at least one-half of the original value of the manure remains in the soil after the first crop has been taken, and compensation to that extent should be given to the outgoing tenant, always assuming that the soil is one needing phosphatic fertilizers, so that the original expenditure was justified. When phosphatic fertilizers are used on suitable grass land, the scale of compensation should be even higher and should last for more than four years, because of the cumulative change wrought in the herbage as well as the actual phosphoric acid left behind.

1095 – **Prohibition of Collection of Guano in the Ballestas Islands, Peru.** — *La Riqueza Agricola*, Vol. IV, No. 27, pp. 161-163. Lima, Peru, 1914.

Owing to the steadily increasing consumption of manures in the development of Peruvian Agriculture, it has been necessary to restrict the exportations of guano from the country (1).

In 1890 the Peruvian Corporation obtained the rights of exploiting the existing deposits, but later deposits were reserved to the native cultivation. As the demand for guano increased in Peru, owing either to the exhaustion of the soil in cultivation or to the extension of the area of land under cultivation or to the adoption of more intensive methods, or to the better education of the rural classes, the simultaneous exploitation of the guano deposits presented great difficulties, since the agricultural interests, which had insufficient command of labour, were injured by the Peruvian Corporation which extracted the largest quantity of guano with the highest percentage of nitrogen. As a result of this, by decree of the 25th February 1909 (promulgated for that particular year but which remained in force until 1914) the guano deposits were divided into two zones: north of Callao for the "Peruvian Coorporation" and south of Callao for the country requirements, except the Ballestas Islands and Lomita Point, which were included in the first zone. This decree however did not remedy the unfair distribution of the product, to the detriment of the agricultural community, as shown in the following table.

This table shows that the Peruvian Corporation extracted six times the quantity of guano obtained for the agricultural community of the country.

Consequently a new Government decree of February 5, 1914 declared the deposits of the Ballestas Islands to be reserved for the three years, after which period they are to be worked for the benefit of the farmers.

This is considered to be the first step towards supplying the needs

(1) See *B.* February 1914, No. 107. — Also: International Institute of Agriculture. *Production et Consommation des engrais chimiques dans le monde.* 2nd Editon, 1914. (*Ed.*)

Yield of Guano from the different zones.

Year	by the Peruvian Corporation		for the farmers of the country
	Ballestas Islands	Total	
	tons	tons	tons
1909	5 342	23 236	2 708
1910	6 650	24 403	4 109
1911	7 700	22 377	3 168
1912	4 272	16 865	4 176
	23 964	86 881	14 161

of agriculture in Peru with all the guano it requires, as is contemplated by art. 21a of the contract cancelling the external debt of 1890, which granted the right of exportation to the Peruvian Corporation.

1096 – **Recent Inoculation Experiments on Virgin Sphagnum-Moor Soils, with Various Cultures of Bacteria of Leguminosae.** — Von Feilitzen and Nyström in *Journal für Landwirtschaft*, Vol. 62, Part 3, pp. 282-283. Berlin, October 1, 1914.

The writers conducted at the Swedish Moor Experiment Station at Jönköping comparative inoculation experiments with inoculated earth, with earth cultures of Kühn's Nitragin, with earth cultures of Simon's Azotogen, and with Earp-Thomas' American Farmogerm. The experiments were carried out in a greenhouse in unglazed stoneware pots, each of which was filled with 33 lbs. of virgin undecomposed sphagnum peat fresh from the pit, all precautions having been taken to prevent any infection by contact.

For every special inoculation, five parallel pots had been prepared and manured at the rate of 4460 lbs. of slaked lime, 357 lbs. of superphosphate, and 357 lbs. of 38 per cent. potash salts per acre.

The plants grown were yellow lupins. The seeds were sterilized by being steeped for 5 minutes in 90 per cent. alcohol and then dried aseptically. The lupins developed quite normally and yielded the following amounts of green stuff per pot :

Not inoculated	347	gram
Inoculated with inoculated soil	541	»
» » Nitragin	583	»
» » Azotogen	601	»

The effect of inoculation was thus very marked, and the yield of lupins was nearly doubled. On the average, Azotogen gave the best, while Farmogerm gave the smallest results. The difference between the first three substances was so small, that considering also the differences in the parallel pots, it is not possible at present to give the preference to one rather than to another.

The examination of the roots showed that Farmogerm had caused much less abundant formation of nodules than the other substances employed.

1097 – **The Consumption of Fertilisers in South China.** — CARLETON, A. E. (Vice Consul General, Hongkong), in *Daily Consular and Trade Reports*, Year 17, No. 214, p. 1404. Washington, September 1914.

The consumption of manures, both natural and chemical, in China has not materially increased in the last few years, but the prospects are rather in favour of an improvement for the future. A large amount of money has been spent already in demonstrating the advantages to be derived from the use of proper manures, and many farmers in the delta of Canton and elsewhere have been supplied with fertilisers free of charge in order that they might see for themselves the efficacy of modern methods.

A considerable trade in bird manure has developed in Canton and the neighbourhood, and it is estimated at about $ 175 000 per annum. This class of manure is sold at about $ 1.75 per picul of 133 1/3 pounds.

A considerable amount of natural manure is exported to China from Macao (Portuguese Colony), the total trade in 1912 being over $ 80 000. To these manures must be added a certain per cent of bean cake which comes from North China. The trade of Chilian nitrate of soda is on the increase, although the total imports into Hongkong amounted last year to only about 1 500 tons. This manure costs c. i. f. Hongkong about $ 50 per ton. This high price has restricted its use to market gardening purposes and for manuring mulberry trees. The Chinese Government treats nitrate of soda as dangerous goods like gunpowder and it is necessary to obtain a permit from the central government for its importation.

The duty on nitrate is about $ 0.17 per 100 lbs. Sulphate of ammonia comes chiefly from England and Germany, and the importations amount to about 1500 tons per year; the c. i. f. price Hongkong is about $ 4.25 per picul. This fertiliser is used mostly for rice but in a very small way, as the price is prohibitive for the Chinese farmers. A very little guano is imported from islands in the Pacific. It is said that a Chinese company intends to work the deposits in Pratas Islands. Most of the phosphate output of Christmas Island goes to Australia and that of Ocean Island to Japan.

The total value of manures, including chemical manures, imported into China during 1912, was $ 503 205 and in 1913 $ 700 872 (1).

1098 – **Fractional Analysis of Wheat.** — BARBIERI, N. A., in *Comptes Rendus hebdomadaires des Séances de l'Académie des Sciences*, Vol. 159, No. 7, pp. 431-434. Paris, August 17, 1914.

By the successive action of various neutral solvents on 44 lbs. of wheat (*T. turgidum*) ten distinct fractions including the ash were obtained.

1st *Fraction:* Washing with distilled water; the slightly coloured solution is concentrated on a water bath after filtration; on treatment with chloroform the mixture separates into two layers, an aqueous solution above and a chloroformed solution below.

(1) See: The International Movement of Fertilizers. *B.* Sept. 1914. (*Ed.*).

2nd *Fraction*: *Maceration.* — The washed grains remain for 15 hours in chloroformed distilled water; they are then stirred and filtered. This highly coloured solution, is concentrated on a water bath and treated with chloroform, when it separates into two layers as above.

3rd *Fraction: Extraction with hot water* (at 50°-60° C.) so as to soften the completely macerated grains, without breaking the periderm. The solution is concentrated on a water-bath and precipitated by means of strong alcohol, the precipitate being separated by filtration.

4th *Fraction: Extraction with boiling water.* — The softened grains are boiled for one hour, causing them to swell and break. The liquid is then filtered through a porcelain filter, concentrated on a water bath and precipitated by means of strong alcohol, the precipitate being separated by filtration.

5th *Fraction*: *Sifting.* — The swollen grains are sifted and treated with strong alcohol, which dehydrates and disintegrates them into a white homogeneous finely granular mass, which has the appearance of a meal without bran, obtained by coagulation with alcohol without mechanical means. This meal is separated from the alcoholic liquor by filtration.

6th *Fraction*: *Pericarps and germs* —. The two epidermal layers and the germ remaining behind on the sieve are extracted with strong alcohol and filtered.

7th *Fraction*: *Chloroformed solution.* -- The preceding solutions in water and alcohol are mixed and distilled until free from alcohol. The residual aqueous solution is concentrated on a water-bath, filtered and treated with chloroform. The two layers thus formed are separated by decantation. The lower chloroform solution is mixed with the preceding chloroform solutions and distilled. The residue is extracted with ether, the solution filtered and the ether distilled. The residue is then extracted with absolute alcohol, the solution is filtered and evaporated in vacuo to dryness, leaving about 2 gm. of a yellow colouring matter known provisionally as *bleine*, which is probably a physiological transformation product of chlorophyll. It does not give the biuret and acrolein reactions, is insoluble in water, but soluble in benzene, carbon disulphide, petroleum ether, etc.

Alcohol is added to the aqueous solution until a slight cloudiness appears. It is then dialysed and the dialysed liquid is concentrated on a water-bath. On the addition of excess of acetone, two salts, monopotassium phosphate and potassium sulphate, are precipitated and purified by dialysis and reprecipitations.

These salts have been obtained by extraction from wheat grown on land which has not received mineral manures for a considerable time. Analysis of the dialysed salts shows the absence of chlorides and monocalcium phosphate.

8th *Fraction: Ethereal solution.* — The flour, seed-coats and germs, and the first two precipitates free from alcohol, are extracted with ether. The ethereal solutions are filtered together and distilled, leaving 225 gms. of an oily residue, which, when treated with acetone, is separated into two parts, one soluble, the other insoluble; they are separated by decantation.

he insoluble portion consists of 211 gms. of an oil insoluble in alcohol and ee from phosphorus, sulphur, nitrogen and ash, and 6gms. of stearin. The etone-soluble portion contains traces of bleine, palmitin, and oleopalmitin, id traces of phosphates that can be separated by dialysis with ether.

The fact that the total phosphorus of a complete ethereal extract of heat is found only among the products of treatment with acetone and that ie supposed lecithins are insoluble in acetone, would appear to prove the bsence of lecithin from wheat, as previously stated by the writer (*Comptes-endus*, 1st August 1910).

9th and 10th Fractions : Insoluble ash. — 1 kilogram of the flour from the h extraction is well dried and incinerated with 1 kilogram of seed-coats id germs. This ash contains the insoluble salts of the flour, 0.30 per cent, id the insoluble salts of the pericarp and germs, 0.62 per cent. They nsist chiefly of calcium sulphate and tri-calcium phosphate. Carbonates re entirely absent.

Former determinations of the mineral matter of plants were entirely ased on studies of the ash. The amounts of acids and bases were deter-ined and the salts were estimated by calculations from these figures with-ut recognising the many changes induced by the high temperatures during cineration. By means of the methods described above all the soluble lts can be separated by dyalisis and the insoluble ones, which probably ie high temperatures do not affect, by incineration.

99 – **Studies on the Mulberry Leaf.** — I. Chemical composition of mulberry leaves attacked by *Diaspis* and of healthy leaves. — II. Chemical composition of mulberry leaves in the morning and evening. PIGORINI, L., in *L'Italia Sericola*, Year I, No. 5, pp. 1-3; No. 6, pp. 11-12: Milan, September and October 1914.

1. No extensive and systematic researches have been hitherto under-ken with the object of establishing the relation between the chemical mposition of mulberry leaves and yield of silkworms. It is generally lmitted that the chemical composition of the leaf has considerable effect n the quality of the silk, and according to ABDERHALDEN and DEAN the nino-acids are of most importance in this connection.

The leaves chosen for the experiments by Prof. VERNON were very se-ously damaged by *Diaspis*. Control leaves were taken from trees of ie same age but free from the disease owing to severe pruning and the esence of *Prospaltella berlesei*. It should be noted that the leaves were thered in the beginning of June at 8 a. m. during dull weather, seeing at leaves are much richer in substance at the end of the day after exposure sunshine.

The 200 diseased leaves subjected to analysis weighed, without petioles, 0.3 gms. while the 200 healthy control leaves weighed 205.6 gms. The sults of the analysis are shown in the fololwing table :

Table I. — *Compostion of the leaves.*

	Healthy trees	Diseased trees
	per cent	per cent
Water	73.4	68.6
Dry matter at 100° C.	26.6	31.4
100 parts of dry matter at 100° C. contain :		
Ethereal extract	3.41	3.87
Crude fibre	12.78	11.34
Ash	12.70	10.54
Total nitrogen	4.19	3.05
Proteid nitrogen	3.78	3.04
Non-proteid nitrogen	0.41	0.46
Percentage of non-proteid nitrogen in total nitrogen	9.78	13.17
100 parts of the fresh leaves contain :		
Water	73.4	61.6
Dry matter at 100 °C.	26.0	31.4
Ethereal extract	0.9	1.2
Crude fibre	3.4	3.56
Ash	3.37	3.30
Total nitrogen	1.11	1.09
Proteid nitrogen	1.005	0.954
Non-proteid nitrogen	0.109	0.144
Percentage of non proteid nitrogen	9.82	13.21

No general conclusion can be drawn from this analysis as to the great or less value of the diseased mulberry leaves, since no account has been ma of the amounts of sugar, starch and other substances such as pentosans whi can be utilised by the silk worms to a greater or less extent. The followi conclusions however may be drawn :

1) The leaves attacked by the *Diaspis* become thicker, tougher a almost coriaceous and seem therefore less digestible than healthy leaves

2) The low percentage of water is not conducive to their easy dige tion and assimilation.

3) The total nitrogen and protein of the dry matter is considerab less in the diseased leaves.

4) The percentage of fatty matter, on the contrary, is increased.

5) crude fibre is more abundant in the fresh leaves of the diseas plants.

Thus, healthy mulberry leaves have a greater food value than tho diseased, though the differences may not be sufficiently great to justify t rejection of diseased leaves as food for rearing silkworms.

II. — For these experiments leaves were collected on land belongi the Royal Silkworm Station of Padua, at sunset after five days duri which the leaves had had good exposure to sunlight, and at daybreak.

TABLE II. — *Chemical composition of mulberry leaves of the variety Limoncina collected during the first days of September,*

	Morning		Evening	
	Percentage of dry matter	Percentage of fresh matter	Percentage of dry matter	Percentage of fresh matter
ater	—	68.419	—	63.156
ry matter at 100° C. . . .	—	31.581	—	34.844
thereal extract	5.521	1.743	5.443	1.880
otal nitrogen	2.445	0.772	2.534	0.883
roteid nitrogen	2.309	0.729	2.368	0.824
on-proteid nitrogen	0.1105	0.043	0.166	0.059
otal saccharides calculated as glucose	7.326	2.313	8.064	2.810

These results support the following conclusions :

1. The analysis of the leaf distinctly shows the characteristics of autumn aves. The percentage of water is less and the percentage of dry matter greater than during the spring and summer, as seen from KELLNER'S ana- ses and results obtained by the writer on the leaves of healthy mulberries the beginning of June. The greater quantity of substances extracted by her (fat) is in agreement with the results of SCHULZE and SCHÜTZ con- rning the leaves of *Acer Negundo* (Die Stoffwandlungen in den Laub- ättern des Baumes insbesondere in ihren Beziehungen zum herbstlichen lattfall, *Landw. Versuchs-Stationen*, XXI, 313, 1909). In these analyses e ethereal extract of the dry matter was 4.87 per cent one evening during ay and reached 10.86 per cent on the evening of September 6. The de- ease in total nitrogen, proteid nitrogen and non-proteid nitrogen of the utumn leaves compared with spring and summer leaves is very apparent d agrees entirely with the results of KELLNER'S analysis, as well as with ose of SCHULZE and SCHÜTZ.

2. As in the case of other plants, mulberry leaves during the day un- r the action of sunlight increase their quantity of organic matter, including ts and nitrogenous matter, both proteid and non-proteid, as well as carbo- drates. These results are fully confirmed by those of SCHULZE and HÜTZ for the leaves of *Acer Negundo*.

3. Leaves collected at sunset contain more food material than leaves llected in the morning.

It is reasonable to suppose that these differences will be still greater ring the spring and summer.

1100 – **Methods of Estimating Carbohydrates. II. The Estimation of Starch in Pla Material** (1) — DAVIS, W. A., and DAISH, A. J. (Rothamsted Experimental Stati in *The Journal of Agricultural Science*, Vol. VI, Part. 2, pp. 152-168. Cambrid May 1914.

The writers summarise their conclusions as follows :

" 1. The Sachsse method of estimating starch is unreliable in t case of plant material ; not only does the presence of pentosans falsify t results, as pentoses are formed during the hydrolysis, but actual destructi of dextrose occurs during prolonged treatment with dilute acid.

" 2. O' Sullivan's method gives low results owing to the loss of dextr which occurs during the purification of the solution after the conversi by diastase.

" 3. A method is described for estimating starch based on the use takadiastase ; under suitable conditions this converts the starch into malto and dextrose only, and no loss of these sugars occurs when the solution treated with clearing agents such as basic lead acetate.

" 4. The necessity of removing substances soluble in water, such gums, etc., which are optically active and thus cause error in the esti ation of starch in plant material is emphasised. Special care is al necessary in sampling ".

1101 – **The Estimation of Hydrocyanic Acid in Feeding-Stuffs and its Occurren in Millet and Guinea Corn.** — FURLONG, J. R., in *The Analyst*, Vol. XXXI No. 463, pp. 430-432. London, October 1914.

A new method of estimating hydrocyanic acid in feeding-stuffs described ; it consists essentially in the conversion of hydrocyanic ac into Prussian blue and in the comparison of the resulting coloration wi standards ; it avoids the disturbing influence of hydrolytic and distillati

oducts which accompany the hydrocyanic acid in the usual iodine or ver nitrate titration methods.

Millet and guinea corn (*Panicum maximum*) plants from Northern geria were recently examined for hydrocyanic acid by the above method. ie results are shown in the Table on the opposite page.

All the young plants contained a cyanogenetic glucoside, the amount ntained increasing up to a certain point in the life-history of the plant d then diminishing, so that the full-grown plants were free from such dies. The results indicate the probable course of the development d disappearance of the cyanogenetic glucosides in millet and guinea corn ants, but no general conclusions can be drawn until a larger number of mples have been investigated.

02 – **Some Accessory Factors in Plant Growth and Nutrition.** — Bottomley, W. B. (King's College, London) in *Proceedings of the Royal Society*, Vol. 88, No. B 602, pp. 237-247. London, September 15, 1914.

During the summer of 1913, a number of experiments were made at e Royal Gardens, Kew, (1) on a series of plants to test the manurial lue of Sphagnum peat which had been incubated with a mixed culture aërobic soil organisms for a fortnight at a temperature of 26° C. It d been discovered that by this bacterical treatment the humic acid in e peat is converted into soluble humates, and this bacterised peat, after erilisation, forms an excellent medium for the growth and distribution nitrogen fixing organisms. As the experiments progressed it was evint that, in addition to the ordinary plant food constituents, there was esent in the bacterised peat a substance which stimulated growth in a narkable manner. Further experiments showed that this substance s soluble in water, and was effective in very small quantities. It was und that seedlings of *Primula malacoides* potted up in loam, leaf-mould d sand, and treated twice with a water extract of only 0.18 gm. of cterised peat, were, after six weeks' growth, double the size of similar treated plants, and it was noted that flower production and root delopment were promoted equally with increase of foliage.

These results suggested that the growth stimulating action of the cterised peat might be due to the presence of a substance or substances nilar in nature to certain accessory food bodies known to play an imrtant part in animal nutrititon. The latter are also known to be soluble water and alcohol, so the bacterised peat was extracted with absolute ohol, the extract was evaporated to dryness, and taken up with warm tilled water, portions of 100 cc., containing the extract from 1 gm. peat, being placed in each of 12 flasks. Six of these were boiled for e minutes and all, including six other flasks, containing only distilled ter, received 0.2 gm. of potassium phosphate (K_2 H Po_4), 0.02 gm. magnesium sulphate and 0.2 gm. of calcium carbonate, and were inoated with 1 cc. of a uniform suspension of *Azotobacter chroococcum*. e contents of two flasks from each of the three series of six were analysed

(1) See also No. 410, *B.* May 1914.

at once to serve as controls while the remaining four of each series were incubated for eight days at 26° C., at the end of which period they were analysed by the Kjeldhal process for their nitrogen content. The results are given in Table I.

TABLE I.

Series		Nitrogen content	Nitrogen fixation
		mgm.	mgm.
I. Complete food	1 Control	0.4	—
	2 »	0.4	—
	3 Culture	4.6	4.2
	4 »	4.4	4.0
	5 »	3.6	3.2
	6 »	4.4	4.0
II. Complete food + alcoholic extract of bacterised peat	1 Control	2.6	—
	2 »	2.3	—
	3 Culture	20.7	18.2
	4 »	20.5	18.0
	5 »	19.9	17.4
	6 »	20.9	18.4
III. Complete food + boiled alcoholic extract of bacterised peat.	1 Control	2.3	—
	2 »	2.5	—
	3 Culture	19.6	17.2
	4 »	19.0	16.6
	5 »	20.6	18.2
	6 »	19.4	17.0

The results indicate clearly that there is present in the bacterised peat a substance which stimulates plant growth and which is of fairly stable nature, as almost equally good results were obtained with the boiled as with the unboiled extract.

In order to test whether the active substance is present as such in the original peat, or whether it is produced in the bacterised peat as a result of treatment, an extract of the raw peat was made in precisely the same manner as described for the bacterised peat and incubated as before. No increased growth was apparent in the cultures containing alcoholic extract of raw peat.

The active substance being evidently produced in the bacterised peat as a result of treatment, and since this treatment consists essentialy in the production of soluble humates by bacterical action, a test was made to ascertain whether the chemical production of soluble humates would be

equally effective. Two equal portions of raw peat were saturated with solutions containing 1 per cent. of their weight of sodium carbonate, and were stirred at frequent intervals for several hours. One portion was allowed to dry slowly at room temperature and an alcoholic extract taken as before; the other portion was leached with water until the washings were colourless, the water extract was then evaporated to dryness and the residue thus obtained extracted with alcohol. The effect of both the alcohol extracts was tested with *Azolobacter* and again the cultures failed to reveal any stimulation of the organism.

The accessory bodies concerned in animal nutrition have been shown to be precipitated by phosphotungstic acid; the alcohol extract of the bacterised peat was therefore treated with phosphotungstic acid and a fraction separated which was used in solution in the proportion of 17 parts per million. This fraction was tested upon wheat seedlings: ten seeds were germinated in clean sand in each of nine pots which were arranged in three series of three pots each. Series I was treated with a complete food solution (containing nitrogen, phosphorus and potash estimated as NH_3, P_2O_5 and K_2O in the proportion of 400, 200 and 1220 parts per million respectively). Series II was treated with complete food plus alcoholic extract from 10 gms. of peat per litre of solution, and Series III with complete food plus phosphotungstic fraction from 10 gms. of peat per litre of solution. Each pot was treated with 100 cc. of its solution one week after sowing the seed and the treatment repeated once a week for five weeks at the end of which period the plants were uprooted, washed, dried and weighed. The results are given in Table II. —

TABLE II.

Series	Weight of 30 plants (green)	Increase over Series I
	gms.	per cent.
I. Complete food	11.94	—
II. » » + alcoholic extract . . .	14.46	21.1
III. » » + phosphotungstic fraction	15.45	29.4

The results indicate that the stimulative substance in bacterised peat is precipitated by phosphotungstic acid and that this phosphotungstic fraction is quite as effective as the original alcoholic extract.

Again working by analogy with the accessory bodies concerned, in animal nutrition a further fractionation was carried out with silver nitrate. The final solution contained 0.35 part per million of the dry silver fraction and was also tested concurrently with the phosphotungstic fraction upon wheat seedlings as before. The results are given in Table III.

TABLE III.

Series	Green weight 45 plants	Increase over Series I	Dry weight at 100° C.	Increase over Series I
	gms.	per cent.	gms.	per cent.
I. Complete food	64.5	—	13.3	—
II. » » + phosphotungstic fraction	96.8	50.0	16.4	22.7
III. » » + silver »	91.5	49.6	15.7	17.7

The silver fraction having thus given results approaching the phos photungstic fraction its effect was next tested on wheat seedlings in wate culture. At first the growth of the test and control plants was approxi mately equal, but after the first fortnight the seedlings in the contro set seemed unable to utilize the food elements supplied to them whil those in the silver fraction series went on growing up to the end of th experiment (50 days).

It has previously been shown that seeds of barley, oats, peas an flax fed to guinea pigs, contained no accessory bodies having a curativ effect on scurvy, but that these were developed during germination. Thes facts indicating the possibility of the development during germinatio of special growth substances which enable the embryo to utilize the foo material present in the seed, a further series of water cultures was carrie out in which the wheat seedlings were carefully separated from their seed as soon as possible after germination. The difference in growth betwee the control and silver fraction set was even more marked than in the pre vious experiment as the control set never increased more than 5 per cent of its original weight, while at the end of the experiment the silver fractio set had increased 59 per cent. of its original weight.

It would therefore appear that during the germination of wheat seed certain substances are formed which enable the young embryo to utiliz the food materials present. The supply of these substances formed b the seed during germination is sufficient to establish the embryo as a independent seedling, then some other source is necessary. It has bee shown that these accessory food substances are produced when peat (de cayed vegetable matter) is acted upon by certain soil bacteria, and th natural inference is that during the bacterical decomposition of organi matter in the soil, that is during humus formation, these substance are formed, hence the beneficial effect of farmyard and other organi manures. The specific action of these accessory substances is not know and experiments are in progress to test various hypothesis in thi connection.

PLANT BREEDING

1103 — **Lax- and Dense-Eared Wheats.** — PARKER, W. H., in *The Journal of Agricultural Science*, Vol. VI, Part 3, pp. 371-386. Cambridge, September 1914.

The crosses which are here described were made in 1900 by Professo Biffen, with the object of continuing his investigations on inheritance o

susceptibility and immunity to attacks of *Puccinia glumarum*. The material, however, displayed so much diversity in the density of the ears that it was ultimately used only for investigating the mode of inheritance of this character.

With regard to preceding investigations, it should be noted that SPILLMAN, STRAMPELLI and v. RÜMKER all get an F_1 of intermediate character, and an F_2 of 1 dense : 2 intermediate : 1 lax ; while WILSON and TSCHERMAK find dense to be distinctly dominant in F_1, and the former got a ratio of 3 dense : 1 lax in F_2. NILSSON-EHLE and BIFFEN obtained different results from different crosses.

In the present investigation, two crosses were utilized : American Club × Square White and American Club × Square Ghurka.

American Club is a typical *compactum* wheat, while Square White and Square Ghurka are both *vulgare* wheats of hybrid origin which had bred true to type for a series of years.

In *compactum* wheats the average space between the spikelets of the ear in millimeters, or the density, is 2.1 or 2.2 while in *polonicum*, whieh is typical of the lax ear, it is 6.6. Between these two extremes there is an almost umbroken series among the *vulgare* wheats : the internode length of Square Ghurka vaiies from 3.9 to 5.1 and that of Square White is practicaly the same; they would thus both be considered lax by NILSSON-EHLE, whereas American Club is a typical *compactum* with internode length from 1.9 to 2.5,

The F_1 generation of American Club × Square Ghurka was apparently almost intermediate, but the tendency was toward the dense parent.

F_2 showed, besides all intermediate forms, a large number of plants the ears of which were either more lax or more dense than the ears of either parent. Their curve, though continuous, gives evidence that segregation is taking place. Offspring was grown from each plant of F_2 ; in F_3 nearly all of the lax-eared plants bred true to laxness and a certain proportion of the dense-eared plants bred true to denseness, but it was practically impossible to see which plants bred true to their particular degree of denseness or laxness. It is particularly noticeable that although a large porportion of the very dense-eared plants threw no lax, there were several which were heterozygous, and that the curves which the F_3 series form have shifted towards the high, or lax, side.

Similar results were obtained in the F_2 and F_3 of the Square White × American Club cross.

From the Square Ghurka American Club cross, 36 F_3 plants were grown on, being chiefly selected either because they lay between the two peaks of the curve or because they lay at the extremes of the curve. In the curve for the partial F_4 (1913), the peaks revert almost exactly to the position which they held in 1911, and this seems to suggest that some such factor as the wetness of the summer of 1912 was responsible for the shift shown in the curves for that year.

A fact which is noticeable in the descendants of the F_2 and F_3 plants is that in the non-splitting dense and lax, especially in the former, there seems to be a distinct correlation between the degree of density of the parent and the average degree of density of the offspring. There can only be two possible theories to explain this phenomenon. It may be due to nutrition, admitting that the grain of the very compact ears is lighter than that from ordinary ears, that weak plants develop from small grain and that the ears of weak plants are appreciably more dense than those of normal plants. But this theory is not very probable (see the works of JOHANSSEN and others). It seems safe therefore to conclude that the alternative theory is the true one, namely, that underlying the main 3 : 1 ratio, there are other factors which have a modifying effect on the laxness or denseness of the ear. This is probably also the explanation of the appearance of plants which exceed the limits of either parent.

From the comparison of the number of nodes and the rachis length of the ears of lax, dense and Squareheads Master wheat of 1912 (wet year) and of 1913 (relatively dry), it appears that the first number in 1913 was greater respectively by 33, 39 and 10 per cent, and the second was respectively greater by 15 and 21 per cent and smaller (Squareheads Master) by 2 per cent. Consequently, the larger variation is a meristic variation, and external conditions would seem to cause an alteration of nearly 40 per cent in the number of parts. As the nodes are already completely formed in young wheat plants, the conditions which control this variation can only be operative during the early life of the plant, while those which control the length of the rachis act during the whole growing-period of the plant. Thus weather experienced after the earlier period of growth might nullify the effect caused by the weather of that time, and then the variation of the two characters would become practically independent.

From the above it will be seen that the actual method of classifying wheats according to the density of their ears is unreliable, as the number of internodes and the total rachis length vary largely from season to season and it might be possible to get a variability of well over 50 per cent in a variety from one year to another, and that even when grown on the same soil with identical manurial and cultural conditions.

1104 – **On the Emasculation of Giant Maize in Serbia.** — HECKEL, EDOUARD, in *Comptes Rendus hebdomadaires des séances de l'Académie des Sciences*, Vol. 159, No. 16, pp. 595-597. Paris, October 1914.

Previous work (1) by the writer has shown that the giant maize of Serbia (13 feet in length of stems and 8 inches in length of ear), which normally contains about 9 per cent of saccharine matter in its sap at the beginning of September, has its sugar content increased to a maximum of 12 per cent by partial removal of the male flowers and to 11.57 per cent by removal of the female flowers. After the end of September the amount of sugar rapidly diminishes and at the period of harvest it is less than half.

Later experiments with plants grown close together under identical

(1) See No. 1618, *B.* Dec. 1912. (*Ed.*)

conditions have shown that the effect of emasculation on the sugar content of the sap is very variable and may even be negative. With the formation of a reserve of sugar there is also a formation of starch reserves, except when the sugar content remains low after removal of the male flowers or when the flowers are left intact.

The writer proposes to increase and to fix the sugar content by means of selection. Partial emasculation does not affect the yield of grain and is easy to carry out; it also provides a good winter forage much liked by stock.

1105 – **Alfalfa Hybridization.** — SOUTHWORTH, WILLIAM (Department of Plant Breeding, Ontario Agricultural College, Guelph, Canada) in *The Journal of Heredity*, Vol. V, No. 10, pp. 448-457 + 3 figs. Washington, October 1914.

Nothwithstanding the immense economic value of the present day strains of alfalfa grown in the United States they may still be improved on at least two lines:

1. To obtain a strain having the capacity to seed more freely under various environmental conditions.

2. To obtain a variety which will be better adapted for grazing

The first part of the problem might be solved by simple selection; unfortunately all the types which offer possibilities for grazing appear to be below the average in the production of seed. The writer therefore endeavoured to solve the problem by crossing with black medick (*Medicago lupulina* L.), which yields good grazing but not good hay. In the United States it is looked upon as a weed.

At the Ontario Agricultural College at Guelph experiments were commenced with the aim of breeding better strains of alfalfa. It was found necessary to arrange a preliminary series of experiments in order to elucidate the complex and still unsettled problem of the pollination of its flowers. The results obtained showed: 1) that alfalfa flowers are incapable of becoming fertilized when insects do not gain access to the flowers (1); 2) that if the stamens and pistil be liberated artificially the flower is capable of producing seeds; hence it is not self-sterile; 3) that bees are the most numerous visitants, but they have the power to extract the nectar from the flower without causing pollination; the bumble bee is fairly active in fertilizing the flowers; a species of *Andrena* is apparently very useful, too; but the most effective of all was found to be a wild bee belonging to the *Megachile* group, as it will pollinate from eight to twelve flowers a minute.

DARWIN and BURKHILL had observed, and the writer has confirmed their observation, that the flowers of *Medicago lupulina* are autogamous and produce seed even without the aid of insects. Burkhill found that where these flowers were left exposed to the visits of insects 95 per cent. produced seed; when enclosed in a net 75 per cent. set seed. In practice

(1) The results obtained by PIPER and his collaborators show that in sufficiently good conditions of temperature and dryness of the atmosphere, alfalfa produces seed spontaneously also (by automatic pollination) without the assistance of insects. See (*Ed.*).

M. lupulina produces abundant seed under any condition of climate and soil.

The writer commenced the work in 1911. The F_1 generation (24 plants) showed considerable variations, even among individuals produced from different seeds out of the same pod, and for the most part the plants differed considerably from both parents. Their height ranged from 7 to 23 inches; the stem in some was thin and flexible, in others rigid, and the leaves varied from few and small to many and densely crowded.

The second generation was obtained from a plant distinguished for its vigour and abundance of flowers and seeds. The plants composing it showed all the degrees between Talls and Dwarfs, ranging in height from 2 to 11 inches, 78 plants being above the height considered as medium, namely 5.5 inches, and 30 below it, which would give the ratio of Talls to Dwarfs as 2.6 to 1 instead of the calculated Mendelian ratio of 3: 1. As for the habit of growth, 88 plants were non-erect (3 prostrate and 85 decumbent) and 20 erect (12 semi-erect and 8 erect), which gives the ratio 4.4 non-erect to 1 erect, instead of 3 :1.

The experiments are being continued. In the course of these tests the writer observed that those seeds which remained hard and dormant after having been for several days in the germinator at 70° F., sprouted in one or two days, when replaced in the germinator after immersion for 10 minutes in strong commercial sulphuric acid and subsequent washing free from acid. The few seeds which resisted this treatment were treated to a second immersion in sulphuric acid, after which they sprouted.

AGRICULTURAL SEEDS

1106 – **Tree Growth and Seed.** — BERRY, JAMES B (Department of Forestry, Pennsylvania School of Agriculture, State College, Pa) in *The Journal of Heredity*, Vol. V, No. 10, pp. 431-434 + 2 figs. Washington, October 1914.

Dr. ARNOLD ENGLER (1), at the Forest Experiment Station of Zürich, has a number of investigations in course, which illustrate the inheritance by seedlings of the main characteristics of the parent tree. In one of these experiments two plots are occupied by spruce seedlings varying in height from 3 to 10 feet. The seedlings on Plot I show more than 50 per cent. crooked and twisted plants, while Plot II contains less than 5 per cent. of this material. The seed used on Plot I was collected from a gnarled and twisted mother tree, yet not an extreme form. The seed used in Plot II was taken from a mother tree of normal form grown under the same conditions as the deformed one.

A second experiment occupies two adjacent plots, both supporting a growth of spruce seedlings about 15 years of age planted at the same distances from each other. The seedlings on Plot I, while entirely healthy and vigorous, are rounded in form, very dense in character and with branches uniformly small; their height ranges from 12 to 30 inches and they are as broad as they are high. The seedlings on Plot II are entirely normal in form and growth; they are between 3 and 6 ft. in hight. The seeds of Plot I were taken from a mother tree which was characterized by density of

(1) Influence of Source of Seed. — *Journal of Heredity*, Vol. V, No. 4, p. 185, April 1914.

branching and slow growth, while, those of Plot II were from a normal mother tree grown on the same quality site and under similar conditions.

A third investigation deals with the effect of temperature in its relation to transmitted characteristics. Seed was collected from regions of mean temperature varying by 10° F, from that of Zürich to Northern Sweden, altitude and latitude both forming a basis for computation. Two or three rows were planted from each lot of seed, the arrangement being in regular order from the lowest to the highest mean temperature. At present, eight years after the inauguration of the experiment, there results a "terrace" like formation, the relative height growth varying directly with the mean temperature. Further, the plants resulting from seed from a locality of high mean temperature are the first to show active growth in the spring and, having a longer growing season, their annual increment is greater and their form is less dense. It is thus very important for the forester to know the origin of the seeds and the quality of the mother plants.

These facts may afford an explantion for some of the unsatisfactory results in forestry. For instance it is said that Scots Pine (*Pinus sylvestris*) gives very poor results in the United States and that it is not adapted to that country. The writer suggests that better results might be obtained by choosing the seed better.

The seedling resulting from seed from a region of higher mean temperature than that of the locality in which it is to grow will preserve its original slim bearing and the long willowy previous year's growth is easily crippled or broken by the weight of the snow. The seed should be chosen from localities having an average altitude and temperature similar to that of the place where it is to be sown, and lastly when regeneration of the forest is to be obtained by spontaneous seeding, the best plants should be left for this purpose and not the deformed and the cripples, as is too frequently done at present.

1107 — **The Controlling Influence of Carbon Dioxide in the Maturation, Dormancy and Germination of Seeds.** — KIDD, FRANKLIN (Fellow of St John's College, Cambridge) in *Proceedings of the Royal Society, Series B*, Vol. 87, N.s B. 597 and 599, Biological Sciences, pp. 408-422 and 609-625. London, June 1914.

The object of this research is to solve the problem of the non-germinating of maturing seeds while still upon the parent plant and the large number cases of delayed germination or non-germination of shed seeds which to all appearances are in good condition for germinating.

The dormancy of moist seeds must be due either to the absence of an essential stimulus or to the presence of an inhibitory agent. CROCKER found that *Xanthium* seeds would not germinate at a temperature of 19° C. though provided with a sufficient supply of water and a normal atmosphere with a partial pressure of oxygen equal to 150 mm. On removal of the testa, however, germination immediately took place. SHULL found that these seeds will germinate at a temperature of 21° C. with a minimal oxygen pressure of 12 mm. when the seed coat is removed, thus showing that the wet testa is able to reduce the partial pressure of oxygen in its passage through it, from 150 mm. pressure to less than 12 mm.

It is possible that the absence of germination during the maturation of the seed and later during its normal resting period may be due not only to an insufficient oxygen stimulus but also to some inhibitory cause, such as a relative rise in the actual carbon dioxide pressure in the embryo tissues.

Experiments were conducted with various seeds in atmospheres with various partial pressures of carbon dioxide. It was found that increases in carbon dioxide pressure retarded germination and that this retardation was not accompanied by injury. The seeds used in these experiments fell into two classes: 1) those which germinated at once after removal from the inhibitory doses of carbon dioxide (beans, cabbage, barley, peas, onions); 2) those in which the retardation continued indefinitely after removal from the carbon dioxide (*Brassica alba*) and was terminated only by complete drying and re-wetting, or by the removal of the testa.

This suggests that carbon dioxide lowers the degree of permeability of the testa in the second class of seeds, thus causing a reduction in the amount of oxygen reaching the embryo and a relative rise in the actual carbon dioxide pressure in the embryo tissues. The condition of prolonged inhibition after removal to air produced in *Brassica alba* is strikingly suggestive of the condition of seeds often met with in nature, the germination of which is delayed in spite of suitable conditions of temperature and water. Similar results were obtained with *Brassica alba* seeds in the soil under natural conditions by carbon dioxide arising from decaying vegetable matter. The high carbon dioxide content of the soil was found to continue for a considerable period (7 months). *It would therefore appear that caution is necessary in sowing seed in ground in which green crops or dung has been recently ploughed in.*

A further series of experiments was carried out to determine the relation of the retarding effect of carbon dioxide to temperature and oxygen supply. It was found that low temperatures and low oxygen supply both increased the inhibitory effect of given partial pressures of carbon dioxide and inversely a rise of temperature or rise of the partial pressure of oxygen diminished the inhibitory value of the given carbon dioxide pressure.

The growth of the embryo of a seed proceeds continuously after fertilisation and up to a certain point resembles in some respects the subsequent growth on germination. Beyond this stage partial inhibition begins and increases in the case of most seeds until, at the stage of complete maturation, growth is arrested or suspended. Experiments were conducted to ascertain the nature of this inhibiting factor. It was found that removal of the testa in the case of peas greatly increased the rate of germination, and that beans, germinated after complete air drying in the laboratory, at the moment of sprouting actually contain less water than when originally removed from the fresh green pods. It would appear therefore that neither lack of water nor any physiological insufficiency can be regarded as the factor limiting germination.

The carbon dioxide content of maturing and germinating seeds was then determined by grinding with baryta and titration with hydrochloric

acid. It was found that the carbon dioxide content of maturing seeds was considerably greater than that of germinating seeds in the case of peas and beans.

In the case of seeds with a low carbon dioxide content, the writer confirmed the conclusions of DRABBLE and LAKE that small quantities of carbon dioxide have a stimulating effect on germination. It would appear therefore that the effect of larger percentages of carbon dioxide is that of a true narcotic and that the *results induced by carbon dioxide in the resting seed are a phase of narcosis.*

In the case of rapidly deteriorating seeds, such as those of *Hevea brasiliensis*, the carbon dioxide naturally produced by respiration in a closed flask rose to 40 per cent, and the presence of this was found to be accompanied by a marked prolongation of the vitality of the seeds.

The biological importance of the dormancy of moist seeds in relation to the struggle for existence and in evolution is also pointed out.

CEREAL AND PULSE CROPS

1108 – **Studies upon Influences affecting the Protein Content of Wheat** (1). — SHAW, G. W., in *University of California Publications in Agricultural Sciences*, Vol. 1, No 5, pp. 63-126. Berkeley, Cal. October, 1913.

In 1905 the Merchants' Exchange of San Francisco, the State Board of Trade, the Sacramento Valley Development Association, and the more prominent millers and grain dealers of California, called the attention of the Agricultural Department of the University to the low gluten content of the local grown wheat, which necessitated the importation of many hundred tons of wheat per year to maintain the quality of Californian flour.

In 1906 the Department of Agriculture initiated these researches to investigate : 1) the effect of changes of environment upon the growth of cereals, particularly as regards the composition of the wheat kernel and with special reference to the causes of the production of a low protein content; 2) to discover or produce such wheat as will yield the largest profit per acre for the farmer, and will supply the millers with wheat of superior quality ; 3) to conduct similar experiments with oats, barley, and other cereals as may be desirable ; 4) to determine the effectiveness of various methods of culture as affecting the production of cereals.

This publication contains a very detailed account of the results of researches on the variation in the protein content of wheat grown under different conditions as regards : 1) latitude, 2) season, 3) time of planting, 4) time of harvesting, 5) amount of sunshine, 6) irrigation, 7) reduction of night temperatures and 8) the different fertilizers.

Summarising the results of this work carried out over a period of six years the writer draws the following conclusions :

1. There are important seasonal, varietal, and individual variations in wheat plants with respect to protein content.

2. The chief factor causing the most pronounced variation in protein content is climate, particularly the moisture supply in the final stages of

(1) See also No. 228, *B.* March 1913 and No. 331, *B.* April 1914. (*Ed.*).

growth. Wheat grown in the coast States is, as a class, much lower in gluten content than wheat grown in the central-west or the northwestern States.

3. The tendency of wheat kernels to change from a glutenous to a starchy condition is not constant, but is mainly dependent upon the individuality of the plant and seasonal influences, particularly moisture supply in later stages of growth. The use of a perfectly typical glutenous seed is invariably followed under Californian conditions by a lowering of the gluten content, as indicated both by the physical appearance of the grain and by its protein content.

4. In wheats all of which are entirely starchy there may be a reversion to an entirely glutenous condition in a single season, or the reverse may occur, according to the seasonal condition.

5. Allowing the grain to stand on the straw in the field until fully ripe does not materially affect the protein content.

6. The protein content of wheat is affected by the time of seeding, the product of late-seeded grain having a higher percentage of protein than that of early-seeded grain.

7. The protein content of wheat is very largely influenced by the water content of the soil in the later period of its growth, and the effect of either irrigation or rainfall during this period is to lower its protein content.

8. The percentage of sunshine which the grain receives during its period of growth has a somewhat direct bearing upon its protein content, but other seasonal conditions are more important.

9. Retarding the growth through cooling the atmosphere has a tendency to increase the protein content.

10. The quantity of available nitrogen beyond that required to supply normal growth has little, if any, influence upon the protein content.

11. The low gluten content of Californian wheats is not due to soil exhaustion, but rather to the following causes: *a*) the long growing period, *b*) relatively early seeding, *c*) the use of varieties of naturally low gluten content, and *d*) the absence of selection of highly glutenous seed.

1109. — **The Variaton of Gluten in Wheat Flour and Grain.** — MARCHADIER and GOUJON (Director and Chemist of the «Laboratoire municipal agréé du Mans»), in *Journal de Pharmacie et de Chimie*, Year 106, Series 7, Vol. X, pp. 191-202. Paris, September 1914.

According to BALLAND (1), the decrease in gluten in flour observed of late years, that is to say since roller-mills have been substituted for grindstones, is due not only to a degeneration of the grain, but also to methods of grinding which eliminate the germ and the portions of the grain which are richest in nitrogen, to more complete sifting and to the hydration caused by excessive moistening with a view to facilitating the removal of the pericarp.

(1) See No. 778, *B.* Aug. 1914. (*Ed.*).

According to VUAFLART, the decrease is to be attributed to atmospheric variation. SCHRIBAUX observes that in 1911 (a hot year) the grain was much richer in gluten than in 1912 (a rainy year) and that glutenous varieties grown near Paris had a lower gluten content. On the other hand the gluten content increases in the case of wheat grown on almost virgin soil, without any fertilizer, in the plains of America.

Gluten is a characteristic of wheat flour. It is stated that gliadin and glutenin (which is an oxidised anhydride of the first) are wholly, or partially, transformable into one another. FLEURENT has shown that a flour produces a softer dough and more digestible bread, the nearer the composition of the gluten approaches to 75 per cent gliadin and 25 per cent glutenin. A deviation of only 2 per cent from this proportion is sufficient to cause a noticeable difference in the bread.

It has been observed that the addition to wheat flour of only a small quantity of other flours causes a great change in the gluten, and a decrease in the amount which is capable of coagulating. When the amount of the other flour introduced passes beyond certain limits, the gluten no longer coagulates at all. Thus its power of coagulation disappears on the addition of 40 per cent of rye flour (COLLIN), 40 per cent of barley meal, 65 per cent of rice flour, 70 per cent of maize flour. These facts have been proved by experiments made by the writers.

The coagulation of gluten is also prevented or hindered by the addition of powdered minerals, and by wheat starch, which suggests that the result is due simply to physical causes.

If the amount of gliadin be diminished, the quantity of gluten decreases in a parallel manner, and since the smallest variation in the proportion of gliadin to glutenin is sufficient to cause very sensible changes in the bread-making quality of the gluten, in the same way a variation in the total of gliadin + glutenin in the paste brings about very rapidly: first the occlusion of a part of this gluten, and finally the complete loss of its power of coagulation.

As has been said, this abnormal decrease in the coagulable gluten has also been noted in the wheat grain. Further, it has been recorded, that gliadin and glutenin are easily transformed into one another, the slightest influence being sufficient to bring about the change. In germination, the ferments which produce solubility hydrate the glutenin, transforming it into gliadin: the proportion $\frac{\text{glutenin}}{\text{gliadin}} = \frac{1}{3}$ is altered, whence the flour gives a lax dough and the bread made from it rapidly hardens and is indigestible.

By too rapid grinding, the grain becomes heated, this giving rise to the dehydration and oxidation of the gliadin to form glutenin.

Keeping damp flour in a warm place in the presence of dry air causes slight oxidation and dehydration of the gliadin and improvement of the product. If, on the other hand, a good flour is kept in a damp warm atmosphere, the glutenin becomes hydrated and is transformed into gliadin and the product deteriorates. Such hydration may also be the effect of

meteoric influence: in fact the wheat of wet seasons always yields inferior flour.

It is well known that when the acidity of flour is above 0.050 per cent, the coagulation of the gluten is hindered and its elasticity either lessened or lost. An increase of 0.025 per cent in acidity corresponds to a decrease of 10 per cent in the damp gluten *i. e.*, of a little more than 3 per cent in the dry gluten.

It is logical to admit a similar effect of acidity upon the grain also, and it cannot be denied that acids influence the formation of gluten.

Nowadays, and especially during the last twenty years, the soils under wheat in Europe have been dressed with superphosphates, which carry into the soil their acid reaction.

This super-acidity due to strong acids (sulphuric chiefly and hydrofluoric in some cases) must have some effect upon the elaboration of gluten in the grain. In fact species of wheat rich in gluten become softer when cultivated in Beauce and Brie, districts which are highly cultivated and much manured with superphosphates, while the gluten is preserved in wheat grown on the unmanured soils of America.

There are no data at hand to show that the acidity of grain has diminished during the last twenty years, but according to the writers three facts speak in favour of their hypothesis :

1) On adding rye flour to wheat flour, while the gluten diminishes the acidity increases.

2) Rye flour, which contains no gluten, possesses an acidity ten times greater than that of wheat flour.

3) Acetic acid oxidises and dehydrates gliadin, and when a wheat flour with the proportion $\frac{\text{glutenin}}{\text{gliadin}} = \frac{1}{3}$ is treated with this acid, a gluten is obtained by evaporation, in which this proportion is equal to one.

In conclusion, the diminution of gluten in native wheats is principally due to the effect of acidity.

1110 – **Experiments with Autumn Sown Crops in Ontario, in 1911.** — ZAVITZ, C. A., in *The Agricultural Gazette of Canada*, Vol. I, No. 9, pp. 740-742. Ottawa, Canada, September 1914.

Winter wheats. — About 280 varieties of winter wheat and a large number of selections and crosses have been grown under experiment at the Ontario Agricultural College at Guelph, during the past twenty-five years. Nearly all the varieties have been carefully tested in each of five years, after which the inferior kinds have been discarded and those which have given the best results have been continued in the experiments. Of the named varieties, the fourteen given in Table I were grown for nineteen years. The average yields during this period are shown in the Table. The lowest average yields in the nineteen years were 20.2 bushels in 1912; 28.3 bu. in 1895; 32 bu. in 1908; 34.1 bu. in 1904; and the highest yields have been as follows: 66.7 bushels in 1900; 61.6 bu. in 1902; and 60.5 bu. in 1903. In 1899 and 1901 the results were so poor that no satisfactory returns could be made.

TABLE I. — *Yield per acre of winter wheat, average of 19 years.*

Variety	Tons straw	Bushels grain
Dawson's Golden Chaff	2.9	51.1
Imperial Amber	3.2	48.1
Early Genesee Giant	3.0	46.5
Egyptian Amber	3.2	46.4
Early Red Clawson	2.8	46.1
Rudy	2.7	45.0
Tasmania Red	2.9	44.4
Geneva	3.0	43.9
Tuscan Island	2.9	43.3
Kentucky Giant	2.8	43.2
Turkey Red	2.7	43.0
Treadwell	2.8	41.7
Bulgarian	2.8	41.5
McPherson	2.6	41.5

The varieties of wheat which produced the largest loaves from equal quantities of flour, as it appears from careful tests for bread production carried out at the Bakery Branch of the Chemical Department at the Guelph Agricultural College, were as follows: Banatka, Crimean Red, Yaroslaf, Tuscan Island, Tasmania Red, Egyptian Amber, Buda Pesth, Rudy, Treadwell, McPherson and Bulgarian.

In 1913 the Agricultural College distributed five varieties of winter wheat to a great number of farmers who wished to test them in various parts of Ontario. The average yields per acre are given in Table II. It will be seen that Imperial Amber, which occupies the second place in the average of the College experiments, is classed first in the cooperative experiments with farmers. Crimean Red, although a rather weak-strawed variety, is a good yielder and produces grain of excellent quality.

TABLE II. — *Average yield per acre of winter wheat in 1913-14, in various parts of Ontario.*

Variety	Tons straw	Bushels grain
Imperial Amber	1.63	31.7
American Banner	1.40	30.8
Crimean Red	1.34	30.4
Banatka	1.28	28.8
Yaroslav	1.57	28.3

In the cooperative experiments with the farmers, different fertilizers were applied in the autumn to winter wheat: the average yields of grain per acre for eight years were as follows:

	bu.
Farmyard manure: 20 tons per acre	25.8
Mixed fertilizer: nitrate of soda 53 lb., chloride of potash 53 lb. and superphosphate 107 lb. per acre.	23.5
Nitrate of soda: 160 lb. per acre	22.5
Chloride of potash: 160 lb. per acre	21.5
Superphosphate: 320 lb. per acre	21.2
Without manure	18.1

Winter rye. — In each of the past eleven years four varieties of winter rye have been under experiment at the College. The following average results in yield of grain and in weight per bushel have been obtained.

	Bu. per acre	Bushel weight lbs.
Mammoth White	58.3	57.5
Washington	55.2	57.6
Common	53.2	57.0
Thousand Fold	53.0	57.4

1111 – **On the Botanical Origin of Cultivated Rices.** — CHEVALIER, AUG., and ROEHRICH, OLIVIER, in *Comptes Rendus hebdomadaires des Séances de l'Académie des Sciences* Vol. 159, No. 14, pp. 560-562. Paris, October 5, 1914.

The extensive geographical distribution of cultivated rice and the antiquity of its cultivation have prevented botanists from determining whether the numerous varieties are derived from one common type or from several, as well as from discovering precisely in which country they originated.

The wild rices of Asia, except one found in Indochina by one of the writers, are distinct from the cultivated varieties. This exception shows no specific differences from cultivated rices and is probably the original species from which all the varieties of the species *Oryza sativa* have been derived.

Four wild species distinct from *O. sativa* have been found in Africa. Nevertheless one of them appears to belong, if not to the original type, at least to a type very similar to some varieties cultivated exclusively in West Africa, and which is often found amongst the crops of the typical rice introduced from the Middle East by the Portuguese some centuries ago.

The five principal species studied by the writers are as follows:

1) *O. latifolia* Desv. = *O. punctata* Kotschy. The species *O. punctata* of the Egyptian Soudan is identical with *O. latifolia* of India and M. Chevalier found that it occurs also in Dahomey.

2) *O. breviligulata* A. Chev. et Roehrich. = *O. Barthii* A. Chev. *pro parte*: occurs wild in the regions of the Soudan (French Nigeria) inundated

(1) See also, No. 802 *B.* March 1911. (*Ed.*).

by the Niger and in the swamps of Baguirmi. A certain number of wild rices of Central and Western Africa are related to this species, and only differ from it in a few characters. Some of the cultivated rices of West Africa are also related to this species. *O. glaberrima* Stend. is a variety of these cultivated rices, of which some show also a second variation of long glumes.

3) *O. brachyantha* A. Chev. et Roehrich. = *O. Barthii* A. Chev. *pro parte*: in the Western Soudan and Egyptian Soudan.

4) *O. longistaminata* A. Chev. et Roehrich. = *O. Barthii* A. Chev. *pro parte*. Perennial rice with rhizomes, largely distributed throughout tropical Africa (Senegal). It is the perennial rice of Richard-Toll found by AMMANN (1). It is found growing with other wild rices in Nigeria, Baguirmi, Chari, Egyptian Soudan, Tanganyika, and the Belgian Congo.

5) *O. sativa* L. (*sensu lato*). Occurs wild in Annam, Cochinchina and Cambodia, on lands flooded during the rainy season and in rice fields which remain wet after the harvesting of cultivated rices. It is considered as a weed by the natives.

1112 – **Accumulated Fertility in Grass Land in Consequence of Phosphatic Manuring,** — SOMERVILLE, W. in *The Journal of the Board of Agriculture*, Vol. XXI, No. 6. pp. 481-492 + 1 pl. London September 1914.

FORAGE CROPS. MEADOWS AND PASTURES

During the past 20 to 30 years extensive areas of grass land have been treated with phosphatic manures, notably basic slag, and in most cases, with large profit.

The initial cost of the manure, about £ 1 per acre, is, in the great majority of cases, recovered with interest in the first 3 or 4 years by the greater production of grass, so that the accumulated nitrogen and humus is practically gratuitous.

The experiments carried out by the writer at Oxford were calculated to determine to what extent the soil is enriched by the phosphatic manures applied to grass land. Samples of soil were taken from five farms which included grass fields, part of each of which had been treated with basic slag in previous years, while part had been left untreated. Two sets of flower pots were filled with the soil from each centre, five with the treated and five with the untreated soil. The experiments with the soil of one farm had to be abandoned, so the results apply to four localities only. Each pot contained the same weight of dry soil, about 3 lbs., and was sown with Black Bell oats which were thinned down to seven plants in each pot. The five pots filled with soil from the manured part and the five from the unmanured portion of the grass land from each locality were treated as follows: Nos. 1 and 2 did not receive any direct manuring for the oats; No. 3 was given 1 gram of basic slag, equivalent to a dressing of 15 cwt. per acre; No. 4, 0,5 gram of rape meal, equal to about 7.5 cwt. per acre; and No. 5, 0.5 gram of rape meal and 1 gram of basic slag. When the plants were mature they were harvested and yielded the following results:

(*Ed.*)

(1) See also, No. 802 *B.* March 1911.

	Total weight of plants — grams	Total weight of seeds — grams
Unmanured oats:		
8 pots of untreated soil	82	22.980
8 » » treated »	136	34.140
Oats manured with slag:		
4 pots of untreated soil	56	14.600
4 » » treated »	81	17.260
Oats manured with rape meal:		
4 pots of untreated soil	41	11.055
4 » » treated »	60	17.605
Oats manured with rape meal and slag:		
4 pots of untreated soil	46	14.110
4 » » treated »	67	19.735

Thus even the abundant manuring with rape meal and slag yielded a crop inferior to that due to the accumulated fertility in the grass land that had received phosphatic manure.

The experiment is being continued; the same pots were sown with white mustard; at the end of August its appearance showed evidently that a single crop had not exhausted the accumulated fertility in the soil.

The writer summarises the results as follows:

1. Phosphate manures, besides having a direct beneficial effect on grass land, are advantageous to the tillage crop grown on the broken-up pasture, which is likely to be improved by 50 per cent.

2. Naturally, such improvement will vary with circumstances. In the above experiments the productive power of a soil that had been dressed three times with 10 cwt. of basic slag per acre during 17 years was increased 153 per cent; while another soil that had received 7 cwt. of basic slag only three years previously was improved by 124 per cent. The other two soils showed improvement of 31 and 15 per cent.

FIBRE CROPS

1113 – **Cotton in South Africa.** — Taylor, H. W. (Assistant Chief of the Tobacco and Cotton Division and Officer in Charge, Rustenburg Experiment Station) in *The Agricultural Journal of the Union of South Africa*, Vol. VIII, No. 2, pp. 160-175 + 8 figs. Pretoria, August 1914.

In those districts where the soil and climatic conditions are favourable to the growth of cotton, farmers in South Africa will find that it will prove a remunerative crop for their non-irrigable lands. This has been demonstrated by experiments conducted by the Rustenburg Experiment Station of the Tobacco and Cotton Division of the Department of Agriculture, where eight varieties of cotton gave yields of more than 1100 lbs. of seed cotton per acre. Of these, three gave more than 1400 lbs. and one variety went as high as 1684 lbs. of seed cotton per acre. Each of these varieties gave yields of more than 400 lbs. of lint and two gave more than 520 lbs. per acre.

In the Cape Province most gratifying results have been obtained. Of six varieties tested in Pondoland in 1911, five gave yields of more than 1000 lbs. of seed cotton per acre, and one variety as much as 2067 ½ lbs. of seed cotton per acre.

Experiments are just being established in Natal, but from previous results it may be said that cotton is a crop eminently suited to a large part of that Province. On the British market practically every consignment of South African cotton has realized higher prices than American cotton of similar types.

The soils which give the best results are sandy and clay loams and alluvial soils. Considering the irregularity of the climate in South Africa, the crop is not so certain on light sandy soils, on stiff clays and on turf soils, in the latter of which cotton germinates badly during dry seasons. Since cotton is planted in October or November, it is necessary that the rainfall during these months and December be sufficient, or else a full yield will not be obtained; these three months may therefore be considered the critical period of cotton cultivation in South Africa.

Among the staple crops grown in South Africa, cotton is the least exhaustive of soil fertility, as may be seen from the accompanying table, which gives the amounts of plant food removed from the soil by various crops.

Crop	Nitrogen — lbs. per acre	Phosphates — lbs. per acre	Potash — lbs. per acre
Cotton	21.36	10.97	9.21
Maize	73.74	23.96	63.06
Wheat	33.32	10.20	16.82
Tobacco	56.00	7.00	69.00

At the present time this Division is not in possession of sufficient data from all sections of the Union to be able to advise what varieties to grow in each of the several districts. From the results already obtained, it can be stated that for the greater part of the Transvaal the varieties of the big-boll group, including Cleveland, Christopher, Russell's, Pullnot, Bancroft and Bohemian, give the best results. In some parts of the Transvaal, where the soil is very fertile and the growing season long, the best results are obtained from Cook's Long Staple. This applies to the vicinity of Tzaneen and the Brak River Valley. Along the coastal belt the best returns have been secured from the varieties of the long staple group, which includes Cook's Long Staple, Nyassaland, Griffins, Sunflower and Allen's.

All the above varieties are annuals. The results obtained with the perennials have not, as yet, been sufficiently satisfactory to recommend their cultivation.

1114 – ***Urena lobata* in its Wild State in Madagascar.** — DROUHARD, E., in *Colonie de Madagascar et Dépendances, Bulletin économique*, Year 14, Part 2, No. 2, pp. 142-145. Antananarivo, 1914.

This plant occurs in a wild state in Madagascar, but it is not used by the natives as a textile plant. They occasionally use it in the manu-

facture of their of ropes, but they do not cultivate it; on the contrary they destroy it by setting it on fire when it is dry, but the seeds retain their vitality owing to their thick shell.

It grows in a wild state in the State of São Paulo, Brazil, and is cultivated with success in the neighbourhood of Campinas, whilst the fibres are worked in a spinning mill and weaving shed at São Paulo.

The plant is cut at the end of the flowering season and retting is carried out by the ordinary process of immersion of the fresh or dried stems in water. The water should be clear and running with a strong current. Retting lasts from 5 to 15 days or more according to the age and thickness of the stems, the best fibre being obtained from the thinnest stems.

The process of decorticating is very simple and it is easier when the stalks are dry. The fibre is used like jute in the manufacture of sacks and cloth. A native of Madagascar can cut about 440 lbs. of green stems per day, and 100 lbs. of stems yield about 5 lbs. of dry fibre.

The crop may be sown broadcast or better by means of a drill, but it should always be sown thickly, to prevent branching and to obtain very long stems. There is little disadvantage in cutting after the maturation of the seed, the fibre being perhaps of slightly less fine quality.

Though the plant occurs in rich alluvial soils, it adapts itself also to poor soils.

1115 – ***Agave Sisalana* and *Fourcroya gigantea* at Cape Verde.** — *Revista Colonial*, Year II, No. 21, pp. 289-290. Lisbon, September 25, 1914.

Agave Sisalana was introduced into Cape Verde some years ago in the form of bulbils, which were distributed amongst the agriculturists in different localities. They appear to have struck wherever planted, but though they developed into good plants in the high lands and valleys, they were stunted in growth in the arid soils near the coast.

Fourcroya gigantea has been established in the wild state in the mountainous islands in the Cape Verde Archipelago for more than a century and in some places it covers considerable areas. The fibre is prepared by the natives, but in such a crude manner as to render it unfit for export. In 1908 private enterprise attempted mechanical extraction with considerable success, the fibre being now sold in the markets of Hamburg, London, Antwerp and Marseilles. In 1903 the Portuguese Government carried out experiments at the National Rope Factory (Cordoaria Nacional) with textile fibres from the colonies. *Fourcroya* fibre from Cape Verde was tested and gave good results.

On the initiative of the present Governor, important plantations of Sisal and *Fourcroya* have been established on certain State lands (Ruy Vaz, Cancello, Trinidade, at an altitude of 1000 to 2500 feet). At the beginning of April, 1914, 620 000 plants had been planted and 80 000 more will be planted before the end of the year. Since the bulbils require a considerable time to grow, plants which will begin to yield in 3 years and yield about 1 ton of fibre per 1000 plants per annum after 5 years, have been bought from the natives. The present price of the fibre is £ 30 per ton.

1116 – **The Seeds of *Trichilia* from the Nigerian Sudan.** — AMMANN, P. and VUILLET, J. in *L'Agronomie Coloniale*, Year 2, No. 14, pp. 34-36. Paris, 1914.

The various species of *Trichilia* have not yet been thoroughly investigated, although they yield various interesting products; the bark of some of them is an excellent substitute for Ipecacuana, while their seeds contain varying quantities of fatty matter suitable for soap and candles.

M. F. PELLEGRIN, in a monograph on the Meliaceae of West Africa, enumerates 12 species of *Trichilia*, of which 6 belong to West Africa proper and 6 to Equatorial Africa. The six species belonging to West Africa are: *T. Prieureana* A. Juss, *T. emetica* Vahl and *T. Hendelotti* Planchon, all of them small trees belonging to the savanna region; *T. acutifoliata*, *T. Candollei* and *T. cedrata*, all three described by A. Chevalier and forming large trees in the virgin forests of the Ivory Coast.

The seeds of *T. emetica* have been exported from Mozambique to Marseilles for a long time under the name of *Mafuraires*. It was therefore desirable to know if the West African products gave seeds of equal value. Seeds were therefore obtained from various species found between Bamako and Koulikoro and studied at the Chemical Laboratory of the Colonial Garden of Vincennes. The types of seeds were as follows:

I. Small dark red seeds.
II. Medium-sized seeds of orange vermilion colour.
III. Large orange-coloured seeds.

The results of the analyses are given in the Tables I and II.

TABLE I. — *Analysis of seeds.*

	I	II	III
Weight of 100 seeds, gms	12.7	29.4	79.1
» » 100 kernels, gms	4.68	17.08	46 04
Percentage of kernels in seeds	36.9	58.1	58.2
Shells %	63.1	41.9	41.8
Moisture % in shells	6.42	4.16	4.74
» » in kernels	5.73	6.71	5.76
Fat in shells	41.50	38.10	51.90
» » kernels	30.10	44.70	43.70

TABLE II. — *Analyses of the fats.*

	Medium seeds.	Large seeds.	
	Fat of kernels	Fat of kernels	Fat of shells
Colour	light brown	light brown	lighter brown.
Solidifica ion point of glycerides	18°–19°	15°–16°	abont 13°
Acidity % as sulphuric	0.97	0.49	0.53
» % as oleic acid	5.60	2.82	3.05
Fixed insoluble fatty acids %	92.0	90.3	92.0
Melting point of insoluble fatty acids	52°	51.5°	44°
Solidification point » »	48.4°	47.2°	40.5°
Glycerine %	6.3	—	5.8

The large seeds most nearly approach the Mafuraires from Mozambique as regards size and fat content. The medium seeds are identical with those of *T. Prieureana* preserved in the Kew Museum.

French West Africa should be able to export at least several hundred tons of the Mafuraire seeds each year.

RUBBER, GUM AND RESIN PLANTS

1117 – **Recent Data on Rubber Plantations.** — Plantation Rubber Acreages. — Rubber Planting in Malaya. — WILLIAMS, G. C. (Rangoon): Rubber Cultivation in Burma — Report of Gold Coast Government.— *The India Rubber World*, Vol. 4, No. 6, pp. 678-679. New York, September 1, 1914. — Rubber Cultivation in India *Daily Consular and. — Trade Reports, Issued by the Bureau of Foreign and Domestic Commerce*, Year 17, No. 197, p. 1034. Washington, August 22, 1914.

The area under rubber in 1913 is estimated at 1 250 000 acres, distrfbuted as follows :

Malaya, etc.	500 000 acre
Java.	150 000 „
Sumatra, etc.	250 000 „
Ceylon	220 000 „
India and Burma	50 000 „
German Colonies	60 000 „
Borneo	20 000 „

In 1910 the total acreage under rubber was 767 000 acres, in 1911, 865 000 and in 1912, 987 000. It will thus be seen that the increase shown by 1913 over 1912 is about 27 per cent.

The following table shows the relative importance of the rubber acreage in various parts of the Malayan peninsula :

	1912 Acreage	1913 Acreage	1913 Output in tons
Federated Malay States	399 197	433 324	21 229
Straits Settlements	94 263	111 316	6 047
Johore	91 827	117 022	1 646
Kelantan and Kedah	34 837	45 373	246
Trengannu	1 497	1 510	Not yet producing
	621 621	708 545	29 168

In 1912 there were in all 235 912 workers employed on the Malayan estates.

The production of rubber in India is confined to Assam, Burma and the Madras Presidency, which exported in the fiscal years ending March 31, 1913 and 1914, 14 627 and 23 264 cwt. respectively. The acreage under rubber and the number of trees in 1913 was as follows :

	Acres	No. of trees
Assam	4 681	137 430
Madras	12 022	1 636 476
Burma	29 544	4 911 399

The yield of the Assam plantations is relatively small and the number of trees to the acre much less than in Madras and Burma. In 1913 the outturn of Madras was still more than double that of Burma, because most of the trees in Burma, being less than six years old, are not yet productive.

In 1914 the total acreage under rubber cultivation was about 34 000 acres. The rubber-growing districts are in Lower Burma, including Tenasserim. The soil is principally a reddish yellow friable sandy loam, with occasional districts which have a subsoil of laterite. The land is easily drainable. It is slightly undulating and in nearly all cases is protected from the south-west monsoon by high ranges of hills.

The rainfall varies slightly in different districts, from 110 inches in North Tenasserim to 200 in Tavoy. There are two seasons: December to April, the dry or cold season, and May to November, the wet or monsoon season. The driest months are February and March, when there is very little or no rain, but there are heavy mists and dews which compenste for the lack of rain. The temperature is about 88.8° F. in the daytime and 74° F. at night—the mean temperature for the year being about 80° F.

All planting is stump planting about 9 to 12 months old. The plants attain a height of from 10 to 12 feet and a girth average of 2 1/2 to 4 inches in one year. All the trees can be tapped in 4 years from the date of planting, the girth average 3 feet from the ground being 18 to 24 inches and more if planted 20 × 20 feet. The average yield for 4 to 6 year-old trees 1 1/2 to 3 lbs. per tree per year. The rubber is of excellent quality. Tapping can be done now practically all the year round. It is principally done by Burmese girls.

The capital invested is from £ 22 to £ 25 per acre to bring to bearing. The average cost of production is about 1*s* 6*d* to 1*s* 10 1/2 *d* per pound.

The exports of rubber from the Gold Coast Colony in 1912 were 1 990 699 lbs. as against 2 668 667 lbs. in 1904. The average annual yield of Para rubber (Hevea) at the several experimental stations was 3 3/4 lbs. per tree. *Funtumia* has given over 56 per cent of its total yield at the first tapping, in contrast with Para, where the quantity of latex tends to increase after the first tapping.

1118 – **Rubber: Tapping and Tapping Systems.** — SPRING, F. G. (paper read at Batavia Rubber Congress) in *The India Rubber Journal*, Vol. XLVIII, No. 14, pp. 15-16. London, October 3, 1914.

Under normal conditions from 300 to 350 trees per tapping coolie per day are recommended if work of good quality is to be maintained. At least twenty cuts to the inch of bark removed should be obtained, and when four years is allowed for bark renewal the cuts should be 18 inches apart. The depth and uniformity of cut are extremely important. It is considered a bad practice to place water on the cuts to facilitate the flow of latex.

In discussing the merits of the different tapping systems two points require consideration: 1) the production of maximum yield of rubber at minimum cost, and 2). the maximum yield of rubber with minimum injury to the tree. With regard to the periodicity of tapping it is generally

recognised in Malaya that daily tapping, over a period, gives more total rubber than alternate-day tapping, but that the latter yields more per tapping. In the case of young rubber, the difference is at its minimum, but as the tree ages the excess of rubber obtained in daily tapping increases and becomes sufficient to pay for the additional labour involved. This age limit appears to be about six years for trees planted at sufficient distance apart to allow good bark renewal. Bark renewal depends on the age of the trees and their distance apart.

At least four years should be allowed for bark renewal in the case of young trees and six years for old trees, especially if the distance of planting is small.

The writer has conducted experiments to test the merits of the following tapping systems :

1. *Opposite qaarter system.* — This system is unsatisfactory on account of the high cost of marking out the guiding lines, tapping, collecting latex and washing cups, and requires double the number of latex cups, spouts and holders. It is also doubtful if the renewal of bark in this system is as rapid as in others.

2. *Single quarter (or half herringbone) system.* — This system is largely in use in the Malay Peninsula. At the Kuala Lumpur Experimental Station it was found that two cuts gave considerably more total rubber than three in the case of young trees, and since the length of the cuts increases with the age of the tree, it is doubtful if it is advisable to have more than two cuts even with old trees. It has been found in Java (1) that more rubber is obtained by tapping to the left than to the right of the vertical channel. This system is infinitely superior to the opposite quarters system and over a period of two years it has given results nearly equal to the 'V' system. The superiority of the latter system cannot be decided until the results of tapping the renewed bark are known.

3. *The 'V' system.* — Some planters object to this system since it tends to flatten out the trunk of the tree. This is however no disadvantage and the results of the Kuala Lumpur experiments show a gradual and continuous increase in yield greater than that of any other system

SUGAR CROPS

1119 – **The Use of Sweet Sorghum as a Source of Commercial Sugar or as Fodder.** – ANNETT, H. E., (Agricultural Chemist to the Government of Bengal) in *Agricultural Research Institute, Pusa, Bulletin* No. 41, 9 pp. + 2 diagrams. Calcutta, 1914.

From time to time attempts have been made to grow sweet varieties of sweet jowar (*Sorghum* sp.) for the purpose of sugar production. The seed has in many cases been imported from America, but in certain parts of India local varieties are found which contain much sugar.

The experiments here described were made at Lyallpur and at Gurdaspur, Punjab.

At Lyallpur a local variety was grown. It was sown on July 2 at the rate of 12 lbs. per acre, without manure ; the ground was irigated four times. In order to determine the best time for the harvest, the whole

(1) See No. 1039, *B.* Sept. 1913. (*Ed.*

plot was divided into 20 equal sections which were gathered two at a time at 10 different intervals. From every lot the juice was boiled down. The best results were obtained from the sections cut towards the end of October or beginning of November. The lot cut on November 9 yielded 6 tons to the acre of stripped cane with 6587 ½ lbs. of juice, and from this 875 lbs. of raw sugar (gur), or 13.3 per cent, containing 57.90 per cent sucrose and 13.42 per cent reducing sugar, were obtained. This is quite a poor quality gur.

From the results of the Lyallpur and Gurdaspur experiments it appears that as a source of sugar, saccharine jowar is not worth growing in India. Even in America it is only grown to make syrup, for which there is a demand in that country, while there is none in India.

The high glucose ratio of the juice militates against the production of good crystalline gur. The juice contains also substances which produce, at times, a very objectionable taste in the gur.

The yield per acre obtained from a very good crop of sorghum only worked out at about 8 cwt. per acre. Hence the yield of sugar per acre would be only about one-third of that from the average country sugarcane crop.

These results tally with others obtained previously at Poona with the Collier and Amber varieties, which yielded 1174 and 1072 lbs. of molasses per acre respectively.

The experiments made by the writer indicate that the total sugar content of the crop is highest when the seed contents begin to dry. Thereafter until the seeds are dead ripe the total sugar in the crop decreases, but the decrease is mainly at the expense of the reducing sugar. As the plant approaches ripeness the amount of juice expressed from it decreases.

As a source of fodder saccharine sorghum seems valuable. The crop is fairly quick-growing and, as has been seen, yields abundant green produce. After the seed is in the thin milk stage no increase in total weight of the crop takes place and also the amount of total sugar in the crop has almost reached its maximum. Hence, when being cut for fodder, the crop should not be allowed to get beyond this stage.

1129 – **Tea: Manuring Experiments at Peradeniya.** — BAMBER, M. K., in *Department of Agriculture, Bulletin* No. 9, pp. 119-134, 3 plates. Colombo, Ceylon, May 1914.

STIMULANT, AROMATIC, NARCOTIC, AND MEDICIN CROPS

This circular contains a detailed account of the results of manurial experiments on the tea plots at Perideniya since 1911. Though no obvious conclusions are drawn from the tabulated results, the writer states that the experiments continue to bear out the advantages of green manuring, and demonstrate that with this class of tea, the application of expensive nitrogenous manure is not essential for the production of highly profitable yields.

As a green manure., Dadaps (*Erythrina lithosperma*) appears to give the best results.

1121 – **Irises Used in Scent-Making.** — BLIN, HENRI, in *Le Jardin*, Year XXVIII No. 659, pp. 230-231. Paris, August 5, 1914.

France does not produce sufficient iris rhizomes to supply the scent factory at Grasses (Alpes Maritimes), where 650 000 lbs. are required annually ; therefore there is a large importation of these roots from Tuscany. Further the Itatian product is of superior quality to the French. The writer is of opinion that iris cultivation might be extended in the South of France, and especially on the somewhat poor soil of the coast zone, which is not far from the centres of perfume manufacture.

The scent iris was grown for a long time in the Department of the Ain, in the communes of Anglefort and Carbonnot, near Seyssel. This crop has, however, decreased in importance owing to the competition of the South of France and of Italy. In 1903, the above-named communes produced from 33 000 to 35 000 lbs. of iris rhizomes, which fetched from 40 to 50*s* per cwt. The price has now fallen to about half this. Iris roots from Florence make 35 to 50*s* per cwt., while the less valuable ones from Verona are sold at 25 to 30*s*.

The varieties most used in scent-making are *Iris florentina* (*I. pallida*) and *I. Clio*, which is a variety of it. *Iris germanica*, which is coarser and hardier, grows wild throughout Provence.

The soil is prepared by digging, and fragments of the rhizomes are planted at 8 inches each way, towards the end of August and in September. They are hoed in spring and autumn. From 6 to 8 tons of manure are applied per acre to every crop, which occupies the ground for two or three years. In the South of France, good results are obtained by the application of 6 to 8 cwt. per acre of sesame or oil cake. The rhizomes are lifted at the end of the second or third year. The French crops vary from 20 to 36 cwt. of dry rhizomes per acre. An average crop of 28 cwt. per acre, fetching 28*s* per cwt., gives a gross return of £ 40 per acre.

The rhizomes are peeled, washed, dried in the sun and kept in a dry place. The old method of making the scent consisted in grinding the dry roots and thus obtaining iris powder (which is itself used for many purposes). The essence was distilled and the residual powder macerated in pure alcohol, either the essence or the maceration liquid being used. The better and more modern method is the process of extraction by means of volatile solvents such as dichlorethylene or trichlorethylene ; the latter is preferable for manufacture on a large scale.

1122 – **The Effect of Shading on the Transpiration and Assimilation of the Tobacco Plant in Cuba.** — HASSELBRING, HEINRICH, in *The Botanical Gazette*, Vol. LVII, No. 4, pp. 257-286, + 1 fig. Chicago, Ill., 1914.

The experiments described in this paper were undertaken in the year 1908-09 at the Cuban Agricultural Experiment Station at Santiago de las Vegas (Western Cuba) with the object of determining the effect on transpiration and assimilation in the tobacco plant of the cheese-cloth shade which is frequently used in that region for shading tobacco. This cheese cloth is a kind of network of coarse thread with meshes about a tenth of an inch wide ; during the middle of the day this cloth casts a barely

perceptible shadow, which, however, is more noticeable early in the morning or late in the afternoon.

Six tobacco plants were grown in vessels in the open, and six under cheese-cloth shade. The light intensity under the two conditions was measured by the photometric method. The temperatures were recorded by thermographs; the relative humidity and rainfall were also determined.

It was observed that:

1. The shade of the cheese-cloth tent reduced the total light by about one-third, but the diffuse light showed very little difference on bright days; when, however, there was no bright sun the total light (all diffuse) was reduced by about one-third.

2. There was no marked difference between the temperature within the tent and that outside. The average daily excess of the temperature outside the tent over that inside was, for 60 days, 0.14° F. It seems that the tendency of the tent to retain heat is balanced by the smaller quantity of radiant energy which passes into it.

3. The relative humidity is higher inside the tent than outside, the difference being more marked during the day, for at night in both stations it reaches 100 per cent. During the day the difference is enhanced by the partial retention of the moisture transpired by the plant.

4. The rate of evaporation is greater in the open than under the tent. The difference in the rates of evaporation in the two stations increases with the development of the plants and the consequent increase in relative humidity under the cheese-cloth. Besides diminishing the amount of light and increasing the relative humidity, the tent reduces the currents of air; all these changes tend to diminish transpiration.

The plants used in this work were grown from seed obtained from a single self-fertlilized mother-plant of a pure strain.

The shade plants attained a nearly uniform height of 6 ft. 10 in., while the height of the sun plants averaged about 5 ft. 9 in. The leaves of the shade plants were much larger and thinner than those of the sun plants and the internodes of the stem were longer. In 60 days the plants in the open transpired an average of 45.539 litres of water per plant and required 241.72 cc. of transpired water per gram of water-free substance produced, while the corresponding figures for the shade plants were 35.212 litres and 186.90 cc. The sun plants thus transpired on the average about 30 per cent more water per plant than the shade plants, while the average weight of dry matter produced was, in the mature plants, nearly the same in both sets. It follows that the series having the higher total transpiration also has the highest transpiration per gram of dry plant substance. This is corroborated by the above figures. The quantity of water transpired per unit of dry matter produced is remarkably uniform for the plants within each group. This confirms the conclusion that under the same aerial conditions the quantity of water transpired per unit of dry matter produced is constant and independent of the nature of the nutritive solutions or of their concentration or of the state of development of the plant.

The other observations gave the following averages per plant:

	Plants in the open	Plants shade
Leaf area, in square centimetres	21 442	29 442
Transpiration, total for the last five days, in cc.	10 566	7 862
» hourly per sq. decimeter leaf surface, in cc.	0.412	0.224
Fresh weight, in grams:		
leaves	401	469
stems	380	489
roots	212	205
total	993	1162
Weight of water-free substance of plants (at 78° C. and at a pressure of 6 cm. mercury) in grams		
leaves	74.50	66.94
stems	68.66	79.68
roots	45.26	41.51
total	188.42	188.14
Percentage of water.		
leaves	81.39	85.68
stems	81.91	83.71
roots	78.59	79.70
total	81.01	83.82

After a discussion of the observations and opinions of the most competent authorities on the subject of the relation between transpiration and production of plant substance, the writer draws the following conclusions:

Under the climatic conditions of Western Cuba the transpiration of tobacco plants grown in the open ground is nearly 30 per cent greater than that of plants grown under the cheese-cloth shade commonly used for shading tobacco in that region. The transpiration per unit area of leaf surface is nearly twice as great in the sun plants as in the shade plants.

The shading of tobacco plants by this grade of cheese-cloth does not seem to result in a diminished production of total plant substance by the shaded plants, as compared with other like plants not shaded. Since, however, the leaves of the shade-grown plants have a much greater total area than those of the plants grown in the open, it is evident that the quantity of plant material elaborated per unit of leaf area is greater in the plants grown in the open.

Although the total production of dry plant substance is not influenced in any marked degree by the cheese-cloth shade, the distribution of this substance is affected in such a manner that in the shade-grown plants relatively less material is deposited in the leaves and more in the stems than in the corresponding organs of the plants grown in full light. No evident influence is exerted om the deposition of material in the roots.

1123 – **Medicinal Plants in South Africa.** — SCHÖNLAND, S., (Professor of Botany, Rhodes University College) in *The Agricultural Journal of the Union of South Africa*, Vol. VIII, No. 2, pp. 201-205. Pretoria, August 1914.

In South Africa the native medical practitioners make use of a number of local plants; very few of these, however, are included in the official phar-

macopoeia. Among these the following wild plants may be mentioned: *Brassica nigra*, which is widely spread in South Africa; *Cannabis sativa*; several species of *Cassia; Datura Stramonium*; *Foeniculum vulgare*, *Marrubium vulgare*; several native species of *Polygala*, which appear to be at least as good as *P. Senega*; *Ricinus communis*, etc.

Numerous other medicinal plants have been grown here and there in South Africa, but rather for experimental or ornamental purposes and without attaining any commercial importance. Among these the following have been successful: *Aloe* (Barbados) at Grahamstown and Capetown; *Aspidium athamanticum* Kze, which is said to be superior to male fern, at Salem; *Carum Carvi* near East London; *Cassia marilandica* at Komgha; *Cinnamomum Cassia* at Durban and Maritzburg; *Convolvulus Scammonia* at Somerset East; *Coriandrum sativum* near East London; *Curcuma longa* in Natal; *Digitalis purpurea* in Albany; *Erythroxylon coca* in Natal; *Glycyrrhiza glabra* near East London; *Illicium verum* in a garden at Komgha as an ornamental plant; *Linum usitatissimum;* it grows freely at Komgha and Kei River, and has been very successfully grown near East London and in Lower Albany; *Matricaria Chamomilla*, grows freely at Komgha and was grown at Salem for many years; *Menta piperita*, successfully grown in several localities; *Pimpinella Anisum* near East London; *Pyrethrum* spp. have been grown very successfully for local consumption in South-east Cape Colony; *Rheum officinale*, successful at Komgha; *Tamarindus indica*, grows freely at Komgha, also grown at Durban, where it does not bear pods freely enough to make it worth cultivating; *Taraxacum officinale*, near East London.

Considering the special economic conditions of South Africa and especially that labour is expensive, mostly unskilled and unreliable, the writer does not believe that an important export trade in medicinal plants could be built up, even with those abundantly growing wild.

MARKET GARDENING

1124 — **Market Gardening in Spain.** — ZULUETA, José (Report presented to the VIII « Curso Internacional de Espansión Commercial ») in *Resumen de Agricultura*, Year XXVI, Part 309, pp. 390-398. Barcelona, September 1914.

The exportation of market-garden produce from Spain is continually increasing with the improvement of the means of communication. According to the last available official statistics, those of 1912, the exports during that year were as follows:

	£
Onions	624 873
Preserved vegetables	370 550
Potatoes	278 270
Chillies, ground and unground	181 315
Garlic	87 908
Tomatoes	37 382
Peas	10 930
Artichokes	650
Capsicums	159
Asparagus	29
Various vegetables	9 583

The statistics estimate the value of the annual vegetable production of Spain at 15 millions sterling. The writer, however, considers that this estimate falls far short of the reality, seeing that vegetables form the principal articles of food of the people. The above figures do not include all the vegetables consumed by the producers. Very many families possess kitchen gardens; even agricultural labourers and some towns-folk and factory hands possess them.

With the exception of Madrid, where the scarcity of water in the Manzanares precludes irrigation, all the large centres of population in Spain are surrounded by belts of market gardens. In the central "meseta" (plain), the first place is occupied by Aranjuez, with its 30 000 acres of well irrigated land thickly covered with market gardens and associated fruit plantations. In Aragon the irrigated land of Calatayud is noted; however, both in this district and in the "vegas" (fertile, gentle irrigated slopes at the foot of the mountains) of Saragossa, sugar-beets and lucerne predominate, so that market gardening has little commercial importance. The valley of the Ebro is only to a limited extent under intensive cultivation; however, Logroño Haro should be singled out, as it supplies a large preserve trade.

The typical market-garden zone which produces early outdoor vegetables, is the coast zone of the Mediterranean. From the town of Mataró the "huerta" (irrigated fruit and vegetable garden), extending as a long narrow belt along the coast from the suburbs of Barcellona to the French frontier, takes its name. Its speciality is in early potatoes, which are planted in November or December, and forced by the application of an abundant supply of manure; these potatoes are sent, in constantly increasing quantities to Paris and to England and elsewhere at a time when the tubers are still green. The annual exportation is estimated at 33 million lbs,, and its value at £120 000; but the price varies very much according to the greater or less competition of the products of other warm countries. The exportation of green peas is estimated at 3 ½ million lbs., with an average value of £12 000; these are grown without irrigation between rows of vines. In the "huerta" of Mataró no fruit trees are grown, while the more extensive plain of the Llobregat, which occupies the whole delta and extends some miles up the valley, is an uninterrupted fruit plantation, with vegetables below the trees.

According to official data, which, however, fall below the actual figures, the province of Barcelona possesses 16 200 acres of market gardens, of which the produce is worth £1 290 000. The name of "huerta" is not given to the cultivated zone extending between Rens and Tarragona; nevertheless the scanty water supply available is turned to such good account, that large crops of vegetables are also obtained there. The "huerta" proper commences in the Castellón plain and includes all the ancient kingdom of Valencia, where it reaches its greatest perfection. The Villareal "huerta", which now comprises about 2500 acres, uses subterranean water brought to the surface from a depth of about 200 ft. by means of Artesian wells with mechanical motor pumps. On an

average there is one well for every 57 acres of land, which is for the most part under citrus groves. The soil was prepared according to the system used in Santa Cruz (Teneriffe) in preparing the land for the celebrated Canary tomatoes: the solid rock is blown up with dynamite, the layer of earth beneath is extracted, the cavity is lined with fragments of rock and filled up with soil. At Villareal, however, the soil was transported for a long distance in order to obtain a layer 20 in. deep. The same thing is done at Almeria in order that the roots of the famous vines can penetrate deep into the soil and thus resist the drought. In the "huerta" of Valencia the cultivation is so intensive that there are families living upon little over an acre of land.

The "huerta" of Murcia is distinguished by the cultivation of capsicum. Vegetables are grown there in trenches covered during the winter with straw matting. Orihuela, Denia, Gandía, the "vega" of Granada and Motril are all important horticultural centres. The Motril zone is especially characterised by the cultivation of cotton and sugarcane.

The prices of "huerta" in full production are exceedingly high, rents amounting to £10 or £16 per acre and sale prices usually to £200 to £300 per acre. At Carcagente, Alcira and Gandía, citrus groves fetch as much as from £650 to £800 per acre.

As a rule, the ground is leased to families of colonists who usually do all the work; day labourers are very rarely employed. The management of the soil and the crops is carried out with the greatest exactitude.

1125 – **A Kaki Classification.** — HUME, HAROLD H., in *The Journal of Heredity*, Vol. V No. 9., pp. 400-406 + 6 figs. Washington, September 1914. FRUIT GROWING

As long as any kind of fruit is represented by only a few varieties the botanical classification can be followed, but when the number of varieties increases considerably, it becomes necessary for the pomologist to introduce some system of classification based on some well-marked characteristic in order to facilitate identification and handling.

Such is the case with the Kaki (*Diospyros Kaki*) of which the number of varieties grown in the United States for many years has been quite limited. But recently a very large number of new varieties have been introduced from China, Japan, Algeria, France, etc.

The writer is of opinion that the flesh characters form a satisfactory basis of classification. In the final analysis the flesh characters are fixed by the pollination factor and this factor finds its most striking expression in the colour and texture of the flesh.

All the varieties of *D. Kaki* known in America at this time are light fleshed when seedless, while certain varieties always show darkening of the flesh when seeds are present and other varieties are always light fleshed when containing seeds. Thus far in the writer's experiments parthenogenesis, that is the formation of seeds without pollination, does not occur in *D Kaki*, and if it does it is so rare as to have no practical importance. In *D. virginiana* it is said to have been observed in some instances, but it has not been proved experimentally.

Kakis may be divided from the pomologist's point of view into at least two groups — first those which show no change in colour under the influence of pollination, and second those in which the flesh of the fruit is darkened under the influence of pollination.

Since the change in colour in the one case is directly due to pollination and in the other pollination has no effect, those varieties which undergo no change in color are called *Pollination Constants* and those which are light coloured when seedless and dark coloured when containing seed are called *Pollination Variants*. If varieties which are constantly dark fleshed whether seedy or seedless should be found, they would belong to the group of *Pollination Constants*, which would be divided into two groups of light and dark fleshed Pollination Constants. It is hardly probable that there are varieties which are dark fleshed when seedless and light fleshed when seedy.

The varieties known at this time are divided as follows :

Group I, *Pollination constants*, Costata, Hachiya, Lienha, New Sien, Ormond, Phelps Siang, Tamopan, Tanenashi, Triumph, Tsuru.

Group II, *Pollination Variants :* Dai Dai Maru, Gailey, Godbey, Hyakusae, Lonestar, Masugata, Myotan, Nectar, Okame, Taber No. 23, Taber N. 129, Yeddoichi, Yemon, Zengi.

The amount of dark flesh found in fruits of varieties of the group *Pollination Variants* depends both upon the number of seeds and upon their location with reference to one another : It is partial or arranged round the seeds when only one or two close to each other are present ; if two seeds are present diametrically opposite one another, or if there are more than two seeds, the whole area may be more or less darkened.

Associated with the changes in the colour of the flesh there are well marked variations in time of ripening, shape and size of fruits, quality and texture of flesh.

Considering the extraordinary variability shown by *D. Kaki* due to cultivation, it is not improbable that the present cultivated varieties are derived from two distinct species.

Certain varieties of kakis bear both staminate and pistillate flowers. Some of those which bear staminate flowers do so every time the tree blooms, while other varieties are very irregular in this particular. The first class of staminate trees are designated as *Staminate Constants*, while the second class may be called *Staminate Sporadics*. Those which produce only pistillate flowers may be referred to as *Pistillate Constants*. It is interesting to note that staminate-flowering varieties of both classes are more commonly found among the *Pollination Variants* than among the *Pollination Constants*. To the former group belong Gailey, Masugata, Okame, Taber Nos. 23 and 129. Among the *Pollination Constants* only two staminate-flowering sorts, *viz.* New Sien and Siang, have so far been found. It is not improbable that they belong to a different species from the other varieties or at least a different section of *D. Kaki*. These two varieties were recently introduced from Northern China. It must be borne in mind that *D. Kaki* is not native to Japan, but was introduced from China several centuries ago ; no

doubt the two groups (light-fleshed and dark-fleshed) have diverged greatly, even granting that they were originally one.

The different varieties so far studied may be grouped on the flowering habit as follows:

Group I: *Pistillate Constants*. Tanenashi, Hachiya, Costata, Tsuru, Tamopan, Hyakume, Yenon, Yeddoichi, Phelps, Triumph, Zengi.

Group II: *Staminate Constants*. Gailey, and probably Masugata, Siang (S. P. J. No. 21910 and S. P. J. No. 27037).

Group III: *Staminate Sporadics*. Okame, Taber No. 23, Taber No. 129.

Experiments conducted by the writer tend to prove that it is possible by selection to transform strains of staminate sporadics into staminate constants.

1126 – **The Siamese Seedless Pomelo.** — BOYLE, H. H. (Bureau of Agriculture, Manila, P. I.) in *The Journal of Heredity*, Vol. V, No. 10, pp. 440-444 + 1 fig. Washington, October 1914.

In 1902 the Office of Foreign Seed and Plant Introduction of the U. S. Department of Agriculture introduced from Bangkok some plants of the Siamese pomelo which had been described as seedless. But the only plant which reached Washington alive produced fruit which contained many seeds and was decidedly inferior; it was consequently destroyed.

In 1912 the writer was sent by the Philippine Bureau of Agriculture to Siam to study the seedless pomelo on the spot and to obtain plants of it. He was able to find it about 30 miles to the north-east of Bangkok and in the Nakon Chaisii district, which produces the best pomelos. He found that some trees bore only seedless fruit, but some also bore fruit with seeds, especially those trees which stood on the side of the grove nearest the ordinary seminiferous pomelo trees; the presence of seeds was apparently due to cross-pollination. The seedless pomelos are all propagated by marcottage by the natives, to whom budding in unknown. In research work carried on in the United States it had already been observed that the seedless navel orange bore seeds when crossed by pomelo.

The writer classifies the seedless pomelos of the Nakon Chaisii district according to four types:

1. Medium size, 4 ½ inches in diameter by 5 inches in length; colour light yellow; flesh white; taste very aromatic, free from bitterness.

2. Medium size, 4 7/8 inches in diameter by 3 ¼ in length; colour bright yellow; flesh white; taste aromatic and excellent.

3. Medium size, about the same as No. 1, pyriform; colour orange yellow; flesh pinkish white; taste good, rather heavy.

4. Size very large; colour yellow; flesh deep pink; taste bitter.

Type 1 is the finest of all, Types 2 and 3 are the commonest, while Type 4 is inferior to the others.

The Siamese seedless pomelo has been introduced into the Philippines and into the United States.

1127 – ***Prosopis juliflora*, the Mesquite or Algaroba Tree, and *Prosopis pubescens*, the Screw Bean.** — ROBERTSON, C. C. (Research Officer, Forest Department) in *The Agricultural Journal of the Union of South Africa*, Vol. VIII, No. 2, pp. 233-239. Pretoria, August 1914.

The Mesquite or Algaroba and the Screw Bean or Screw Pod Mesquite deserve to be introduced and grown for their pods, which are excellent fodder for live stock.

Prosopis juliflora, the mesquite, is widely distributed in North America from Western Kansas to California and southwards into Mexico, and probably various forms occurring in Central and South America and there known as algaroba should be included in the same species. Even in the United States the species varies a good deal, and two extreme forms, the varieties *glandulosa* and *velutina*, are recognized.

The mature pods are yellow, or often tinged with red, and are about four to nine inches long and one-third of an inch wide, and contain about six to twenty seeds embedded in pulp.

In its home in North America, *Prosopis juliflora* is found in the hotter, drier parts of the country, where the average annual rainfall is about 25 inches; it occurs even in arid localities where the rainfall is as low as 10 inches. It develops a remarkbly long taproot, which enables it to derive moisture from a great depth and to become independent of the surface water supply. It grows to a height of from 3 to 20 feet. The *velutina* variety reaches its greatest height of about 40 feet and a diameter of 1 ½ or 2 feet in the valleys of Southern Arizona. The species is said to be extending its range naturally in some of the prairie States, and in California it will grow on soils containing a large proportion of carbonate of soda.

Prosopis juliflora has been naturalized in several countries. It is abundant in the drier parts of the island of Jamaica, where it grows in dry gravelly soils. In the Hawaiian Islands it has spread rapidly since its introduction about 70 years ago and now covers an area of at least 50 000 acres on the south and west coasts, where it is protected from the trade winds. It grows on gravelly soils and steep stony slopes, occupying land which is worthless for other purposes.

In some of the drier parts of India, *Prosopis juliflora* is now naturalized and has proved extremely hardy to drought and is used for reforesting dry, waste lands and for arresting drift-sands. The tree is also said to be naturalized in the Philippine Islands and in Australia.

In German West Africa it was introduced about thirteen years ago and seems to withstand the drought well and to grow on poor soil.

Seed of *Prosopis* and its vareties has been imported from different sources by the Forest Department of the Union of South Africa at intervals during the last seventeen years. It seems to thrive in the different localities in which it has been planted, but its growth has been somewhat slow and bushy, and the writer recommends it for hedges and for arresting sand-dunes.

Wherever it has been introduced it is extending its range naturally by regeneration from seed which is disseminated by stock in their droppings. It is of slow growth. Its wood is heavy, hard and close-grained.

t has been used for railway sleepers, wood-paving, fence-posts and furiture. It is an excellent firewood and makes good charcoal. The flowers re eagerly sought by bees. The pods are relished by cattle, horses and igs and form an important stand-by for times of drought. About 53 er cent of their weight is nutritious and consists of vegetable albumen, um, grape-sugar, with traces of fat and salts.

The Mexicans and Indians grind the pods into a coarse flour which hey bake into cakes for food. In the Argentine a liquor is distilled from he pods.

Prosopis pubescens is distinguished from the other mesquite by its ods, which are twisted into a spiral. Its wood is similar to that of *P. juliflora*. The pods, although nutritious and used for fodder in America, are of less value because of their smaller size. This species has also been successfully introduced into South Africa.

1128 – **The Jaboticaba (*Myrciaria*).** — POPENOE, WILSON (Agricultural Explorer, U. S. Department of Agriculture), in *The Journal of Heredity*, Vol. V, No. 7, pp. 318-326. Washington, D. C., July 1914.

The jaboticaba is a fruit tree belonging to the Myrtaceae, indigenous to central and southern Brazil. Berg distinguished three species: *Myrciaria cauliflora*, *M. Jaboticaba* and *M. trunciflora*; but they are not distinguishable with certainty, at any rate under cultivation.

The tree, which is evergreen, may reach 30 to 40 ft. in height; it branches from the ground, producing an almost spherical crown. The fruits are borne on the branches from the ground-level to their tips; they are nearly sessile in *M. cauliflora*, but in *M. Jaboticaba* are produced on slender peduncles less than an inch long; they ripen within two or three months of the flowering -period, and a tree may flower and fruit several times during the year. In appearance the fruits rather resemble large grapes, reaching 1 in. or more in diameter in *M. cauliflora*; the most usual colour is a deep maroon purple; the skin contains tannin and is rejected, while the pulp is translucent and juicy, in flavour something like grapes; each fruit contains from one to four seeds.

The jaboticaba will not stand more than the lightest frosts; it seems to prefer a rich, deep soil. The trees should be planted 30 ft. apart; when grown from seed (which is the usual method of propagation) they require six to eight years to come into bearing.

1129 – **Manurial Experiments on Coconuts at Peradeniya.** — BAMBER, M. KELWAY. in *Department of Agriculture, Ceylon, Bulletin* No. 10, pp. 135-146. Colombo, May 1914.

These experiments were conducted, to determine the effect of manurial constituents, alone and in combination, on the development and formation of nuts and to what extent old coconut palms can be improved by means available to most cultivators. The trees used were all old, growing on a quartzy loam at an elevation of about 1600 feet and about 51 miles from the sea in a direct line. The rainfall of the district varied between 62.37 inches in 1908 and 120.70 inches in 1913 and averaged 83.35 inches.

The results tend to show that:

1). Ploughing twice a year is as beneficial as manuring.

2). Tying cattle to the trees in 1911 and 1912 had an immediate effect lasting over two years.

3). The application of a soluble manure twice annually and a general manure annually produced a steady increase which was maintained during 1913.

4). Green manure with basic slag and sulphate of potash showed a marked improvement, which, however, was not fully maintained during the wet season of 1913.

5). The application of salt (NaCl) or nitrate of soda has had no beneficial effect during the years of the experiment.

6). No treatment of any kind results in a gradual falling off in yield.

7). The effect of cultivation and manuring has not so far decreased the number of immature nuts (1) falling annually.

8). The number of mature and immature nuts increased annually. while the proportion of female flowers producing mature fruit showed a steady decrease during the same period.

9). The reduction of the percentage of mature nuts to female flowers is rather more marked in the manured plots than in the unmanured, but the percentage increase of total female flowers is more marked in the unmanured plots.

1130 – **The Manuring of Bananas** (2). — BRÜNNICH, J. C. (Chemist of the Department of Agriculture and Stock, Queensland) in *The Queensland Agricultural Journal*, Vol. II, Part 2, pp. 132-141. Brisbane, August 1914.

Hitherto, in general, large areas under bananas have been for years continually cropped, without any attention to manuring, and abandoned when the crop, became unprofitable owing to exhaustion of the soil.

In the State of Queensland it was found that the abandoned banana lands were eminently suitable to other crops and more particularly sugarcane, and thus the great waste of leaving stretches of land uncultivated was avoided, but the production of bananas, which in 1898 had been 4 ½ million bunches, dropped to an average yield of a little over one million bunches in the last few years.

Several manurial experiments carried out in Southern Queensland under sub-tropical conditions, gave excellent results and demonstrated that exhausted banana lands may, by thorough cultivation and heavy dressings ot fertilizers, produce crops equalling those obtained from virgin lands, provided that they be in good physical condition, and above all, contain a fair amount of humus. From what has been written about bananas in different countries it appears that they require a well drained loamy soil, containing a fair amount of humus, and good amounts of potash, lime and phosphoric acid in readily available form.

With regard to the conservation of humus, a good deal is returned to the soil by the rotting of the stalks on the ground after the bunches

(1) See also No. 248, *B.* March 1914. (*Ed.*).
(2) See also No. 1278, *B.* Sept. 1912. (*Ed.*).

have been cut. The growing of green manure crops like velvet beans, Mauritius beans, etc., is practised in some localities and can be strongly recommended.

No other cultivated plant exhausts the soil to such an extent as bananas. This is fully borne out by the following analyses carried out in the Queensland Departmental chemical laboratory, on virgin soil and exhausted banana land, both taken from Buderim Mountain, where the soil is a volcanic sandy loam.

	Virgin soil per cent.	Exhausted land per cent.
Humus and other organic matter	18.86	17.04
Nitrogen	0.560	0.292
Lime	0.450	0.180
Potash	0.109	0.067
Phosphoric acid, soluble in 1 per cent. citric acid	0.0142	0.0634

This is confirmed also by analyses, made in the same laboratory, of the fruit and of different parts of the plant of three varieties of bananas. They show that a fair crop of Cavendish bananas (555 bunches per acre, weight of bunch 39 lbs.) removes in the fruit 123 lbs. of potash, 12½ lbs. of phosphoric acid and 43.7 lbs. of nitrogen, whilst the stalks left on the ground contain 150 lbs. of potash, 6 lbs. of phosphoric acid and 41.4 lbs. of nitrogen. Practically speaking therefore 273 lbs. of potash, or about 5 cwt. of sulphate of potash per acre, must be available to the banana plant in a readily assimilable form to produce its growth and crop in a few months.

In the manuring experiments conducted by the writer on Buderim Mountain, 160 lbs. of potash, 80 lbs. of phosphoric acid and 40 lbs. of nitrogen per acre were applied to normal crops and in double quantities to the exhausted lands, the composition of which is given above.

The unmanured and lightly manured experiments showed the want of vigour in the plants; the banana sucker, as soon as the bunch appears, seems to lose its vitality; the leaves drop off and the stalk bends over and often breaks under the weight of the small bunch. On the other hand the heavily manured plots produce good heavy bunches and the plants withstand better the cold weather during the winter.

In some cases very heavy manuring was tried, as much as two tons of artificials being given yearly, at a cost of £ 25 per acre, and, in the plots where lime was applied, attaining £ 29 per acre.

The average yield of the eight experimental plots (K P. N, see Table) for three years was 345 bunches with 3035 dozens of bananas per acre per annum, valued £ 38, the artificial fertiliser costing annually about £ 12 10s.

In the experiments 2 (K P N) the average yield was 457 bunches, with 4330 dozens of a value of £ 54 per acre, showing an increased net profit over the yield obtained from the preceding plots.

These experiments further showed that nitrogen acts best in form of dried blood and as nitrate of lime, that the addition of salt to the manure does not appear to make any appreciable difference, and that in the case of old plantations it is best to apply part of the artificials in holes made

Crop Results of Manuring Experiments on Buderim Mountain.

Number of Experiment	Fertilizers Used	Average yield per acre	
		No. of bunches	Dozens
1	K P N b	156	1 348
2	2 (K P N b)	243	1 900
3	½ (K P N b)	132	762
4	Nil	20	110
5	½ (K P Nn)	216	1 510
6	2 (K P Nn)	372	3 412
7	K P Nn	315	2 551
8	K Pt Na	221	1 937
9	2 (K P Na)	410	3 508
10	K Pt Na	350	3 118
11	2 (K P Nb)	388	3 266
12	2 (K P Nn)	471	4 237
13	2 (K P Nn) + salt	428	3 478
14	2 (K P Nb) + salt	410	3 347
15	Nil	273	1 760
16	Nil + lime	323	2 163
17	2 (K P Nn) + lime	388	3 322
18	2 (K P Nb) + lime	421	3 532
19	2 (K P Nn) + lime + salt	356	3 087
20	2 (K P Nb) + lime + salt	374	2 989

The figures of the first 10 experiments are averages of four years; those of the other of three years ending in 1914.

K = 160 lb. K_2O applied as 320 lb. potassium sulphate per acre.
Nb = 40 lb. N » » 290 lb. dried blood per acre.
Nn = 40 lb. N » » 290 lb. nitrate of lime per acre.
P = 40 lb. N » » 200 lb. ammonium sulphate per acre.
Pt = 80 lb. P_2O_5 » » 470 lb. superphosphates per acre.
2 (K P N) means double quantities; ½ (K P N) means half quantities.

All manures applied twice a year — in spring and autumn. Salt applied 2 cwt. per acre; lime applied in two dressings of 2 tons per acre.

with a crow-bar to a depth from 18 to 24 in. all round the banana stool at a distance of from 3 to 5 feet, and the rest as top dressing. Lastly, it appears that physical conditions of the soil are improved by cultivation and manuring.

In the close neighbourhood of the experimental plots other persons carried out some experiments which proved that manuring with insuf-

ficient potash yields disappointing results and that on virgin soil the application of the standard fertilizer mixture, K P N, gave the most profitable harvest, namely £62 2*s.* 3*d.* per acre.

The table includes the results obtained by the writer. The literature quoted in the paper mentions twelve works.

1131 – **A New Oak for Breeders: *Quercus insignis.*** — *The Journal of Heredity*, Vol. V, No. 9, pp. 406-407 + 1 plate. Washington, September 1914. FORESTRY

Dr. WILLIAM TRELEASE, of the University of Illinois, has called the attention of the American Genetic Association of Washington to *Quercus insignis*, and to the value it might have for hybridizing. The species in question was discovered in 1843 in the State of Vera Cruz, Mexico. It is found in considerable quantities about midway down the flanks of Mount Orizaba and especially near Chiapas. It is a rapid grower, attaining a height of 60 to 80 feet; its bearing is erect and it sends out large branches at the height of 30 or 40 feet from the ground. Its acorns are suitable as food for stock, and very large, usually two inches in diameter and sometimes two and a half. Their weigh is 50 to 60 grams each.

In view of its habitat the tree is probably unsuited to a temperate climate, but Dr. Purpus, who has explored its home, thinks that it could be raised in Florida, Cuba, Porto Rico, etc. The office of Foreign Seed and Plant Introduction of the U. S. Department of Agriculture is now endeavouring to introduce it and experiment it. If it is found to be well adapted, it is possible that native species of oaks could be grafted with it, thus yielding a large crop of acorns. Hybridizing experiments should also be made with some local species with a view to obtaining larger acorns.

Close relatives of *Q. insignis* are *Q. strombocarpa* of the same region and *Q. Skinneri* of Guatemala; the acorns of the latter, however, are presumably bitter or astringent.

1132 – **West Indian Boxwood.** — SPRAGUE, T. A., and BOODLE, L. A., in *Royal Botanic Gardens, Kew, Bulletin of Miscellaneous Information*, No. 6, pp. 214-219, London, 1914.

By means of specimens of flowering and leafy twigs sent to Kew by the British Consul at Caracas, Venezuela, it has been possible to identify the West Indian or Venezuelan boxwood as *Casearia praecox* Griseb. According to information supplied by the same Consul, West Indian boxwood is a product of the district of Maracaibo only, whence all that exported from other ports is originally shipped.

Boxwood is a yellowish hardwood, used mostly for turning. It is cut into pieces about 6 ft. long and from 4 to 8 inches thick. The best time for cutting the wood is from December to June.

Casearia praecox Griseb. had hitherto been recorded only from Cuba; it has, however, been collected also in the district of Santa Marta, Colombia, but under another name. The three forms (Cuban, Venezuelan and Colombian) differ so slightly in their characters and in the structure of their wood, that they may be considered as varieties belonging to the same species.

There are also other species of *Casearia* which yield useful wood.

1133 – **Experiments on the Grazing of Woodlands.** — ZEDERBAUER, E., in *Mitteilungen aus dem forstlichen Versuchswesen Oesterreichs*, Part XXXVIII, pp. 78-83. Vienna, 1914.

By ministerial decree of March 30, 1888, the Royal Institute of Experimental Forestry established a scheme of experiments on the influence of pasturage on woods, planned to ascertain : *a*) the losses of intermediate and direct products caused by pasturage in 1) plantations of spruce, 2) natural growths of spruce ; *b*) the nature and extent of the damage caused by the grazing and trampling of animals ; *c*) the measures to be taken to prevent damage to the wood, 1) of young trees transplanted and grown from seed. 2) of 3 and 4 year old trees from seed, 3) of 3 year old trees from seed, isolated, and in groups, 4) of 3 year old trees planted out in ordinary holes and with a small hoed area round them ; *d*) the most practical means, apart from fencing and hedging, of preventing damage by live stock, to 1) isolated trees with and without supports, 2) trees in groups with and without supports, 3) plantations without artificial protection.

This scheme of experiments was carried out in State forests and also in private forests. The results are summarised in the following table :

The effect of live stock in plantations with or without protection.

Period	Trees without protection		Trees with protection	
	Number	Height	Number	Height
		metre.		metre
a) *Plantations with* (1) *and without* (2) *enclosure :*				
1 May 1894	100	0.16	100	0.17
1 September 1909	12	1.55	61	1.62
2 May 1893	100	0.25–0.30	100	0.25–0.35
2 October 1899	45	0.5–0.7	63	0.7–1.0
b) *Trees not transplanted and transplanted :*				
June 1900	100	—	100	—
September 1911	14	0.81	21	0.64
c) *Trees with* (1) *and without* (2) *supports :*				
1 May 1894	100	—	100	—
1 September 1909	2.8	1.30	71	1.44
2 June 1895	100	—	100	—
2 September 1911	13	0.77	38	1.15

These results show that : 1) spruce plantations enclosed or with supports made a stronger growth than those without this protection ; 2) enclosed spruce plantations at 10 to 20 years contained about two-thirds

(61-63 per cent) of the original plants, whilst plantations without enclosure had only 12 to 45 per cent ; 3) 20-year plantations of spruces protected by supports contain 38 to 71 per cent of the original trees, as against 3 to 13 per cent in plantations without supports ; 4) 16-year stands of untransplanted spruces are less resistant to the movements of live stock than those of transplanted trees, while the differences in height are very slight ; 5) the expenditure incurred in enclosing or providing supports appears to be justifiable from a forestry as well as financial point of view. Protection by means of supports is also an advantage to pasturage.

LIVE STOCK AND BREEDING.

1134 — **The Hygienic Importance of Acid-Rennet Bacteria in the Udders of Cows.** — HYGIENE.
GORINI, COSTANTINO (Communication to the VI International Dairy Congress, Berne, June 1914), in *La Clinica veterinaria, Rassegna di Polizia sanitaria e di Igiene*, XXXVII Year, No. 17, pp. 47-51. Milan, September 1914.

In 1901 the writer showed the presence in the udders of cows, of acid-rennet producing bacteria (cocci causing coagulation by means of acid and rennet) which are generally found in the lactiferous ducts. Later he found some very small bacillus forms, which he called *Bacillus minimus mammae*.

These acid-rennet bacteria are capable of causing the premature coagulation of milk, *i. e.* before the normal acidity has developed, even immediately it is drawn from the udder and before external contamination.

They develop exceptionally in the lactiferous ducts, being probably favoured by the milk remaining in them after milking, and they cause inflammatory conditions of the udder or other complications. This inflammation differs from mastitis due to pyogenic or specific germs and usually disappears spontaneously, though it is liable to affect the quality and quantity of the milk.

The changes in the milk due to these organisms are very different from those caused by other bacteria and cannot be detected either by acidometric or by alcoholic methods, by boiling or by the reductase tests, etc. They are detected by zymoscopic or fermentation tests, which are also of great importance in judging the cheese-making value of a sample of milk and in detecting abnormal conditions of the udder.

The following practical conclusions may be drawn from these results :

1) To prevent the abnormal development of the acid-rennet microflora in the udder it is advisable to ensure that the cow is milked dry so as to empty completely the lactiferous ducts.

2) In zymoscopic testing of milk, the type of coagulum produced by the bacteria may be used as a guide by both cheese-maker and veterinary surgeon for indicating faulty milking and abnormal conditions of

the udder, which are as important to the health of the animal as to the quality of the dairy products(1).

1135 – **Poisoning by *Sorghum halepense*** (2). — *Royal Botanic Gardens, Kew, Bulletin of Miscellaneous Information*, No. 6, pp. 229-230. London, 1914.

Sorghum halepense is, after rice, probably the commonest food and fodder plant in India, besides being much used elsewhere; yet the constituents which are liable to exert a poisonous action are not well understood. It has therefore been deemed desirable to publish a note dealing with the matter.

In 1902 DUNSTAN and HENRY isolated a glucoside, which they called dhurrin, from the leaves of the great millet (*Sorghum vulgare*). This substance, on hydrolysis with hot hydrochloric acid or the enzyme emulsin, splits into prussic acid, parahydroxybenzaldehyde and dextrose. The enzyme emulsin is present in the parts of the plant containing the glucoside. *Sorghum halepense* Pers. (*Andropogon halepense* Brot). is considered by Hackel to be a variety of *S. vulgare* Pers. (*Andropogon Sorghum* Brot.) and there is little doubt that dhurrin is found in it as well as in the typical plant. The cases of poisoning observed are thus to be attributed to prussic acid produced by the hydrolysis of dhurrin in the stomachs of animals.

An examination of the numerous records of cases in which *Sorghum* was used as fodder, establishes two important facts: Firstly, the young vegetative parts of the plant are the most dangerous to stock, the mature plant being nearly or quite harmless; analyses of old plants have shown that little or no cyanogenetic substance was present. Secondly, the poisonous effect of the grass is enhanced in times of drought. One writer states that the grass is dangerous only in the green state and that when it is cut and dried and used for fodder it has no injurious effect. This may be due to the destruction of the glucoside or the emulsin or both, but it is possible that the grass was not cut till near maturity, that is after the disappearance of the glucoside.

1136 – **The Modifications produced in the Anthrax Bacterium by Means of Ultra-Violet Rays.** — Mme. VICTOR HENRÍ, in *Comptes Rendus hebdomadaires de l'Académie des Sciences*, Vol. 158, No. 14, pp. 1032-1035 + 12 figs.; Vol. 159, No. 4, pp. 346-348 + 6 figs. Paris, April 6 and July 27, 1914.

It is well known that ultra-violet rays cause the death of micro-organisms. M. and Mme. VICTOR HENRI have demonstrated that the abiotic effect of these rays is due to chemical reactions taking place in certain molecular aggregations which are to be found in the protoplasm, and especially in the cell nucleus. When the irradiation is weak, either in the case of the numerous micro-organisms studied by M. and Mme Henri or in that of the developing *Ascaris* eggs studied by FAURÉ-FREMIET, a series of more or less

(1) These conclusions, presented at the International Dairy Congress at Berne, June 1914 were adopted by the International Commission, which introduced zymoscopic testing for the study of the veterinary control of milk, in preference to all other tests (reductase, etc.) recommended for the laboratory control of milk. (*Ed.*).

(2) See also No. 1644, *B.* Dec. 1912, and No. 694, *B.* June 1913. (*Ed.*).

deep changes takes place. The fact that ultra-violet rays only attack certain chemical constituents of the cells, leaving all the rest intact, led the writer to believe that by regulating the irradiation, it would be possible to produce modifications in micro-organisms.

The writer exposed to ultra-violet rays an emulsion of sporogenetic anthrax 24 hours old in quartz tubes revolving round a lamp for 1, 2, 3, 5, 10, 20 and 40 minutes respectively, and then sowed 1 cc. on gelose and 1 cc. in broth. This treatment killed the greater number of the microbes, but some remained alive and capable of multiplying. A large number of the latter presented a normal aspect, but some colonies differed markedly. From these colonies, the writer has isolated a series of new forms distinct from normal anthrax in morphological, biochemical and biological characters. The character which is least stable under the action of the ultra-violet rays seems to be the uniting to form filaments. Further, the shape of the bacteria was changed (all forms being obtained, from bacilli to cocci), as well as their size (they became ½ or ⅓ the normal thickness), their sensibility to Gram's reagent (five forms being obtained which gave no reaction), and their pigmentation (two forms gave deep yellow cultures).

While the morphological and biochemical modifications produced in the cultures of bacteria grown in different media, *e. g.* in a medium containing sugar, are unstable and revert to the normal form on being transplanted to a normal nutritive medium, the morphological and biochemical modifications due to exposure to ultra-violet rays are distinguished by their great stability in successive artificial cultures.

On inoculating a guinea-pig with the modified form, the writer obtained in two cases from cultures of the blood from the spleen and liver, colonies with the characters of the normal anthrax bacteria. He therefore concludes that by passing into an animal organism the more modified, yellow, slender, Gram-negative form, which forms no spores, does not liquefy gelatine and has lost most of its virulence, can return almost to the primitive anthrax type.

1137 – **Pyroplasmosis in Cattle in Hungary in 1913: Means of Control.** — WOLLÁK, KÁROLY, in *Allatorvosi Lapok*, Year XXXVII, No. 33, pp. 387-389. Budapest, August 15, 1914.

In Hungary haemoglobinuria in cattle is relatively rare and seems to be restricted to the wooded regions of the North-East (1). Of late years, however, this disease has also appeared in the country on the left bank of the Tisza, where it sometimes takes a virulent form.

In 1913 pyroplasmosis appeared for the first time on May 20, in the commune of Hajduhadház (Hajdu county), and raged in a herd of 137 head of cattle which were grazing on some slightly elevated ground covered with oaks and robinias.

The writer describes the evolution of the disease and classes the symptoms observed into four groups according to the organs most affected. On the bodies of the diseased animals, the greatest number of ticks was found

(*Ed.*)

(1) See No. 353, *B.* March 1914.

at the end of May, whilst towards the middle of June their number diminished and the disease also began to disappear. As the disease had caused, in a relatively short time, considerable losses (by June 1, 10 animals had perished), in order to prevent its spreading, the writer subjected the herd to examination and then to treatment. Of the remaining 127 head, 30 were still affected and 97 were apparently healthy. The herd was removed from the infected spot and the 30 affected animals were isolated and kept in a stable ; 7 among them were kept as controls and the others were subjected for ten days running to arsenical treatment. They were given every day, in a small ration of bran, the following mixture : 1 gm. of powdered arsenious acid ; 10 gms. of powdered *calamus* root ; 10 gms. of sulphate of iron. The bodies of the diseased animals were freed from ticks and the skin was washed with a 5 per cent creoline solution. Already after the first and second treatment it was observed that the animals regained their appetite ; their urine presented its normal colour, and the weight of the animals perceptibly increased. The 23 animals under treatment were all cured, whilst among the 7 controls, 1 died and 2 had to be slaughtered.

In the herd which had been removed from the infected spot, 25 animals fell ill. In two cows the disease took a rather mild form, but with symptoms that the writer had never before observed in the symptomatology of pyroplasmosis. During the examination one of the cows used to let itself fall on its knees and remained a length of time in that position, while the other crossed its front legs ; the disease appeared in these two cases under nervous forms, and as the urine emitted was not red but of a deep yellow, the diagnosis was rendered more difficult. Here also arsenic showed its beneficial effects. The useful action of arsenic observed in destroying parasitical protozoa (*Spirochaetes*, *Trypanosomes*) leads the writer to hope that this substance, in the form of powder, will be a valuable means of controlling pyroplasmosis, especially as arsenic acts favourably on metabolism and on the increase of weight. Further experiments will decide whether the use of the new arsenical preparations, (salvarsan and neosalvarsan) can be practically recommended for cattle attacked by pyroplasmosis.

1138 – **Preventive Inoculations against Sheep and Swine Pox.** — Pécsi, Dani, in *Allatorvosi Lapok*, Year XXXVII, Nos. 30, 31, 32, pp. 357-359, 369-370, 381-382 + 2 figs. Budapest, July 25, August 1 and 8, 1914.

The present is a study intended to afford Hungarian farmers information on sheep and swine pox (1) and on the means of controlling this disease. The writer mentions the works of numerous investigators who have sought to find a harmless virus which would ensure the active immunity of sheep. Chaumiers, Voigt and others again have endeavoured to attenuate the activity of the variolous virus by passing it through an animal organism, so as to obtain a curative serum.

The writer, who has studied the question for the last 29 years, relates

(1) See No. 536, *B.* June 1914. (*Ed.*).

his experiments during 1913, made with virus attenuated by passing through calves, which have not given a definite result because calf-pox inoculated into sheep gave only 50 per cent. of immunity.

The study is completed by a report of a series of remarkable experiments by BRIDRÉ and BOQUET (1). Encouraged by the results of BESREDKA'S (2) discovery on the properties of sensibilised virus, they proceeded, by the application of this discovery, to modify the variolous virus in its activity by a contact of a certain duration with anti-variolous serum, or in other words to transform it, by sensibilising it, into vaccine. The experiments have had considerable results. The animals that were vaccinated with the sensibilised virus did not contract the disease and acquired in two to six days after the injection an absolute immunity. This immunity is very constant, and the vaccinated sheep did not prove at all dangerous to the untreated animals with which they were left in permanent contact. The injection must be made under the skin of the thorax behind the elbow; it causes generally, after four or six days, the formation of an oedema of variable size attaining sometimes that of a hen's egg, which is resorbed after a few days, leaving a hard spot which gradually disappears. The local reaction following on the subcutaneous injection of sensibilised virus varies in intensity according to the age of the animals. It is very slight in sucklings, more marked in lambs eight to ten months old and strongest in grown up sheep. Even when the local reaction fails, vaccination produces active immunity. In some especially sensitive animals, four or five days after the injection an increase of temperature sets in, which, however, is independent of the degree of local reactions. Vaccination does not cause any trouble in the physiological condition of the animals. Ewes in lamb or during lactation may be vaccinated without any danger of abortion or decrease of milk yield. Vaccination practised on sheep during the period of incubation of variola, has no unfavourable effect on the evolution of the disease. Anti-pox vaccination is thus applicable in contaminated surroundings, to all apparently healthy subjects. The really sound animals will acquire immunity and those that are already infected will undergo the disease as usual. In 1913 in Algeria 1 245 000 sheep were treated with this serum and not a single accident occurred.

MM. BRIDRÉ and BOQUET placed at the disposal of the writer a small quantity of sensibilised virus with which to experiment upon Hungarian sheep. The tests were made on ten lambs from four to six months old, of which two were kept as controls and the rest vaccinated as follows: two received the prescribed dose (0.2 cc) ; four were given half the dose and two a quarter ; five days after vaccination all the vaccinated animals showed, at the spot where the injection had been made, oedemae of different sizes. In one of the animals the temperature curve showed a maximum of 41.8° C.,

(1) Vaccination contre la clavelée par virus sensibilisé. — *Annales de l'Institut Pasteur*, No. 10, October 1913.

(2) De la vaccination par virus sensibilisé. — *Bull. de l'Institut Pasteur*, 1910, p. 241. 1912, p. 529.

whilst in the others it did not attain 41°C. The quantity of lymph used had no influence on the effect of the vaccination. The controls did not show any change, their temperature remaining unvaried at 39° C. Eight days after vaccination all the animals were infected with pox; five days after infection the two controls presented, at the infected spot, an inflammation which developed after four days into a pustule the size of a pigeon's egg, while the animals vaccinated with the sensibilised virus remained perfectly immune. The spots caused by the infection had disappeared.

Sheep breeding has greatly benefited by the researches of M. M. BRIDRÉ and BOQUET, who have solved the vaccination problem: namely *they have conferred an active, efficient and lasting immunity to sheep against sheep pox, by the inoculation of virus which is harmless to the animals inoculated, and incapable of producing contagious lesions.*

The writer warmly recommends the use of antipox serum, thanks to which sheep breeding in Hungary will be gradually freed from its greatest enemy.

1139 – **Studies on Fowl Cholera: The Inheritance in Rabbits of Immunity to Infection with the Bacterium of Fowl Cholera.** — HADLEY, PHILIP B., in *Agricultural Experiment Station of the Rhode Island State College, Bulletin* 157, pp. 285-307. Kingston, N. Y., April 1914.

The present paper is the writer's third contribution to the study of fowl cholera. In the first ("Fowl Cholera and Methods of Combating it", Bulletin 144, *Agricultural Experiment Station of the Rhode Island State College*) the writer announces the occurrence of the disease, — already known in Europe more than a century ago, — in the United States, especially in New England. Fowl cholera, caused by *Bacillus bipolaris septicus*, has been controlled by inoculations with serum, which, however, have not given uniform results. The writer obtained good preventive results by means of subcutaneous injections with from two to four cc. of 5 per cent carbolic acid, repeated daily for a week.

In the second work, prepared with the collaboration of ELIZABETH E. AMISON ("A Biological Study of Eleven Pathogenic Organisms from Cholera-like Diseases in Poultry", *ibid.*, Bulletin No. 146) the writers set forth the results of a biological study of eleven pathogenic organisms obtained from cholera-like diseases in poultry. The real fowl cholera caused by *Bact. bipolaris septicus* is endemic in New England and probably in all the central part of the Western States of the Union. There are, however, other diseases resembling fowl cholera caused by bacteria of the para-colon, para-typhoid or influenza groups.

The writers studied ten cultures of *Bact. bipolaris septicus* obtained from localities very distant from each other, and they found that the bacteria were in all cases identical. The virulence of the cultures examined varied considerably: the minimum dose of 48 hours' broth culture fatal to a fowl varied from 10 cc. to a millionth of a cubic μ, and the minimum dose fatal to a rabbit from 10 cc. to one hundred millionth of a cubic μ. It was demontrated that less than 50 bacteria, and probably only 4, injected

into the muscles of the chest were sufficient to cause infection. One is led to believe that in infected animals an immediate paralysis of the functions of the phagocytes takes place, whence the terrible infectiousness under natural conditions. The bacterium resists four months' esiccation (the maximum limit is still undetermined) ; it is killed by heating to 63° C for 15 minutes ; and it has very little resistance to carbolic acid and to acids in general.

A very virulent culture finds resistance in a susceptible animal when the latter has been previously inoculated with a homologous non-virulent culture. In rabbits, an artificial resistance to 10 billion times the minimum fatal dose of a highly virulent culture has been produced by a single strong dose : 3 cc. of the homologous culture. Only homologous cultures produced such resistance in rabbits.

The third work is a continuation of the preceding ones and deals with the nature of the immunity in rabbits and the production of a corresponding active immunity in fowls.

The writer gives a historical resumé of the inherited resistance to infectious diseases, from which he concludes : that immunity to certain infectious diseases, together with other phenomena dependent upon humoral factors of the blood, is transmissible from immune mothers to their offspring ; that the immunity thus transmitted and acquired, is due in reality to the transmission of antibodies, is not inherited and transmitted by the male and is not present in the second generation ; that inherited resistance is of short duration, but that in some cases it can be transformed into active resistance by inoculating the young animals with a virulent culture.

The cultures used in this study were the same as those employed in earlier investigations; they can be placed in two groups: the immunizing group and the infecting group. There has been found no morphological or cultural means of differentiating between the organisms of these two groups of cultures; the biological test alone serves to distinguish them. For the present research an immunizing (avirulent) culture was used. From his experimental results the writer concludes :

Female rabbits immunized with an avirulent culture of fowl cholera bacterium are able to transmit to their offspring a high degree of resistance to virulent cultures. Some immune mothers are able to produce such immune offspring for at least more than two years after the date of immunization. Immunity is not transmitted by the immune male. The resistance in the offspring is not permanent, enduring for not more than forty days. This inherited passive resistance can be transformed into a durable, active resistance by inoculating the young animals, some time within the first forty days of life, with a virulent culture.

ANATOMY AND PHYSIOLOGY

1140 – **On Ovariotomy in Sows; with Observations on the Mammary Glands and the Internal Genital Organs** (1). — MACKENZIE, K. J. J.; MARSHALL, F. H. A., and HAMMOND, J. (School of Agriculture, Cambridge in *The Journal of Agricultural Science*, Vol. IV, pp. 410-420; Vol. V, pp. 418-423; and Vol. VI, Part 2, pp. 182-186. Cambridge, 1912, 1913 and 1914.

It is commonly found that the flesh of pigs killed " on heat " produces inferior bacon and pork, and the occurrence of animals in this condition in the slaughterhouses causes considerable losses to various bacon-curing firms. Of recent years, notwithstanding these losses to bacon manufacturers and pork butchers, the practice of spaying has been on the decline and in many pig-raising districts has largely disappeared, the reason being that pigs are now made ready for the butcher before they are nine months old and are consequently less affected while in the feeders' hands by the neglect of the operation than when the are killed at a more advanced age, so that breeders hesitate to expose them to the slight risk of the operation. Moreover, many feeders aver that they find some spayed sows which behave like unoperated animals and consequently that the risk and slight expense are futile.

The writers examined three cases in which spayed sows were said to have behaved as if unspayed and found that in all three cases the operation had been incompletely performed, part of an ovary having been left behind in the body cavity and causing the undesirable symptons in the bacon pig, which consist chiefly in a greatly increased vascularisation in the mammary region and consequent depreciation of a valuable part of the pig. It would therefore appear that the objection to spaying on the grounds of its ineffectiveness put forward by feeders is without foundation, cases of failure being rather due to imperfect operations.

When examining carcasses in order to discard those of pigs killed on heat, bacon curers have been in the habit of regarding the presence of black melanic pigment in the deeper layers of the mammary tissues of coloured sows as due to extravasated blood and therefore a sign that the animal had been killed when on heat and that its carcass could only be used to produce bacon of an inferior grade. The writers examined a very large number of pigmented and unpigmented carcasses of both sexes and in various conditions with regard to their sexual organs; they obtained no evidence that the presence of the pigment was in any way associated with the sexual condition of the animal, but found that the pigment occurs only in certain dark-coloured animals. The remedy for this defect is to breed from animals in which the pigment is absent.

1141 – **On Some Factors Controlling Fertility in Domestic Animals.** — HAMMOND, JOHN, in *The Journal of Agricultural Science*, Vol. VI, Part 3, pp. 263-277 + 2 plates. London, September 1914.

The fertility of domestic animals is a subject of ever increasing importance, for with the improvement of the breeds of live stock there has come in many cases lessened fertility and often sterility. Thus, in Great

(1) See No. 1198, *B. Ang.* 1912. (*Ed.*).

Britain the Royal Commission on horse breeding found that about 40 per cent of the mares selected for breeding failed to produce foals.

PEARL has recently shown that the variation in fecundity (eggs produced) in various breeds of the common fowl is not anatomical; that a fertile strain of fowls does not necessarily contain more oocytes in the ovary than an infertile strain. He concluded that the fecundity of fowls depends on a physiological factor causing the oocytes to develop and grow. In mammals it is known that many oocytes atrophy at some stage of their development, but this has not yet been described in the common fowl. HEAPE and MARSHALL, who investigated the fertility of sheep, came to the conclusion that several factors influenced the number of ova shed during the heat period: among others, service early in the breeding season and the practice of "flushing", which seem to favour the ripening of the oocytes and prevent atrophy of the follicles. Nevertheless, some facts could not be explained as a simple result of the number of follicles which ripened, for instance the fact that in-breeding reduces fecundity while out crossing increases it, as has been observed by HEAPE in sheep, by DARWIN in pigs, by RITZEMA-BOS in rats, and by VON GUAITA in mice.

Since ovulation occurs spontaneously in the pig and is not influenced by copulation, the diminution of fertility on in-breeding must be due to other causes than the number of follicles rupturing at the heat periods. HEAPE suggested that in sheep the decreased fertility when in-bred might be due to some sort of abortion. STEPHENSON attributed many cases of sterility to the male, owing to a want of vitality, varying in degree, in the spermatozoa, which prevents the ovum or foetus reaching maturity and thus causes abortion.

The writer has endeavoured to determine the factors controlling the number of young produced at birth by counting the number of *corpora lutea* and foetuses in pregnant animals at various stages of gestation. The animals observed were rabbits, pigs and a bitch. The writer divides the factors controlling fertility into two groups:

1. Factors controlling the number of ova shed (fecundity, of PEARL).

2. Factors controlling the number of embryos which develop to reach maturity.

1. *Factors controlling the number of ova shed.*

In all probability it is as regards this factor that species and factors vary in the matter of fertility. It seems to be a complicated physiological factor which can be modified to a certain extent by improving the nutrition of the ovary. PEARL observed that the greatest egg production in fowls is in the first year; in general, fertility increases with age up to a certain limit, after which it falls gradually. It is well known that the number of offspring produced by a young animal breeding for the first time is below normal. MINOT has observed this fact with guinea-pigs, P. G. BAILEY with rabbits, WALLACE with sows. The writer has observed in 18 young sows that the number of *corpora lutea* varied from 11 to 19 and averaged 14.3 ± 0.39, whilst in 9 old sows it ranged from 13 to 24 and averaged

19.77 ± 1.26. It appears therefore that the lower fertility of young sows is due to a smaller number of ova being shed.

2. *Factors controlling the number of embryos which develop to reach maturity.* — The writer counted the *corpora lutea* in the ovaries and the number of foetuses in the uterus of pregnant sows, rabbits and a bitch, and found that the average number of ova shed at a heat is larger than that of the foetuses. In sows the number of ova was twenty, while the average litter of pigs is about twelve. In American breeds it appears to be even less: in Duroc Jerseys 9, and in Poland-Chinas 7.5. In rabbits the average number of *corpora lutea* was found to vary from 8.4 to 11, and the corresponding number of foetuses from 6.4 to 8.1. Of some of the ova shed at the time of conception no trace can be found in the uterus; it is supposed they may be lost by wandering into the body cavity instead of being caught by the Fallopian tubes. This, however, could not occur in the Carnivora, where the fimbriated end of the Fallopian tube completely surrounds the ovary. In the bitch examined by the writer the number of foetuses and *corpora lutea* were the same, namely five.

There is also the possibility that some of the ova may have escaped fertilization; or rather that they have been atrophized at a very early stage of development of the embryo, so as to leave no trace of their implantation.

Other ova shed from the ovary, although developing to a certain extent, never come to maturity and atrophy in the uterus.

The writer has found in sows and rabbits, and other observers have found in cows, sheep, hamsters and ferrets, that the pregnant uterus often contains, besides the normally developed foetuses, a few smaller ones in different degrees of development and in various stages of degeneration. Of seven sows observed by the writer, four contained atrophic foetuses with an average of 2.1 for the seven sows. Of 38 rabbits, 11 contained atrophic foetuses.

In animals bearing many young at birth this atrophy of the fertilized ovum is not very important economically, since, as a rule, many more ova are shed than would furnish foetuses to occupy the teats of the mammary gland. In animals producing only one or two young at a birth (mares and cows), however, the matter becomes one of great importance, for in these animals cases of complete sterility are frequent.

The cause of atrophic foetuses is not bacterial, since normal and atrophied foetuses are often found side by side; besides, the writer in his search for bacteria in the atrophic foetuses and in their membranes obtained only negative results.

The nutrition of the pregnant mother cannot be the cause of atrophy, though in many cases it affects the size and vigour of the new-born. From measurements made by the writer it appears that on the whole the longer the foetal membranes in pigs the larger the foetus. No connection has been found to exist (in pigs and rabbits) between the weight of the foetus and its position in the uterus; consequently competitive nutrition has very little effect in determining the size of the foetus. Fraenkel has shown that eth nutrition of the foetus is more especially under the control of the *corpus luteum*.

From an examination of the works of several investigators, it seems possible that the atrophy is due to the low vitality of the foetus owing to constitutional loss of vigour of either parent at the time of mating, or to insufficient vitality in the spermatozoa, or to domestication (the writer observed that in wild rabbits atrophic foetuses are much rares than in domestic rabbits). It seems that the effect of domestication on these animals is to increase the number of ova shed and at the same time to diminish the proportion of those which develop.

The writer does not arrive at any definitive conclusion on the cause of the atrophy, and the several possibilities suggested are still under investigation.

1142 – **Research on the Transformation of Energy in the Domestic Fowl.** — GERHARTZ, HEINRICH, in *Landwirtschaftliche Jahrbücher*, Vol. 46, Part 5, pp. 797-814. Berlin, July 14, 1914.

The most important investigations hitherto made by VÖLTZ, LEHMANN, PARATSCHUCK, RICHET, REGNAULT-REISET and others, on the transformation of energy in the domestic fowl, as well as in birds in general, are now no longer sufficient, as they do not correspond to modern demands upon the technique of observation and do not give due weight to the biological activity of the animals. The writer, with the assistance of the Prussian Ministry of Agriculture, undertook several experiments on this subject. They were carried out with an improved system of Regnault-Reseit's apparatus, in which the bird was in a state of repose throughout almost all the experiments and could be observed without being disturbed. The writer experimented upon fasting birds and birds that had been fed. In the first case the bird was not given any food during the 13 hours which preceded its being put into the respiratory apparatus. In the second case the bird usually ate its ration during the preliminary experiment. The ration was calculated to keep the weight of the body constant. When the bird was not in the respiratory apparatus it was kept in a roomy cage.

The object of the first experiments was to observe the quantity of energy transformed in the fowl when it was in a state of absolute repose and consumed only so much matter as was necessary to keep up its physiological activity. This transformation of energy is called by the writer the " minimum " or " upkeep transformation ", and it amounted to 58.37 calories for the normal fasting fowl and 62.15 calories for the same bird that had been fed, per day and per unit of surface (1000 square centimetres). In the brooding hen of the same breed after feeding, the corresponding figure was 71.78 calories. On comparing these values with those of Zuntz for dogs (75.1) and for horses (94.8), it appears that fowls in a state of absolute repose have not a relatively high transfomation of energy, but a relatively low one. An abnormally high transformation in birds is thus quite out of the question.

The next experiments were aimed at ascertaining how, and to what extent, the organs of reproduction and their functions acted on the minimum transformation. With this object experiments were made during the moulting and the brooding periods. They showed that during the moulting

period the transformation was slightly increased, namely by 5.2 per cent while the brooding period did not cause any change.

In a third series of experiments the writer endeavoured to determine whether the laying period, exclusive of the amount of energy required for the formation of the egg, had a specific action on the transformation. With this aim experiments were made before and after the laying period. If there was a specific surplus of energy beyond that required for the formation of the egg, it ought to be noticeable in the period of transition. The experiments showed that the transformation of energy went on increasing even after the period of egg-laying, which can only be explained by admitting a specific effect of the period of laying on the transformation of energy. Eight days before laying the first egg, as another experiment showed, this effect was not yet noticeable.

A last series of experiments was devoted to determining the influence of the function of egg-laying on the transformation of energy in the hen. With this object several tests were made. Of these the first group led to the following results. The period of egg-laying caused an increase of 70.1 calories in the transformation of energy, or 78 per cent per unit of surface per day. Each day 43.9 calories, or 26.2 per unit of surface, were employed for the formation of the egg. Admitting that the period of egg-laying itself, without considering the outlay of energy directly caused by the formation and expulsion of the egg, increases the transformation of energy by about 35 per cent (experimental results of successive periods), there would always remain 78 per cent — 35 per cent = 43 per cent for the formation of the egg and egg-laying proper.

In the second group of experiments on the egg-laying period, the results differed somewhat, for instead of the 26.2 calories per day and per unit of surface, 24.8 calories were utilized in the formation of the egg.

The figures obtained in these investigations are interesting also from another point of view. If, as has been stated above, 26.2 calories are consumed for the formation of the egg, 10.8 correspond to the protein and 15.4 to the fat. The fixation of these two substances requires, however, different contributions of energy. Admitting, with KLEIN and VON DER HEIDE, that for the formation of 1 gram of protein 7.25 calories are required, and for 1 gram of fat 2.5 calories, the fixation of the protein would have required 13.8 calories and that of the fat 4.1, thus altogether 17.9 But the period of egg-laying caused an increase of 70.1 calories in the transformation of energy. There remains therefore a surplus of 70.1 — 17.9. = 52.2 calories. Taking the specific influence of the laying period at 24.5 calories (that is 35 per cent of 70.1), there remains a difference of energy of 52.2 — 24.5 = 27.7 calories, corresponding especially to the formation of the egg above the expense of energy required for the formation of flesh. The formation of the egg in the hen is thus accompanied by a considerable expenditure of energy.

1143 – **The Preparation of Ensilage.** — SAMARANI, FRANCO, in *Bollettino del Ministero di Agricoltura, Industria e Commercio*, Year 13, Nos. 8-12, pp. 87-103. Rome, August-December, 1913.

The results of the experiments carried out for many years by the writer for the purpose of discovering the best method of preparing ensilage in ordinary silos have shown that during the first few days after the grass has been put in, two typical and different fermentation processes take place at the expense of the sugar and of the cell-sap — an acetic fermentation and a lactic fermentation.

The first is an intracellular process, through which the sugars of the cell substance are transformed, as a result of the vital activities of the cell in a relatively warm place (silo) where there is an almost complete absence of oxygen, into alcohol and carbonic acid. Later, as a result of chemical or physiological, but certainly not bacterial, action the alcohol is transformed into acetic acid. The second process is an ordinary lactic acid fermentation, due to the action of bacilli and cocci such as are found in milk and milk products. Of the total free acid content of normal acid silage, on an average 70 per cent is acetic acid, up to 20 per cent lactic acid, and, roughly speaking, 10 per cent butyric acid.

The predominance of the acetic acid is chiefly due to the fact that the temperature of the silo rises to 40-60° C, which is particularly favourable to intracellular fermentation. If, however, the lactic fermentation has free sugar at its disposal, it can, owing to its power of acting directly upon the latter, produce more acid than the acetic fermentation, which can only transform sugar into acid indirectly. When in the acid ensilage sufficient lactic and acetic acids have been produced, which takes place ten days after the filling and pressing down of the silo, no further bacterial fermentation goes on. If sufficient acidity is not soon attained by the two fermentation processes, a putrefactive fermentation sets up, with formation of ammonia, butyric acid and other malodorous compounds. Unsuitable fermentation, from the experience of the writer, is best prevented by the addition to the silage of a dilute solution of milk sugar.

From these observations, the conclusion can be drawn that in order to succeed in making ensilage, it is above all necessary to avoid overheating the fodder, in order to limit the acetic fermentation and thus to leave the decomposition of the sugar chiefly to the lactic fermentation process. This end can best be attained by providing the silo with mechanical means of applying pressure. The experiments of the writer in this direction showed that mechanical pressure is best applied immediately after the required amount of fodder has been put in, so as by this means to free the silo as much as possible from air. When the interior of the silo is once free of air, the temperature rises with difficulty and the lactic fermentation is promoted at the expense of the acetic fermentation.

According to observations made by the writer, silos with mechanical presses yield a fodder with 70 per cent lactic acid and 20 per cent acetic acid, while the proportion is just reversed in the product of an ordinary silo. Further, they have the additional advantage of producing ensilage containing less free acid and which consequently smells less strongly.

In conclusion, the writer gives some information respecting an ensilage experiment with beet slices straight from the sugar factory. He found that in order to obtain a satisfactory product, it was necessary to remove all the air from the silo. This was of course best effected by heavy pressure.

In order to promote lactic fermentation, Sig. Samarani advises, as in the treatment of grass, the addition to the silage of a solution of milk sugar.

1144 – **The Forage Value of Redshank *(Polygonum lapathifolium)*.** — STÖRME and KLEIN, in *Deutsche Landwirtschaftliche Presse*, Year 41, No. 80, p. 890. Berlin, October 7, 1914.

Redshank (*Polygonum lapathifolium*) was used by many farmers as fodder in Germany during 1914. Its chemical composition is, according to a recent analysis made at the Köslin Experiment Station, as follows :

Water		71.74 per cent.
Dry matter :		
Ash	2.29 per cent.	
Crude fat	0.69 »	
Crude protein	3.07 »	
Crude fibre	8.08 »	
Nitrogen-free extract	14.03 »	
		28.16 »
		99.90 per cent.

The digestible substances are :

Crude protein	1.72 per cent.
Pure protein	1.25 »
Fat	0.35 »
Crude fibre	4.70 »
Carbohydrates	9.35 »
	17.37 per cent.

According to the above analysis, the food value of redshank is equal to that of pasture grasses such as rye-grass and cocksfoot.

All practical farmers agree in stating that redshank has given complete satisfaction as fodder and that it has not caused the slightest injury to the health of the animals. As food for milch-cows it has also been useful. The writer believes that in years of scarcity of forage it will prove a welcome addition to the food supply.

1145 – **The Influence of Temperature on the Microflora of Hay : Lactic and Butyric Hays.** — GORINI, C., in *Rendiconti della R. Accademia dei Lincei*, Vol. XXIII, Series V, Part 1, No. 12. Rome, 1914.

Applying the methods of silo research (1) to hay, it has been possible to determine a main difference between normal and abnormal hay. Those hays are to be called normal which have not undergone abnormal maceration or fermentation, nor become mouldy, scorched or damaged. Normal hays are divided into normal lactic and butyric hays according to the nature of the predominating fermentation.

(1) See No. 541, *B.* June 1914. (*Ed.*).

The writer submitted the same hay stack during its various stages of fermentation to zymoscopic and bacteriological examination. He found that during the first 3 to 5 days of fermentation, with a temperature of 50-55° C., the hay was prevailingly lactic, whilst as the temperature gradually rose to 60-65° C. and beyond, the mass tended to become more butyric, as is unfortunately often the case in ordinary stacks.

The results confirm those obtained in the case of silos :

1) Normal hay may be classified as lactic or butyric according to the predominating microflora.

2) The nature of the microflora is in direct relation to the temperature of fermentation.

3) Most hay, as in the case of ordinary silage, is of the butyric type and is consequently less favourable to the intestinal functions of the live stock and to the sanitary condition of the milk and its products.

4) To obtain lactic hay, care should be taken in stacking it to expel as much air as possible and to maintain a temperature of about 50° C.

These conclusions show the importance of zymoscopic-bacteriological control of fodder in order to estimate its value as forage from a health and dairy point of view. Thus a normal hay may as a result of organcleptic, chemical or simple microscopic examination be declared healthy and yet contain a microflora dangerous to the intestinal functions and health of stock and consequently to the quality of the milk and dairy products.

1146 – **The Food Value of *Stizolobium aterrimum* and *S. pachylobium* Beans.** — SHREWSBURY, HERBERT S., in *Bulletin of the Department of Agriculture, Trinidad and Tobago*, Vol. XIII, No. 81, pp. 194-195; and No. 82, pp. 240-241. Port-of-Spain, June and July, 1914.

The seeds of the two species of *Stizolobium* grown on the same estate in Trinidad, in the same seasons, were recently submitted to the Department with a request for information as to their suitability for fodder.

Their nutritive value is shown by the accompanying table; it is very nearly the same for both species, but *S. pachylobium* is somewhat preferable because it has larger seeds and consequently a lesser proportion of teguments and indigestible crude fibre.

Feeding experiments on guinea-pigs showed it to be highly improbable that the beans were toxic in the slightest degree.

On analysis no poisonous glucosides, saponins, fats, alkaloids, vegetable ptomaines or toxalbumins were found. Besides, the beans of *S. pachylobium* have been used as fodder and also for human food without ill effets. It does not appear, however, that *S. aterrimum* has ever been used, in Barbados, as fodder or as human food, while the leaves are said to have poisoned cattle. It is not yet quite certain that *S. aterrimum* is not a synonym for *S. utile* or *Mucuna utilis* of Wallich, which has been cultivated extensively in Mauritius and Tasmania as a table vegetable and as a fodder for cattle.

In the accompanying table the composition of soy beans is also given for comparison. The two *Stizolobium* are inferior in feeding value

to soy beans, but they are somewhat superior to French, Lima or field beans.

	Carbo-hydrates	Proteins	Water	Crude fibre	Ash	Fat	Feeding units
S. aterrimum	44.3	29.8	12.0	6.2	4.2	3.5	127
S. pachylobium . . .	47.2	29.2	11.0	4.1	4.2	4.3	131
Soja hispida	39.2	33.2	10.0	4.4	4.7	17.5	157

1147 – **Statistics of British Feeding Trials and the Starch Equivalent Theory.** — Wood, T. B., and Yule, Udny G. (School of Agriculture, Cambridge) in *The Journal of Agricultural Science*, Vol. VI. Part 2, pp. 233-251. Cambridge, May 1914.

Summaries of about 400 feeding trials (200 dealing with oxen and 200 with sheep) were compiled from reports of British experiments carried out down to 1907 and were published in the Journal of the Highland and Agricultural Society for 1909-1910. The present paper makes a statistical examination of these summaries for the purpose of investigating the reason why British experimenters, calculating on the basis of Kellner's figures, usually find that the increases produced by various diets are not proportional to the excess of starch equivalent provided by the diets above that required for maintenance.

Swedes were the first to be investigated in this connection, as they represent an article of food used to a much larger extent in Great Britain than on the continent, and it seemed quite possible that Kellner's figures for starch equivalents in roots, which are based on a small number of experiments, are not accurate when roots are used in such large amounts as is usual in British farming. All experiments dealing with the feeding of swedes to oxen were abstracted from the summaries, and, after deducting the food required for maintenance from the other constituents of the diets as far as possible, the results of feeding swedes were obtained in terms of increase as follows :

Corrected weight of swedes in ration above maintenance, per 1000 lbs. live weight per day	Number of experiments	Average live weight increase produced per 1000 lbs. live weight per day	Probable error of average
lbs.		lbs.	
40 to 60	3	1.46	—
60 » 80	4	1.73	—
80 » 100	14	1.72	0.082
100 » 120	17	1.83	0.061
120 » 140	13	1.93	0.078
140 » 160	8	1.85	0.048
over 160	3	2.39	—

Now assuming that the increase consists of 67 per cent. of fat and 33 per cent. of water (LAWES and GILBERT) and that 1 gm. of starch equivalent yields 3.76 calories in the animal and 1 gm. of fat 8.8 calories, the following rough approximation to the percentage utilisation is obtained for swedes used in varying quantities above maintenance:

Corrected weight of swedes in ration above maintenance, per 1000 lbs. live weight per day	Percentage utilisation
lbs.	—
50	51
70	43
90	33
110	29
130	26
150	21

The figures receive some support from the fact that Kellner's average figure for percentage utilization is 50 per cent. which is about the same as the utilisation of swedes in the British trials when used in small quantities. They also agree with figures directly determined in the winter of 1913-1914, when two lots of 10 oxen of similar weights were fed on just sufficient cake and chaff to supply maintenance, the one lot receiving in addition 46 lbs. of swedes, the other 138 lbs. In the former case the percentage utilization was 47; in the latter it fell to 32. In the experiments on which Kellner based his starch equivalents, the amounts of food added to the basal ration varied very considerably, yet there is always direct proportionality over a wide range of diet between the excess of food above that required for maintenance and the amount of increase produced, and in all cases approximately 50 per cent. of the excess of food expressed as calories above maintenance requirements was utilized as increase in live weight.

The next step was to recalculate the results of all the experiments given in the above-mentioned summaries in order to determine their percentage utilization. The new results were as follows:

Lbs. starch equivalent above maintenance: oxen per day sheep per week	Percentage utilisation	
	Oxen	Sheep
3 – 4	—	58 ± 5
4 – 5	—	48 ± 5
5 – 6	—	56 ± 3
6 – 7	39 ± 2	48 ± 2
7 – 8	35 ± 2	46 ± 2
8 – 9	34 ± 1	37 ± 2
9 – 10	32 ± 1	37 ± 2
10 – 11	30 ± 2	42 ± 2
11 – 12	26 ± 2	—
12 – 13	24 ± 1	—
13 – 14	21 ± 1	—

These figures agree with those given above for the utilization of swedes: the larger the amount of food above the maintenance ration, the smaller the proportion utilized, yet the figures are comparable with Kellner's at any rate as regards range of diet. The difference between the two sets of results make it clear why British experimenters do not obtain results in their feeding trials which agree with Kellner's starch equivalent theory: Kellner's starch equivalents are based on figures which indicate a direct proportionality between the amount of food consumed above the maintenance ration and the live weight increase produced, while British feeding trials indicate clearly and with certainty that the percentage utilization of food decreases as the diet is increased, each successive increase giving a smaller return in live weight increase than the last.

As a possible explanation of the divergence between Kellner's and British experience, the probable errors of the results were worked out and removed all doubt as to the significance of the differences observed. Another possibility was that whilst Kellner's figures are based on experiments in a respiration chamber, in which the carbon fixed in the form of increased weight was accurately determined by means of a carbon balance, the British results were obtained in ordinary feeding trials in which the utilization is calculated from the increase in live weight by a factor depending on a very small number of experiments carried out at Rothamsted many years ago. This factor may be assumed to give the proportion of fat in the total increase of weight as a lean animal becomes fat, but it may fail to give with accuracy the proportion of fat in successive increases as the animal slowly fattens from the lean condition. There is some evidence to show that the first addition of live weight increase to a lean animal may contain as much as 50 per cent. of water and only 50 per cent. of fat, whilst the last additions of weight to the animals may be almost entirely fat. In the case of the oxen this would increase the lowest utilization with the highest diet from 21 per cent. to 31.5 per cent., which is still significantly below the highest percentage utilization of 39 per cent. and much lower than Kellner's average figure of 50 per cent.

A further reason for divergence might lie in the fact that whilst Kellner's experiments were confined to the measurement of the carbon balance for a short period including the formation of only a few pounds of fat, the period of the British experiments was some four on five months, during which the animals laid on several hundredweights of live weight increase; it is quite possible that there might be a direct proportionality between food and increase in the early stages of fattening whilst the animal is still comparatively lean. Accordingly all the experiments with oxen were classified according to the period of feeding and their percentage utilization was worked out as follows:

Length of experiments in days	Percentage utilization
20 to 80	32
80 » 100	31
100 » 120	33
120 » 180	32

Evidently the length of time of the experiment has on the average no effect on the percentage utilization of food, the reason of this probably being that in some of the shorter experiments animals already half fat were used, and under these circumstances, the length of the experiment is not a measure of the extent to which the fattening process was pushed. The question was therefore attacked by calculating the percentage utilization during the various stages of fattening in a separate series of trials, the detailed data of which were available. The results are given below.

	Percentage utilization
1st month	39
2nd »	34
3rd »	31
4th »	15

The average utilization is very good during the first month and does not fall off much during the second and third months, but in the fourth month the falling-off is very striking indeed. It would therefore appear that whilst Kellner's starch equivalents may give a fairly accurate measure of the amount of fat production to be expected from various foods in the early stages of fattening, they fail to do so in the later stages, because as fattening approaches completion, the law of diminishing returns asserts itself and a given amount of starch equivalent produces less and less fat as time goes on and the animal gets ripe. Kellner's starch equivalents, too, fail when very liberal diets are used, because here the animal very quickly reaches that stage of fatness at which the law of diminishing returns begins to make itself felt.

The writers point out the remarkable variation in efficiency, as fat-producing machines, among animals of the same breed fed under identical conditions and show that the standard deviation under these conditions is 21 per cent. of the live weight increase and the probable error in the increase of one animal 14 per cent. Calculating on this basis, average-sized animals on average rations having a heat value of 25 400 calories would retain from 6 400 cals. to 8 400 cals. in their bodies and give out heat amounting to 19 000 and 17 000 cals. respectively. Examination of the increase of individual oxen shows that, assuming that similar amounts of food are digested, the differences between the amounts of heat evolved are even larger than those indicated above and may reach 25 per cent. between what the farmer would call a good and bad "doer". Investigations are at present in progress at Cambridge on the variation of digestibility according to the individual peculiarities of the animal and the amount of diet, and on the possibility of estimating the rate of heat evolution from animals of known fattening capacity by measuring the difference between their skin temperatures and the temperature of the surrounding air.

1148 – **Feeding Experiments with Whole Milk and Skimmed Milk with Cream Substitutes** (1). — WELLMANN. — Reprint from *Landwitschaftlichen Jahrbücher*, pp. 499-626. Berlin, 1914.

The writer made comparative experiments on the utilization of whole milk and of skimmed milk with cream substitutes for feeding calves and young pigs.

The fresh whole milk of the day was pasteurized for a quarter of an hour, then cooled and kept in a cool place in well closed cans.

The additions to the skimmed milk consisted of meal and of flour starch saccharified by diafarine (a preparation of diastase); it was also homogenized with a preparation of tallow known in trade under the name of " Premier jus ".

The skimmed milk with meal was prepared as follows: the daily fresh skimmed milk was passed through a sieve and pasteurized; while still warm it received the addition of 54 parts of wheat meal, 27 of rye meal and 1 of common salt per 1000 parts by weight of liquid. The mixture was passed a second time through a fine sieve and then kept in a well closed vessel.

The diafarine skimmed milk was prepared in the following manner: After being passed through a sieve and pasteurized it was cooled to 55-60° C. and mixed with 50 parts by weight of wheat meal, 25 parts of rye meal and 7.5 of diafarine per 1000 parts of liquid.

In another experiment skimmed and whole milk were mixed and to this mixture (containing 2.5 per cent of fat), 50 parts of wheat meal and 25 of rye meal per 1000 were added, together with 7.5 parts of diafarine with the object of saccharifying the meal starch. This preparation is called by the writer " Diafarin-Fettmilch ".

The homogenized milk was prepared by mixing the tallow preparation intimately with skimmed milk.

Eleven pigs from two to four weeks old were experimented upon; two of these were slaughtered at the beginning of the experiment as controls, the others at the end. The milk was always given *ad lib.*

The experiment showed that from a dietetic point of view whole milk, diafarine milk, and skimmed milk with meal gave the best results; no intestinal troubles occurred with the use of these feeds. The animals seemed to relish most of all the diafarine milk. The homogenized milk was always willingly taken, but one animal fed on it had an attack of scour which was soon arrested by some citric acid.

The digestibility of the various milks was, on the whole, the same, even when that of the individual foods was different. The high digestibility of the fat in the homogenized milk was striking; although there was 6 per cent of fat it was utilized even better than in the whole milk. Protein proved more digestible in the milk with wider albuminoid ratio (homo-

(1) See also the original articles: 1) Prof. PAUL SCHUPPLI, Calf Rearing on the Emulsion System, *B.* Feb. 1913, pp. 167-173; and 2.) Prof. ANTONIO PIROCCHI, Utilization of Skimmed Milk as Food for Calves, *B.* Aug. 1913, pp. 1157-1164. (*Ed.*).

genized milk) than in that with a narrower ratio (whole milk, diafarine-skimmed milk). In most cases the young pigs utilized the milk better as they grew older.

The greatest assimilation of nutritive matter per 1000 of live-weight was observed with diafarine-skimmed milk (35.93), and " diafarin-fett milch " (38.5), and meal and skimmed milk (45.53). With whole milk the corresponding figure was only 30, and with homogenized milk 30.47. In the consumption of starch values the difference between the four kinds of milk was barely 15 or 20 per cent.

The daily increase per 100 lbs. of live-weight ranged from 2.2 to 3.5 lbs., and diminished with increasing age. It varied from 3.08 to 3.34 lbs. for whole and homogenized milk; it was 3.25 lbs. for diafarine-skimmed milk and 3.5 lbs. for " diafarin-fett milch ". The pigs retained in their bodies from 36 to 74 per cent. of the digestible nitrogen supplied.

From an economical point of view, diafarine skimmed milk was the most satisfactory and " diafarin-fett milch " the least.

The cost of one pound of gain varied with the different feeds as follows :

	d
Whole milk	7.11
Diafarine-skimmed milk	3.10
Meal-skimmed milk	3.53
Diafarin-fett milch	7.80
Homogenized milk	4.65

Thus, feeding with diafarine-skimmed milk costs about one-half, and with homogenized milk about two-thirds of the expense of feeding whole milk.

In the pigs fed on diafarin the flesh was singularly light coloured.

The paper contains data on the weights of the different organs of the pigs and on the analysis of the flesh.

HORSES ASSES AND MULES

1149 – **The Breeds of Horses of the Sunda Archipelago.** — Von Barnekow, Hans, in *Zeitschrift für Gestütkunde und Pferdezucht*, Year 9, Part 9, pp. 194-198. Hanover, September 1914.

This paper is a brief review of the most important breeds of horses of the Sunda Archipelago, namely : Sandalwood, Macassar, Sumbawa, Savonese, Timor, Batak, Boverlander, Java and Preanger.

The *Sandalwood* horse is a native of Soemba island and is considered on the whole as the best of the archipelago. For scores of years it has been exported in numbers to Java ; consequently the stock has diminished to such an extent that measures had to be taken for the preservation of the breed. Its body is compact and is supported by sound and strong feet, so that the horse is especially suited for the saddle. The strong strain of Arab blood with which it has been credited can no longer be recognized in it owing to long-continued inbreeding. The Sandalwood has a very regular pace and is an excellent trotter. It combines a lively fiery temperament with great good nature. Its coat varies, but jet black, dark brown and piebald are the commonest.

The *Macassar* breed found in Celebes is the one that approaches most the Sandalwood. It is smaller and not so handsome, but its frame is stronger, it is more resistant and thriftier and it is much appreciated as a cavalry horse. It is bred by the natives, who are distinguished above all the other Malays for their skill in breeding. Nevertheless this breed is threatened, more than any other breed, with extinction, as hitherto neither the Government nor the leading breeders have been able to control the destructive disease known locally as "Niewe Ziekte".

The third breed of the Sunda Archipelago is that of the *Sumbawa* horses, from the island of the same name. They are decidedly draught horses and possess powerful limbs with clean bones and sound hoofs. They are smaller than the preceding breeds and combine a good nature with extraordinary resistance, which renders them very suitable for artillery. At present Sumbawas are the most numerous breed in the islands. Their exportation ranges between 8000 and 10 000 head per annum. The dreaded Tambora disease, a consequence of shortage of forage and of drought, has never sensibly diminished the stock of Sumbawa horses.

The next breed allied to the Sumbawas is the *Bimanese*; it is a native of the same island and is chiefly used for the pack saddle.

A special breed is the *Savonese* from the island Savoe. The horses of this breed are not very numerous; they are the result of a cross with the Sandalwood and, like the allied Rottinese breed, are fast carriage horses; they are much esteemed and exported to Java and Celebes.

The *Timor* breed, from the island of Timor, is really a diminutive Sandalwood. It was once held in great repute, but continuous inbreeding has so deteriorated it that its exportation has greatly diminished. Endeavours are now being made to restore this excellent breed to its original high level.

A horse that outwardly much resembles the Sandalwood is the *Batak*, which for its usefulness is superior to all the other breeds. Its real home is the high plateau of Sumatra, and especially the shores of the great Toba lake. Its conformation is handsomer than that of any other breed and renders it as suitable for the saddle as for draught. Batak horses are in great demand on the tobacco plantations of British India, Singapore, Malacca and Penang.

The collective name of *Bovenland* horses is given to all the other breeds of the west coast of Sumatra. They differ a good deal in build and usefulness from each other; they are heavier than the preceding breed, and do not equal them in general utility. Many fine and strong stallions are to be found among them, but unfortunately they are not used for breeding purposes but as saddle horses.

The *Java* horse is an insignificant, weak animal, suitable only for light draught. It is bred chiefly in the mountains; the best animals, however, are found in the rich grazing districts of the south coast.

The last breed of the Sunda archipelago which deserves mention is the *Preanger*, which owes its origin to the crosses of Persian, Arabian, and east European stallions with Java mares. Later Australian, Cape

Sandalwood, and Macassar blood was introduced for its improvement. From this mixture of various bloods a breed has been formed which is equally suitable for riding and for driving, Unfortunately it is bred only in the island of Preanger, and thus it is mostly known to the white population only by name. Its exterior conformation is especially harmonious.

1150 – **Holstein Milk Yield.** — MARSHALL, F. R. (Bureau of Animal Industry, U. S. Department of Agriculture) in *The Journal of Heredity*, Vol. V, No. 10, pp. 436-439. Washington, D. C., October 1914. CATTLE

The study reported in this paper relates to inheritance, through paternal and maternal lines, of factors controlling the production of butter-fat. It consists in the examination of records of cows as reported in the Blue Book compiled annually from the Advanced Register for the Holstein Breed. Here only selected material is dealt with, as only the good yields are registered. These were all seven-day records made at various ages and giving the pounds of milk yielded, pounds of fat and per cent of fat.

In Vol. 10 of the above Register, there were found 1317 cases of cows having official records and whose paternal grandams also had records. In addition, there were 678 cases in which a record-making individual had a maternal grandam with a record.

The difficulty of variation in age was overcome by arranging the "paternal grandam" and "maternal grandam" cards in two parallel sets. Having a much larger number in the paternal set it was possible to select therefrom, for each maternal card, one in which the age of the cow and of the grandam corresponded very closely. This arrangement left 665 cards in each group.

The coefficient of correlation for each group in respect to total milk, total fat and per cent of fat, is shown in the accompanying table (1).

Taking the opposing pairs of cards in order to see in which there was the greatest similarity between the records of grand-daughter and grandam the following results were obtained:

	Number of cases in which resemblauce was closest	
	on maternal side	on paternal side
Pounds of milk	403	262
Pounds of butter-fat	407	258
Per cent. of butter-fat	345	320

(1) DAVENPORT'S statistical method is adopted.
M. represents the average of the readings.
Em, the probable mean error.
σ, the standard deviation.
E σ, the relative probable error.
r or $\sqrt{\ }$, the correlation coefficient.
Er, the relative probable error.

(*Ed.*).

	M	Em	σ	E σ	r	Er
Pounds of milk.						
Through Sires.						
Grand-daughters	370.6	± 2.29	88.5	± 1.67	— 0.05	± 0.025
Grandams	475.3	± 2.56	98.7	± 1.95	— 0.05	± 0.025
Through Dams.						
Grand-danghters	393.4	± 2.63	99.5	± 1.95	— 0.012	± 0.02
Grandams	437.4	± 2.09	80.8	± 1.54	—	—
Pounds of butter-fat.						
Through Sires.						
Grand-daughters	12.68	± 0.089	3.41	± 0.062	— 0.04	± 0.025
Grandams	16.93	± 0.108	4.14	± 0.076	—	—
Through Dams.						
Grand-daughters	14.00	± 0.101	3.97	± 0.07	0.06	± 0.026
Grandams	15.83	± 0.087	3.31	± 0.06	—	—
Percentage of butter-fat.						
Through Sires.						
Grand-daughters	3.47	± 0.009	± 0.432	± 0.008	0.107	± 0.02
Grandams	3.57	± 0.011	± 0.448	± 0.008	—	—
Through Dams.						
Grand-daughters	3.55	± 0.011	± 0.445	± 0.008	0.213	± 0.02
Grandams	3.50	± 0.013	± 0.488	± 0.009	—	—

In the two sets of cases already discussed there was a smaller number of paternal than of maternal grandams, due to the fact that cows have many more grand-daughters through their sons than through their daughters. This objection and the further objection as to environmental influence upon total production is removed in a further study relating entirely to per cent. of butter fat.

In the second part of the study of this case there were taken 126 record cows having record grand-daughters through both sons and daughters. The number of grand-daughters is 340 through paternal descent and 340 through maternal descent from 126 common grandams. Each grandam was represented by not less than one nor more than six grand-daughters in either line. Here also the ages of granddaughters and grandams in one line correspond closely with those in the other line. The means, standards of deviation and coefficients of correlation in this case of common grandams were as follows :

	M % fat	E	σ	E	
Paternal Descent.					
Grand-daughters	3.52	± 0.02	0.442	± 0.01	$\sqrt{\ } = 0.157$
Grandams	3.51	± 0.02	0.406	± 0.01	E ± 0.028
Maternal Descent.					
Grand-daughters	3.60	± 0.02	0.489	± 0.01	$\sqrt{\ } = 0.155$
Grandams	3.51	± 0.02	0.406	± 0.01	E ± 0.028

The difference between 0.155 and 0.157 does not indicate any difference between transmission of the character of percentage of butter-fat in milk through males and females. The impression to the contrary held by some cattle breeders is not borne out by this investigation.

1151 – **Economical Cattle Feeding in the Corn Belt.** — COTTON, J. S. (Agriculturist, Bureau of Plant Industry) and WARD, W. F. (Senior Animal Husbandman in Beef Cattle Investigations, Bureau of Animal Industry) in *U. S. Department of Agriculture, Farmer's Bulletin*, No. 588, 19 pp. + 6 figs. Washington, 1914.

The cattle-feeding business in the corn belt of the United States has changed greatly during recent years. Formerly steers from 4 to 6 years were fed in large numbers upon commercial foods at yards near granaries or mills, or on large farms where only the roughage was grown and the cattle were kept on full feed for six months or longer. This method, however, became too expensive, so the cattle are now usually fed in small herds up to the age of 18 to 36 months, utilizing the products of the farms.

The cattle were either grown in the corn belt itself or came from the western ranges. The native cattle were usually grown on the rougher farms or on small farms where dual purpose cows were kept. They were usually sold to local feeders as yearlings or two-year-olds. Some feeders desiring animals of extra good quality raised their own feeders. The rapid advance in the prices of land and farm products made it unprofitable to compete with the western ranges in the production of stocker and feeder cattle. Therefore the breeding herds were greatly reduced or were changed to dairy cows.

On the other hand, the spread of dry farming has resulted in the best lands of the open range being taken up for grain-growing purposes, and the excessive liquidation of cattle has resulted in a shortage of feeder cattle and raised their price, so that securing feeders is a serious problem which must be solved by many farmers raising their own cattle. On the high-priced lands capable of intensive cultivation it is questionable if this can be done economically, but there are numerous farms within this region where a considerable proportion of the land is too rough for economical tillage and on which, with prevailing prices, stock cattle can be raised advantageously.

Cost of producing cattle. — The cost of raising a calf six months old weighing 450 pounds varies from $17 to $23 in the West and from $20 to $28 in the East. In a ranch in Kansas, where land is worth $50 an acre the cows being valued $70 each and assuming that 85 per cent of them drop a calf every year, the cost of a calf is $22.93 and at the age of 2½ years about $55. This figure is about the maximum cost of such a steer in the maize belt, and many of the western ranches raise similar steers for less money. It has been observed that the cost of the calf will be a little less if it is weaned and the milk sold, than if it is allowed to run with its mother.

While in 1899, 883 857 calves, having an average value of $8.20, were slaughtered in the wholesale slaughtering houses, in 1909, 2 504 728 calves with an average value of $10 were slaughtered, an increase of 183 per cent. in 10 years, whereas the corresponding increase in cattle for the same period was but 47 per cent. This growing demand for veal has raised its price, until a calf will sell from $8 to $12 when only 2 or 3 months old, so that it is usually more profitable to sell them to the butcher than to raise them.

In order to determine as accurately as possible the cost of feeding, cost-accounting records were kept for two years on 24 Iowa farms. During the year beginning with the autumn of 1909 the average profit on 961 cattle fed in 22 bunches was $2.05 per head in addition to the profits on the 1504 hogs following these steers, and which received extra grain besides. Market prices in the spring of 1910 were such that a profit of $6.67 per hog was secured. The following year 1910-11 proved unsatisfactory, due to prices which caused a loss of 78 cents per head on 1138 cattle that were fed on 28 farms. The 1646 hogs following these steers returned an average profit of $3.33.

The following table shows the proportionate cost of different items based on the cost-accounting records of the 24 Iowa farms.

Percentage of the various expenses incurred in cattle feeding.

Year	Purchase price	Feed	Interest at 6 per cent	Labour	Shipping and selling	Total
1909–10	55.8	36.9	1.3	1.6	4.4	100
1910–11	59.9	31.8	1.8	1.8	4.7	100

In this table no account is kept of interest, taxes, and depreciation charges on the feeding plant, as these and other incidental charges are about offset by the value of the manure.

According to experiments made at the Missouri Experiment Station, it appears that a bushel of maize will produce 6.9 pounds of gain when the cattle are fed on pasture in summer, as against 5.6 pounds in winter feeding. Therefore in general summer feeding is considered more profitable. On

the other hand winter feeding allows of the better use of the by-products and of the better distribution of labour.

Formerly 6 to 8 months were required for making prime beef. Now cattle are rarely kept on full feed for more than five months.

The construction of a silo (over ground, on a circular base) is not economical unless at least 100 tons of silage are consumed. Besides, in years of cheap alfalfa or clover, when hay is worth less than $8 per ton, it is doubtful if silage costing $3 a ton will prove economical. However, when hay is dearer silage will be profitable.

Considering the limited margin of profit on breeding beef it is prudent to combine it with hogs following the fattening cattle, for the former utilize a greater quantity of the by-products. The best type of hog to run behind cattle is a shoat weighing about 100 pounds; heavy nearly finished hogs are not profitable behind steers and should be placed by themselves.

It is usually best to allow one shoat per steer when shelled maize is fed and two when ear corn is used. When the maize is ground or soaked, or silage is used, the number of hogs would be less. The aim should be to run enough hogs to clean up all the waste maize.

The daily gain of the hogs varies with the conditions of the feed yard and the quantity and form of the grain given. In general one may reckon on three-fourths of a pound of pork per third of a bushel of shelled maize fed per steer. When ear maize is fed the gains will be greater and when maize, or maize and cob meal is fed, less.

The gain will be greater if the steers are fed some leguminous hay or some concentrate high in protein, such as oil cake.

Nearly all farmers give the hogs some extra maize, which is fed away from the steers.

The shrinkage in weight in shipping cattle from Iowa to Chicago or from points in Kansas to Kansas City would be from 3 ½ to 5 per cent of their live-weight, with an average of 4 per cent.

1152 – **Origin of Karakul Sheep** (1). — YOUNG, C. C., in *The Journal of Heredity*, Vol. V, No. 10, pp. 445-447. Washington, October 1914. SHEEP

Some 26 years ago Dr. Sinitzin described the various breeds of sheep in Bokhara that produce valuable lamb skins. He distinguished; 1) the small Arabi, 2) the large Arabi, 3) the Duzbai, 4) the Shiraz, and 5) the Zigai breeds. He considers the small Arabi as the origin of all the fur-bearing sheep of Central Asia, including the Malitch of Crimea, the Tshushka of Bessarabia and the Reshetilev and Sokoliev of Poltova province.

According to this theory the small Arabi is descended from the Mamai, the oldest breed of domesticated sheep. But as the Mamai is a fat-rumped sheep (*Ovis steatopyga*) while all the Karakul breeds are broad-tails (*Ovis platyura*), the author does not endorse Dr. Sinitzin's classification; his own experience has shown him that when a long-tail sheep is crossed with a fat-rump the result is a broad-tail, and while the first cross looks more like a typical Russian fat-tail (Jirnochvostaja), the second and third crosses

(1) See also No. 929, *B.* Oct. 1914. (*Ed.*).

cannot be classified otherwise than as broad-tails. He therefore concludes that the Karakul breeds resulted from crosses of long-tail sheep on fat-rumps.

In all the cases observed by the writer the black pigment in the wool of the mature sheep did not oxidize into gray as is the case with the Arabi and also with the Duzbai, for which reason he concludes that the small Arabi was a hybrid and a not very well fixed one, and that some black long-tail sheep together with a fat-rump entered into the formation of the breed.

The presence of fat-rump blood is easily traceable in the Duzbai, which has the long drooping ears that characterize *Ovis steatopyga*, the Roman nose, large head, very thick feet, enormous weight and a tail with fat accumulation; besides, the Duzbai lambs frequently come fawn, which is the natural colour of the fat-rump.

According to information collected by the writer at New Bokhara, 60 years ago there were neither Arabi nor Duzbai sheep in Bokhara; the only fur-bearing breed which produced beautiful fur was the black long-tail Danadar. In the spring of this year 1914 the writer was able to see the only flock of gray Danadar sheep which still exists in the Khanate of Bokhara, at about 100 miles from Old Bokhara, the capital of the Khanate. The owner of the flock said that after the conquest of Bokhara by Russia in 1865 the demand for Danadar lambskins increased and the natives began to cross their black sheep with white fine-wool Afghans. This in time produced the gray Danadar breed, the lambs of which produce skins with small curls rather open and lustreless. This introduction of white blood contaminated with fat-rump blood in time changed the black Danadar into the small Arabi. The cross of the black Danadar on the fat-rumps produced the Duzbai. The gray Shiraz evolved from the gray Danadar with a fat-rump admixture. The Zigai is a typical Russian breed that never existed in Central Asia, and if there are any they must have been taken there by Russian Tartars who settled in Turkestan. Sinitzin's large Arabi is the same animal as the Duzbai.

There can be no doubt that the Tshushka and Sokoliev — both long-tails — are also descended from the black Danadars. The Luk-Nakbo of Tibet and the black Gadik of Afghanistan, some few of which are still found between Mazar-i-Sherif and Cabul, are closely related to the black Danadar.

The writer has started an experimental farm in Bessarabia for the breeding of Karakul sheep; hitherto he has succeeded in securing Karakul sheep from the districts of Karshi, Kerki, Gissar, Tjarjui, Burdalik and Karakul. In Bokhara the Karakul breeds are hastening towards extinction owing to the killing of all the good lambs and to the continuous infusion of fine-wool Afghan blood.

PIGS 1153 – **Pasture and Grain Crops for Hogs in the Pacific Northwest.** — HUNTER, BYRON (Agriculturist, Office of Farm Management) in *U. S. Department of Agriculture. Farmer's Bulletin* No. 599, 27 pp. + 9 figs. Washington, July 6, 1914.

Hog pastures in the Pacific Northwest of the United States are generally managed in one of the three following ways: 1. — Continuous close

razing. 2. — Alternate pasturing of equal areas. 3. — Pasturing the meadow on which hay is made also.

With the first method all the hogs the pasture will support are turned in it and left there during the entire season.

The second method consists in dividing the pasture into two or more fields of equal area, which are used alternately every week or ten days. In the case of clover and alfalfa the growth is allowed to become 3 to 4 inches high before the hogs are turned in. When the pasture consists of rape, kale, and vetch, the growth is permitted to reach a height of 8 or 10 inches before the hogs are turned in. A pasture thus subdivided is capable of carrying a much larger number of hogs per acre. Immediately the hogs are removed the pasture is clipped with a mower and sometimes irrigated. The third method consists in using clover and alfalfa for both pasture and ley at the same time. The number of hogs turned to graze is so limited that the usual crops of hay are made. When the forage becomes too large to furnish desirable feed a sufficient area near the watering place is clipped with a mower.

In a few days the clipped area produces a vigorous growth of new shoots upon which the hogs feed without disturbing the rest of the meadow. If necessary more of the meadow is clipped as required. Different portions of the meadow are used in this way from year to year.

Mature breeding stock that is not expected to make any gain in weight requires but little if any additional feed when on good pasture. But hogs which are to be marketed for pork must be fed some concentrated food.

If they are to be sold when 7 to 9 months old, in order to make them reach the weight demanded by the market (170 to 225 lb.) it is necessary to feed them all the grain they will consume. Hogs that are marketed when 10 to 12 months old get a much lighter feed of grain (from 1 to 3 per cent of the live-weight of the hog) or none at all during the grazing season.

Sometimes, instead of feeding the grain, the hogs are turned into a standing field of wheat, barley, peas or corn and allowed to feed it will until the crop is consumed. If they are provided with water, shade and salt, they require very little other attention, which saving of labour is very desirable during the busiest season of the year. This method is especially useful on the poorer soils, where the cost of harvesting is relatively high in comparison to the value of the crop and where the addition of more organic matter is very beneficial. The straw, pea-vines or corn stalks are cut in the autumn by a sharp disk harrow and ploughed in.

Wheat is generally hogged off for four to six weeks from about the stiff-dough stage. A soft variety of wheat with a smooth club type of head is the best for this purpose. The writer mentions two cases in which hogs pastured on wheat made an average gain in weight of 160 lb. and 212 lb. per acre, valued respectively $ 14.40 and $ 15.73 per acre, while the wheat alongside yielded 15 and 19 $^{3}/_{4}$ bushels per acre, the latter giving a net value of only $ 8.04 per acre.

Field peas are one of the most satisfactory crops to harvest with hogs, which utilize them with very little waste. They may be used from the time

PIGS

the last peas are nearly mature until about October or until the beginning of the autumn rains.

Carefully conducted tests at the Minnesota Experiment Station show that hogs waste no more corn in the field than when fed in lots, and that they gather it as clean as most men do in husking. Farm experience bears out this conclusion, especially if a movable fence is used and the hogs are not turned into more corn than they can consume in 15 or 20 days.

For summer and early autumn hogging-off, common early-sown beardless barley is used. For late autumn and winter use the more productive bearded varieties are preferred, after the autumn rains have softened the beards and kernels.

The tables (pp. 1642-1644) give some data on the pasture crops used in Western Oregon and Western Washington.

1154 – **Pig Feeding Experiments in Germany.** – KLEIN, in *Milchwirtschaftlicher Zentralblatt*, Year 43, Part. 47, pp. 452-458. Hanover, September 1, 1914.

Experiments were made with the object of ascertaining whether fish meal freed from fat and dried yeast can take the place of skimmed milk in the fattening of pigs.

In an eight-weeks preliminary experiment, three young pigs were given only skimmed milk besides a basal ration of potato flakes and barley; ten other young pigs divided into two equal groups were given the same ration as the preceding three, with the difference that a part of the milk was replaced in one lot by fish meal and in the other by yeast. One gallon of skimmed milk was always replaced by ½ lb. of fish meal + ½ lb. of potato flakes, or by 1 lb. of yeast. The course of the experiment was normal. The increase of live-weight per day and per head was as follows:

	lbs.
Lot I	1.24
» II	1.10
» III	1.13

The lower result yielded by the group fattened with fish meal is perhaps due to the lower amount of protein in the ration.

In a following experiment lasting 12 weeks the same pigs (minus one, which was eliminated) were divided into three equal lots. The rations were the same as in the preparatory period, with the difference that lot II had all the skimmed milk replaced by fish meal and that an extra quantity of fish meal + potato flakes was given to replace the skimmed milk. Further the yeast was steeped in warm water. The animals fattened with skimmed milk showed in general the greatest appetite, those fed with yeast the smallest. With this exception the course of the experiment was normal. The following is the increase of live-weight per day and per head.

	lbs.
Lot I.	1.44
» II	1.42
» III.	1.39

The small difference in the three lots leads to the conclusion that the fish meal and yeast produced almost, if not exactly, the same effect as skim milk. Yeast and fish meal, but especially the former, gave a better result with the older pigs than with the younger ones. As regards fish meal, this is probably due to the fact that the older animals gain chiefly in fat and are satisfied with less protein than the younger ones, which have to form flesh also.

From the economical point of view the principal experiment yielded the following results. If for the skim milk the values of 1.07 *d* or 1.6 *d* per gallon be assumed, and for the other feeds the prices actually paid on the market (fish meal 10*s* 6*d*, yeast 11*s* 6*d*, potato flakes 8*s*, and barley 7*s* 6*d* per cwt.), the cost of 1 lb. of gain in live-weight will be as follows :

Cost of skim milk per gal.	Lot I	Lot II	Lot III
	d	*d*	*d*
1.07 *d*	3.53	3.69	3.69
1.60 *d*	3.85	3·69	3.90

In general these results are in favour of fattening with skim milk if this is valued at the low price of 1.07 *d* per gal. If the skim milk be valued at 1.6 *d* per gal., the best results are obtained with fish meal and the less favourable ones with yeast. But if the greater dietetic value of skim milk be compared with this result, the conclusion may be drawn that skim milk valued at 1.6 *d* per gal. is at least as advantageous for young pigs as for the older ones. Whenever skim milk may be purchased at a price below 1.6 *d* per gal. its substitution by fish meal or yeast does not offer any advantage.

The carcase weight and the quality of the flesh were the same in the three lots.

BEES

1155 – **Apiculture in Uganda.** – *Communicated by the Acting Director of Agriculture, Uganda.*

In 1907, Sir H. Hesketh Bell, K. C. M. G., Governor of Uganda, being impressed by the value of the exports of beeswax from German East Africa, decided to introduce the industry into the Uganda Protectorate.

In August 1908 two natives of Uganda were sent to German East Africa to study the methods of preparation of beeswax followed in that territory. These men spent two months in German territory. On their return to Uganda they were sent out to instruct the peasantry in the preparation of wax.

The introduction of the beeswax industry was taken up in every district of the Protectorate. The idea was to put up log hives and encourage wild bees to take up their quarters in them. Tens of thousands of these hives were put up all over the Protectorate. Pamphlets were published in several native languages, and beeswax instructors were appointed to all the districts. The following statement shows the exports of beeswax from the Protectorate for the last five years :

Year	Lbs.	Value
1909–10	4 043	£ 154
1910–11	3 950	£ 162
1911–12	3 539	£ 162
1912–13	2 352	£ 117
1913–14	882	£ 42

There are several reasons for this failure of the effort to introduce a new industry. The quantity of wax obtainable from a hive of wild bees in Uganda is very small, several hives have to be taken to produce a small cake of wax. The natives found the taking of the hives unpleasant and the preparation of the wax laborious ; and since, when the process was complete, they got a smaller return than from any other method of earning money, the extraction of beeswax never became a popular industry. In fact, nearly all the wax which was produced was prepared by the beeswax instructors who were paid by Government to teach the peasants.

The following is a brief account of the methods employed : " Log hives were put up in the branches of trees and a few of these were tenanted by bees. When the hives were nearly full, the bees were smoked out and the comb was taken. The brood comb and a small amount of honey comb were left in the hive. The honey was then squeezed out of the comb, and the comb was boiled. The floating wax was drawn off and strained. The wax was subsequently broken up and clarified by melting and straining ".

1156 – **The Silk Weaving Industry of Amarapura, Burma.** — SHROFF, K. D., in *The Agricultural Journal of India*, Vol. IX, Part III, pp. 254-287 + 6 plates. Calcutta, July 1914. SILKWORMS

Sericulture in Burma has been almost exclusively in the hands of a curious race of people, the Yabeins, who numbered about 2 197 in Lower Burma in 1891.

It also exists to a small extent in Upper Burma and the Shan States. The rapid decline of the industry is shown by the decrease in the number of silkworm breeders from 3102 in 1891 to 211 in 1911.

This decline is attributed to the following causes :

1). The crude and careless system of rearing and inter-breeding and consequent degeneracy of the breed.

2). The ravages of diseases.

3). The imperfect knowledge of the reeling of the silk and the consequent production of coarse, uneven thread unsuitable for local consumption or export.

4). The abundance, the cheapness and the superiority of the imported raw silk.

Raw silk is imported from the Straits Settlements, Siam, Indo-China, China and Japan. The value of the silks imported decreased from 29 15 805 Rupees (£195 000) in 1898 to 14 18 306 Rupees in 1910, but since then it has increased to 31 44 189 Rupees (£ 209 000) in 1913.

The imports from China appear to be supplanting those from the Straits and elsewhere.

These figures do not support the opinions that the weaving industry of Burma is in a decadent condition owing to the competition of finished machine-made products. In 1911 there were no less than 18 621 people engaged in silk spinning and weaving.

The writer gives an account of the types of silk and handlooms used by the Burmese, and descriptions of their designs. A cooperative credit society has been established, and improved methods of manipulation and handlooms are being introduced.

1157 – **Researches in Sericulture in Cambodia.** — De Flacourt, Martin (Chef des Services Agricoles et Commerciaux du Combodge), in *Gouvernment Général de l'Indochine, Bulletin économique de l'Indochine*, Year 17, No. 108, pp. 388-389. Hanoi-Haiphong, May-June 1914.

Since April 1913, the Agricultural Service of Cambodia has undertaken the work of improvement by systematic selection of the pure native breeds of silkworms. It was therefore decided that the Service would not purchase any more foreign cocoons for the production of eggs, but produce them all in its own farms. With this object in view the Silkworm Breeding Station at Petit-Takéo conducted the breeding work in three lines: 1) pedigree or line breeding ; 2) reproduction from eggs selected from the best cocoons of the pure lines ; 3) the breeding of the best cocoons for industrial purposes.

The results obtained from one year's work give every confidence for the ultimate success of this method. Two local breeds (one a white worm with yellow cocoon known as Tân Châu, and the other a greenish yellow worm with golden yellow cocoon known as Tâm-sé) were brought to a state of absolute purity and improved with respect to increase of specific gravity of the cocoons and increased fecundity of the females. Thus, whereas it formerly required 1635 cocoons of Tan Châu or 1870 cocoons of Tam-Sé to weigh one kilo (three days after the worms begin to spin), at the end of the breeding experiments in February and March 1914 it required only 970 and 1355 cocoons respectively. During the same period the egg-laying capacity of the females was increased from 275-350 per day to 400-475, with a maximum of 500-550, that is to say, that, according to local methods of calculation, the weight of cocoons from the eggs of 100 females would weigh from 55-66 lb. to 75-105 lb. The average price of 100 batches of eggs decreased from about 1*s* 3*d* to 6*d* and the demand for supplies from the natives increased enormously.

These experiments at Petit-Takéo lead to the belief that pébrine has a marked tendency to diminish and disappear in Cambodia, because the local conditions are undoubtedly unfavourable to the completion of the life-cycle of the disease, owing to the rapid evolution of the silkworms (40 days being sufficient for the complete development of the two local breeds). Very badly diseased eggs (showing 200 corpuscles of pébrine in the field of the microscope) have been bred and reared with healthy eggs of the same breed. Only the new generations showing the most disease were reserved. It was found that not only the number of corpuscles gradually diminished, but cocoons have been obtained from the diseased eggs almost

equal to those from the healthy control lots and after 6 successive generations only 1½ per cent of the individuals were diseased, showing only 6 to 8 corpuscles in the field of the microscope.

FARM ENGINEERING.

1158 – **Motor Tillage Machine with Oscillating Spades turning Sideways.** — *Kaiserliches Patentamt, Patentschrift* No. 273 777. Berlin, May 7, 1914.

Several digging machines with movable spades have been constructed. In some the spades are attached to revolving drums and are driven into the

Fig. 1.

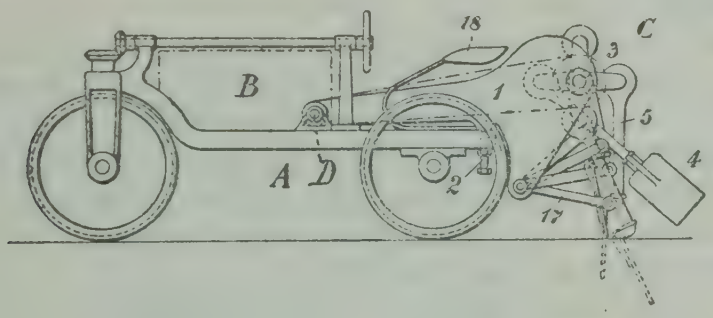

Fig. 2.

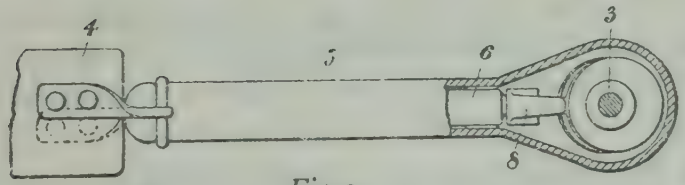

Fig. 3.

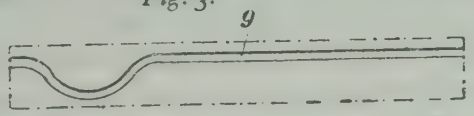

Fig. 4.

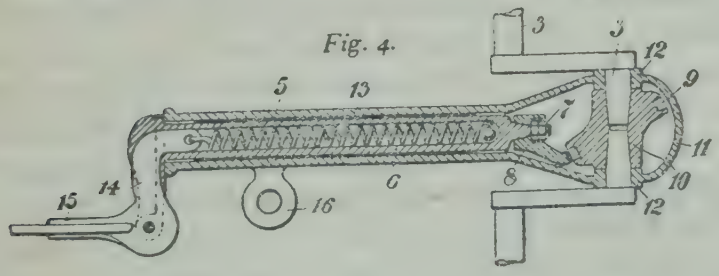

Motor Digger.

Soil

siol by the weight of the machine. In others they are independent of each other and move up and down by an excentric. In both types the spades have also a lateral movement calculated to turn over the earth as it is spaded.

In this machine patented by H. Kleinert in Germany under No. 273 777 the spades oscillate on a crank shaft and turn sideways to discharge and turn over the earth. Fig. 1 shows a side view of the machine and figs. 2, 3 and 4 some of its details. B is the motor, mounted on the truck frame A, which propels the machine and drives the spading appliance C, which is borne by two side plates (1), the front end of which is fixed to the frame in D by pivots ; the other extremity can be raised or lowered by the screw (2).

The plates (1) carry the bearings of the crank shaft (3), each crank of which bears a spade holder(5). The cylindrical part of these holders contains the handle (6) of a spade (4), which is fastened to a knee piece working on a bolt situated on a lateral extension of the handle, the other end of the knee piece being attached to a spring (13) inside the handle (6). The upper end of this bears a head piece (8) carrying a roller that runs in a groove (9) in the head (10), which is fixed to the crank of the shaft (3) and which joins the two portions of the same crank (3). Each of these heads is enclosed in a case (11) fitted with two bearings (12). The case, which efficiently protects the mechanism against dust, earth, etc., is provided with means of lubricating the working parts to ensure smooth running.

On the outside of the holders an eye (16) is fixed for the reception of one end of the lever (17) (fig. 1), the other end working on a shaft, common to all the levers, fixed in the side plates.

When at work these spades are situated with their face to the direction in which the machine travels ; as soon as they are raised they begin to turn sideways and thus discharge and turn the earth over. This turning motion is effected by the roller in the groove (9) of the head (10) ; the development of the groove is shown in fig. 3.

The spring (13) allows of stones and similar obstacles being encountered in the soil without causing injury to the machine.

1159 – **The Rapid Drying and Preservation of Wood by Nodon's Electrical Process.** — DANTIN, CH., in *Le Génie Civil*, Vol. LXV, No. 5, pp. 98-101. Paris, May 30, 1914.

M. Albert Nodon, the electrician, has been studying since 1896 the subject of the rapid drying and preservation of wood, and has now perfected his system and rendered its application practical. He had discovered that a current of electricity sent through wood set up chemical, physical and aseptic actions which led to its preservation ; the first of these consists chiefly in a complete and rapid oxidation of the resinifiable substances contained in the sap. The physical action caused a molecular transformation in the cellulose and its numerous derivates, modifying their mechanical and putrescible properties and rendering them resistant to destructive germs coming from without. Lastly, the aseptic action consists in the complete destruction of all the germs of corruption, such as ferments, bacteria, fungi, etc., contained in the wood. Besides the above effects it has been found that " nodonized " wood withstands the attacks of injurious insects, such as termites, which no longer find in it their usual food.

One of the most important desiderata in the timber trade is the rapidity of seasoning timber, for any long stay in the timber-yard means an immobilization of considerable capital. Consequently the use of heated and

ventilated esiccators is often resorted to, but such esiccation is mostly only superficial and on exposure to the air moisture is again absorbed. As the presence of sap hinders esiccation, steam at high temperatures and under pressure is often used to remove it, but this process is injurious to the resistance, tenacity and preservation of the wood and renders it inferior to air-dried wood. Besides, these processes of esiccation are expensive, as they entail costly plant, and much fuel and labour.

M. Nodon's process, or "nodonization", on the contrary, causes in a few hours the complete oxidation of the sap, which in air-drying requires

Fig. 1.

tt. Jute cloths.

such a long time; the substances other than cellulose, even in the innermost portions of the wood, are transformed into resins and completely deprived of their hygroscopicity; thus nodonized green wood loses its moisture rapidly on exposure to the air, while untreated wood dries only on the surface during the same time.

This process can also be applied to unbarked timber even 5 or 6 months after felling, as it still contains enough sap and moisture to conduct electricity.

The green timber to be treated, if in planks, railway sleepers, etc., is stacked to a height of three to five feet in layers separated from each other

by electrode mats in which the current passes (fig. 1). The mat (fig. 2) which can be rolled up for transport, consists of a pliable galvanised iron wire netting placed between two strong jute cloths. These mats are stretched between the tiers of timber and saturated with water to render them good conductors; the wire nets are connected with electric conductors the poles of the mats being alternated so that the current may pass through the thickness of each layer.

The conductivity of wood varies considerably with its kind, thickness degree of moisture, etc. Its resistance varies from 6 to 20 Ohms per cubic meter (35 cub. ft.), but it remains fairly constant throughout the duration of the treatment. Continuous currents may be used, but alternating currents are preferred. Treatment in the forest where the timber is cut is very advantageous when the wood is in full sap and in summer. The trees are cut up by electric saws driven by a dynamo and a portable engine stoked economically with the waste wood; after being nodonized, the timber is stacked in a place exposed to the wind where it dries completely in a few weeks.

The duration of the treatment varies between one and two full days according to the kind of wood and the use to which it is to be put. When treated too rapidly the wood is liable to split, though its keeping qualities are the same as if it had been treated slowly.

The total quantity of current that 1 cub. metre (35 cub. ft) of wood must have for its complete treatment is 150 Ampère-hours. Wood in full sap does not require above 40 volts electro-motive power, while for unbarked wood that has been kept some time 80 to 100 are necessary.

Nodonized wood is freed from starch and contains resinified substances throughout its whole mass, and its cells present a characteristic regularity. These changes allow nodonized timber to be easily distinguished from that which has not been treated.

The cost of the plant consists in the source of the alternating current and in the electrode mats; the latter cost about 4*d* per square foot, and they last about a year. As 3 sq. feet are required for the daily treatment of 1 cub. foot of wood, the cost of the mats is about 0.03 *d* per day per cubic foot.

The cost of nodonizing wood is bout $^3/_4 d$ per cubic foot, when the work is done in the forest, fuel, carriage and general expenses being cheaper than in factories, where the cost amounts to a trifle over 1*d* per cubic foot.

The process is useful wherever wood is used: in ship building, railway construction, carpentry, etc. The Municipality of Bordeaux has officially recognised that nodonized wood used for road paving lasts longer and wears better than untreated wood.

1160 – **A Latex Hydrometer.** — EATON, B. J., in *The Agricultural Bulletin of the Federated Malay States*, Vol. II, Nos. 9 and 12, pp. 224-226 and 314-322. Singapore, April and July 1914.

Messrs J. J. Griffin and Sons, scientific apparatus makers, Kemble Street, Kingsway, London, have constructed from detailed instructions

given by the writer, a delicate glass hydrometer graduated at 84° F. An average pure latex containing about 30 per cent of rubber has a density of about 0.98. A latex containing about 35 per cent of rubber is so viscous as to render it impossible to test its density directly. It is therefore recommended in such cases to dilute with an equal volume of water. The rubber content will then be double that corresponding to the density of the diluted latex.

Among the various services that this instrument can render is that of allowing the latex to be diluted with water to such an extent that its density will be constant. In this way very uniform results can be obtained in the preparation of smoked sheet. A satisfactory density figure at which to work is 0.9898, indicating a latex containing 15 per cent of rubber.

1161 – **New Water-Raising Device.** — *Les Inventions Illustrées*, Year 17, No. 11, p. 3. Paris, April 30, 1914. — *Engineering*, Vol. XCVIII, No. 25232, p. 10. London, July 10, 1914.

Among the smaller machines exhibited at the Royal Agricultural Society's show held at Shrewsbury this year, a very interesting water-

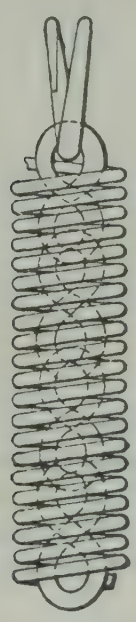

Fig. 1

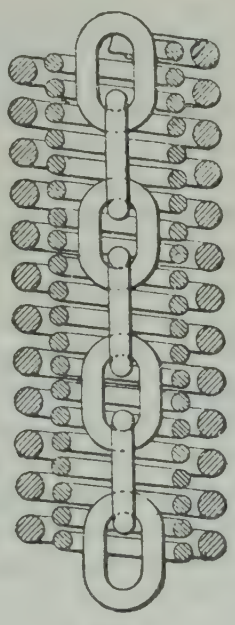

Fig. 2

New Water-raising Device.

raising device was exhibited. This appliance is virtually a chain pump, with nothing but the loop of an endless chain depending into the well. To keep the chain in place a deep rimmed pulley is slung in the lower loop of the chain. At the top end the chain is run over a pulley wheel worked by gearing. This pulley is enclosed in a casing with a delivery pipe leading away from the lower portion. The chain consists of a link chain surrounded by a spiral, fig. 1, and for larger capacities by a multiple spiral, fig. 2. The lower part dipping into the well catches up the water while the spiral is opened by the curvature of the pulley, and retains the bulk of it till the highest part is reached, when the centrifugal force, while the spiral is

bent open at the top pulley, throws the water out into the casing, whence it flows away. The capacity of this simple appliance is surprising, and it will handle water from considerable depths. The apparatus requires no permanent fixtures in the well at all, no buckets, guides, etc.

A double spiral 1. 7 inches in diameter with a 5 HP motor is said to draw up from a depth of 196 feet 2090 gallons per hour.

At a depth of 33 feet a triple chain 2.48 in. in diameter can deliver 5060 gals. per hour with 2.4 HP. For wells in which the level of the water varies, the chain is made up in lengths which can be readily joined together by special hooks, so that about 2 feet of the chain should always dip into the water, with which immersion it has been found to give the best yield.

On account of its simplicity this pump is not expensive; it is easy to transport and to set up without skilled artisans.

1162 – Review of Patents.

Tillage Machines and Implements.

Austria	67 408. Device for regulating the depth of tillage machines with rotary implements.
	67 402. Device for coupling agricultural machines to their tractor.
Canada	155 001. Motor plough.
	155 071. Gang plough.
	155 124, 155 488, 155 635. Cultivators.
	155 137. Clod-crusher.
	155 138. Traction belt for motors of the Caterpillar type.
	155 139. Traction machine.
	155 250. Plough with concavo-convex disk.
	155 357. Reversible plough.
	155 373. Weeding tool.
	155 393. Pulverizer for soil.
	155 412. Plough disk.
France	470 503. Device for increasing the stability of balance ploughs.
Germany	276 371. Ploughing machine with oscillating shares working backwards.
	276 412. Tillage machine with rotating drum carrying spades.
	276 446. Stone collector with elevator screen and conveyor.
	276 447. Adjustable cleat for driving wheels of motor ploughs and the like.
	276 684. Cultivator share.
	276 828. Shaft with hoes for hoeing machine.
	277 065. Device for pulling and steering implements, especially for agricultural purposes.
	277 123. Device for lifting the chains of tillage implements attached to and drawn by levers.
	277 473. Plough with beam that can be raised or moved sideways.
	277 474. Tillage machine with oscillating spades driven by a crank shaft.
	277 475. Device for lifting and lowering, by power, agricultural implements.
	277 610. Driving wheel for agricultural machines with moveable cleats fastened to the inside of the tyre.
Switzerland	66 441. Tillage machine.
	66 443. Spades with adjustable blades.
	66 863. Cultivator share.
	67 056. Plough share.

United Kingdom 10 969. Thinning machine, cultivators.
11 270. Digging machine.
12 780. Detachable point for protecting the points of the mould-board share and landside plate of a plough.

United States 1 106 603. Mechanically propelled plough.
1 106 722, 1 108 286, 1 108 319, 1 109 438, 1 109 661. Cultivators.
1 106 742. Caster wheel truck attachment for cultivators.
1 106 529. Motor plough.
1 106 389. Attachment for plough guards.
1 106 582. Plough beam.
1 107 173. Weeder for harrows.
1 108 600. Cultivator tooth.
1 108 261, 1 109 442, 1 109 813. Harrows.
1 108 787. Self-propelled ploughing machine.
1 109 076. Automatic guiding device for harrows.
1 109 095. Combined plough and cultivator.
1 109 535. Sulky plough.
1 109 063. Subsoiler.
1 108 909. Harrow tooth fastener.
1 109 084. Plough-lifting mechanism.
1 109 806. Gang plough.
1 109 756. Combined plough and fertilizer distributor.

Manure distributors, etc.

Canada 155 182. Manure loader.
155 300, 155 418. Manure spreaders.

Denmark 19 063. Liquid manure distributor.

Germany 277 030, 277 477. Manure distributors.

Switzerland 66 654. Manure distributors.

United Kingdom 10 786. Apparatus for distributing insecticides, manures, etc., by means of an air blast.
11 588. Manure distributor to be mounted on ploughs.

United States 1 108 263. Fertilizer distributor.
1 108 150. Manure spreader.
1 109 896. Straw spreading attachment for manure distributors.

Drills and Sowing machines.

Austria 67 401. Sowing machine.

Canada 155 059. Potato planter.

Germany 276 303, 276 576. Potato planters with device for making holes.
276 866. Agitator wheel arrangement for drills.
277 066. Sowing machine in which the seed issues from holes in the side of the hopper.
277 201. Device for pressing and covering the seed, applied to drills.
277 029. Drill and dibble.

Switzerland 66 656. Apparatus mounted on wheels, for sowing in heaps, with knives to remove weeds and shares to open furrows.

United Kingdom 11 155. Potato planter.
12 844. Seed and like distributors.

United States 1 106 737. Combined disk harrow and seeder.
1 106 373. Corn planter.
1 109 835. Corn planter.

United States 1 107 044. Cotton planter.
1 108 130. Seed planter.
1 108 435. Furrow opener for corn planters.
1 108 878. Planter.
1 109 711. Drilling attachment for disk harrows.

Reapers, mowers and other harvesting machines.

Canada 154 990. Motor harvester.
155 017. Hop-gathering machine.
155 032, 155 618. Mowing machines.
155 149. Carrier for harvesters.
155 179. Grain shocking machine.
155 405. Draft mechanism for harvesters.
155 600. Stacker hood.
France 470 498. Improvements in horse rakes.
Germany 277 124. Device for tilting and raising the cutter-bar in mowers.
277 315. Cutter-bar for mowers.
277 459. Scythe eye with adjustable excentric fastening.
Switzerland 66 444. Mower with fore-carriage.
66 445. One-horse side-delivery swathe rake.
66 657. Device on mowers for cleaning the blades.
66 864. Cutter-bar for mowers.
66 865. Scythe.
66 959. Apparatus for automatic loading of hay carts.
United Kingdom 10 793. Grass box for mowing machines.
11 508. Motor mower.
11 582. Tedding attachment for mowers.
12 397. Horse-rakes.
12 586. Aprons for harvesting machines.
12 766. Appliance for collecting and cocking hay.
13 320. Harvesting machine.
United States 1 107 083 Cotton harvester.
1 106 652. Sheaf loader.
1 108 536. Vertical mower.
1 108 150. Mowing machine.
1 109 525. Nozzle for cotton pickers.
1 110 158. Cotton picker.
1 109 711. Hay gathering and stacking machine.
1 109 687. Harvester.
1 109 897. Hay-rake.
1 109 688. Corn harvester and husking machine.
1 109 664. Hay pitcher.

Machines for lifting root crops.

Austria 67 403. Device for holding beets in beet-topping machines.
Canada 154 924. Potato digger.
Denmark 19 249. Machine for loading beets.
United States 1 106 668. Potato harvester.
1 108 341. Combined beet puller and topper.

Threshing and winnowing machines.

United Kingdom 12 828. Improvement in beater of threshing machines.
13 082. Threshing machine.
United States 1 109 428. Seed cleaner.

Other agricultural machines and implements.

Austria
67 302. Butter worker with intermediate gear.
67 530. Lid for milk pails.
67 531. Butter pressers.

Canada
154 881, 154 882. Baling machines.
154 928. Churn.
154 979. Sheaf loader.
154 998. Milk cooling and bottling apparatus.
155 009. Tool handle.
155 153. Milk separator.
155 156. Tractor.
155 157. Sprayer for plants.
155 233. Butter moulding apparatus.
155 267. Milk can.
155 323. Rossing machine.
155 449. Fibre breaking machine.
155 643. Traction belt.
155 652. Animal trap.
155 658. Peat working machine.
155 727. Machine for sharpening millstones.
155 759. Baling press.
155 797. Hay press.
155 835. Poultry feeder.
155 842. Incubator.

Denmark
19 062. Device for milking machines.
19 064. Machine for singling beets.
19 229. Apparatus for freeing animals in stables.
19 234, 19 280. Automatic straw presses.
19 273. Apparatus for heating milk for a certain length of time.

France
470 945. Stand for drying hay.

Germany
276 305. Apparatus with agitator for extracting wax from empty honeycombs.
276 448. Central cone for milk separators, formed of several rings kept together by adhesives.
276 577. Potato peeling machine.
276 641. Drum for milk separator.
277 067. Adjustable nozzle.
277 096. Incubator with automatic heat regulator, cooler and ventilator.
277 225. Apparatus for rendering milk and other liquids homogeneous.
277 381. Apparatus for catching insects.
277 476. Machine for excavating ditches, canals, etc.
277 575. Fore-carriage for agricultural machines.
277 576. Milk skimming pan.

Switzerland
66 442. Appliance to keep agricultural machines mounted on wheels at the proper distance from the power machine.
66 446. Supports for strawberries.
66 447. Feeding trough.
66 448. Apparatus for untying cattle.
66 449. Cattle drinking trough closing automatically.
66 728. Curd-cutter.
66 961. Adjustable railing for feeding troughs in stables.

United Kingdom
10 772. Machine for gauging and sorting corks.
11 002. Milk cans.
11 164. Propagation and seeding boxes.
11 220. Hopper truck for spreading tea to be dried, fermented, etc.
11 224. Appliance for gathering fruit.
11 271. Traction engine.
11 321. Shoots for conveying sacks.
11 398. Luminous paint lamp-trap for insects.
11 401. Horticultural frames.
11 411, 11 518, 11 726. Cow-milkers.
11 705. Machine for stemming tobacco leaves.
11 931. Apparatus for hulling coffee, grinding maize, wheat, etc.
11 977. Implement for tapping rubber trees.
12 138. Apparatus for extracting oils by means of volatile solvents.
12 141. Megasse furnaces.
12 230. Baling press.
12 414. Machine for cleaning and sorting potatoes.
12 459. Machine for reducing oyster shells, spices, maize, etc.
12 736. Animal traps.
12 873. Combined incubating and rearing apparatus.
12 984. Trap for flies.
13 037. Separator for grain refuse.
13 240. Sack holders.
13 328. Churns.
13 436. Rotary malting drum.

Unitedi States.
1 107 001, 1 110 298. Tongue trucksi.
1 106 512. Hay carrier.
1 106 405. Plant replanter.
1 106 580. Hay press.
1 108 203. Levelling device for traction engine.
1 108 373. Ensilage machine.
1 108 325. Stalk puller.
1 108 163. Feeding device for feed cutters.
1 108 599. Baled hay conveyor and elevator.
1 109 456. Litter carrier.
1 109 429. Farm tractor.
1 109 294. Tractor wheel.
1 108 882. Bug and worm collector.
1 109 752. Wagon steering gear.
1 109 789. Wagon loader.
1 109 687. Seed germinator and plant forcer.

BUILDING CONSTRUCTION

1163 – **Bold Concrete Dam.** — *Engineering Record*, Vol. 69, No. 25, p. 693. New York, June 20, 1914.

In 1907 a dam was built, on a firm lava rock, across the Crowley Creek in Idaho, U. S. A., for irrigation and domestic needs. It is 55 feet high and its plan is a curve of 72 feet radius, the convex side being turned up stream. It is of unreinforeed concrete and only 5 ft. 2 in. thick at the base and 3 ft. at the top. It has been found very satisfactory as it has had more than a foot of water flowing over it on several occasions.

Recently it has become desirable to increase the reservoir capacity, and a State permit has been granted for the raising of the original structure to a height of 90 feet. The thickness at the bottom will be increased to 9 ft. 2 in. and at the top to 3 ft. 2 in. The length of the crest will be 223 ft. At its central point it will be 1 foot lower than at the wing walls, towards which the crest slopes gently upwards so that the overflow tends to concentrate at the centre, but in flood seasons the entire length between wing walls becomes a spillway.

When filled to the 90 ft. level, the reservoir will cover 66 acres to an average depth of about 36.4 feet, storing 2400 acre-feet.

RURAL ECONOMICS.

1164 – **On the Selection of Crop Rotations.** — MARENGHI, E., in *L'Italia Agricola*, Year 51, No. 10, pp. 436-438. Piacenza, October 1914.

1. In the application of economics to agriculture the various difficulties which interfere with the realisation of the maximum profit may be classed as *objective* and *subjective*. The former are due to certain external conditions quite independent of the ability of the person directing the enterprise. The inevitable divergence entailed by many systems of cultivation from the most suitable type, is often due to the very specialised character of the land itself.

The possibility of re-organising agricultural exploitation is therefore subordinated, at least partly, to the special conditions prevailing. Generally, too rapid and radical changes are not possible since they involve loss of capital invested in the soil. For example, although it would be comparatively easy to replace one herbaceous crop by another in a short time, it would be more difficult to extend the forage area and still more difficult to replace one kind of woody growth by another. Admitting that agricultural exploitation can be modified with relative rapidity, no state of equilibrium can be reached, owing to the inevitable dynamism of all the economic factors.

2. The *subjective* difficulties, on the other hand, are due principally to the incapacity of the farmer.

The systems of cultivation suffer always necessarily from the great difficulty of forecasting coming economic events, previsions never being confirmed by facts.

3. A system usually followed, and which enables serious errors to be avoided, consists in adopting from time to time only those methods which tend to prevail and which therefore are presumably sanctioned by experience.

4. The systems predominating in the different zones should be regardad as attempts of the cultivators to realise a maximum profit. Though it is true that this is never completely realised, the predominating or general

system in vogue should be regarded as the best organised and the most remunerative.

The data for the solution of this problem can be obtained from various sources, amongst others, the Land Register, which indicates the distribution of the various crops in the different districts. From an examination of the distribution of crops in the hills and plains of Perugia it has been possible to deduce a rotation which fairly illustrates the subject in question.

5. It is presupposed that the different combinations of crops differ in one sense or another from that giving the maximum return; but this supposition corresponds only approximately to the facts. It often happens that all or almost all the combinations in question are affected by the same error, especially where too much importance is attached to established usage. Even in this case, however, much valuable information may be obtained by observation of facts.

6. Analogous results are more often obtained by the data furnished by statistical observations during a single year and grouped according to the ability of the various cultivators, which may be excellent, mediocre or bad.

The system of cultivation adopted by the most capable agriculturists and which consequently approaches the most remunerative, is a suitable model for the particular conditions of situation and time. But in this case also some reserve is desirable; for though in general the most progressive systems should be followed, it sometimes happens that excellent agriculturists make the same collective error of economic forecasting.

As an instance of this the writer mentions the vine-growing crisis in Apulia several years ago.

Similarly, statistical observation of crop systems has only a very approximate practical value, since it can only provide rather vague and schematic indications, though in any case more trustworthy than the data given by analytical book-keeping. The latter method is only suitable as a help — in the most favourable case — for the solution of small questions of detail and not for the tracing with any reliability of the fundamental basis of rotation systems, which must be selected in the various practical cases.

1165 – **Statistical Data on the Economy of the Farms Belonging to the Cooperative Book-keeping Association of Königsberg in Prussia.** (1) — GÜNGERICH, in *Georgine*, Year 7, No 51, p. 437; No 53, pp. 453-454. Königsberg, June 25 and July 2, 1914.

During the year 1912-13 the average distribution of crops in the 145 farms belonging to the cooperative book-keeping association was as follows: 19.8 per cent of the cultivated area was under winter cereals, 18.8 under spring cereals, 3.6 under pulse, 6.5 hoed crops, 46.8 forage crops, 2.1 fallow, and 2.4 per cent miscellaneous.

The capitals invested in the farms since the year 1904-05, the first

(1) See No 987, *B.* August 1913. (*Ed.*)

of the existence of the Association, have been, per acre of cultivated area, as follows:

Year	Number of farms	Buildings			Live stock			Dead stock		
		£	s	d	£	s	d	£	s	d
1904–05.	18	6	9	4	2	15	11 1/4	0	17	5 1/2
1905–06.	45	6	12	1 1/2	2	17	11	0	17	10 1/4
1906–07.	57	7	4	5	3	2	3 1/2	0	18	3
1907–08.	70	7	4	5	3	3	1	0	18	3
1908–09.	74	7	8	4 1/2	3	5	10 1/4	0	18	7 3/4
1909–10.	89	7	10	4 1/2	3	6	7 3/4	0	19	10
1910 11.	96	7	13	11 1/4	3	5	5 3/4	1	0	7 3/4
1911–12.	118	7	15	6 1/4	3	9	5 1/4	1	1	9 3/4
1912 13.	145	7	1	3	3	17	9 1/4	1	5	9 1/2

The decrease in the value of buildings during the last year is due to the fact that the value of the owner's residence is deducted from the total value of the buildings. The sudden increase in the value of the live and dead stock in the last year is caused by having reckoned as cultivated area only the fields, meadows, and pastures, while in the preceding years a portion of the areas occupied by yards, roads, ditches, and other waste land was also included.

The figures for the individual farms vary according to the degree of intensity of the farming; thus the capital in buildings ranges from about £4 to £12, that in live stock from £2 to £6, and that in machines and implements from £1 to £3.

If the figures for the individual farms be grouped according to the extent of the cultivated area, the following table is the result:

	Number of farms	Buildings			Live stock			Dead stock		
		£	s	d	£	s	d	£	s	d
Class I up to 617 acres .	34	7	9	2	4	10	6	1	16	1
» II from 620 to 1235 acres	58	7	2	5	4	2	1	1	5	0
» III » 1237 » 1852 »	31	6	17	3	3	3	6	0	17	6
» IV above 1852 acres . .	20	6	18	1	3	2	8	0	17	6

The average stock of live stock increased from about 16.6 head of large cattle per 100 acres of cultivated area in the year 1904-05 to 20.2

	Number of farms	Net profits	Returns	From live stock	From sale of produce	Sundries	Outlay	Purchase of live stock	Manures	Fodder	Salaries and wages	Upkeep of buildings and implements	Sundries	Value of wheat used in payments in kind
		£ *s* *d* per acre												
1911-12	118	1 8 9	4 10 10	2 8 5	1 14 11	0 7 6	3 4 3	0 13 6	0 9 6	0 9 6	0 17 3	0 5 11	0 11 6	0 5 4
Average of period 1904-05-1911-12	71	0 18 0	3 11 10	2 0 10	1 2 3	0 8 7	2 14 9	0 12 11	0 4 0	0 6 9	0 14 10	0 4 9	0 11 6	0 4 4
1912-13	145	0 15 8	3 18 2	2 11 2	0 19 10	0 7 2	3 5 1	0 12 4	0 7 6	0 9 11	0 19 10	0 5 7	0 9 11	0 5 2
Average of period 1904-05 1912-13	79	3 16 2	3 12 7	2 2 1	1 1 10	0 8 7	2 15 11	0 12 8	0 4 4	0 7 2	0 15 6	0 4 9	0 11 6	0 4 4

ead in 1912-13, while the number of draught animals has remained fairly onstant at an average of 4.2 head.

The year 1912-13 closed with considerably lower net profits than the preceding year 1911-12, and has thus lowered the average of the net profits, as may be seen from the table opposite, in which the net profits and the total turnover per acre, as average of all the farms, for the years 1911-12, 1912-13 and the periods 1904-05 - 1911-12 and 1904-05 - 1912-13 are shown.

The value of these farms, calculated by capitalising the average net profits at the rate of 4 per cent, amounts to about £20 per acre, which is considerably below the prices paid now for farms; in other words, the net returns obtained represent a low interest on the capital invested. If the landowner is to have adequate interest on his capital and to pay his private expenses, such as interest on debts, taxes, housekeeping, etc., out of the returns of his property, without loss, the average net returns should be, according to the writer, increased to at least £1 per acre.

1166 **Comparative Cost of Food for a Heifer, Stall-fed or at Grass, up to her First Calving.** — ZWANOWETZ, EDUARD, in *Wiener Landwirtschaftliche Zeitung*, Year 64, No. 68, p. 656. Vienna, August 26, 19 4.

The writer works out as follows the cost of food for a cow at two and a half years, according as she has been exclusively stall-fed or has been put out to graze in summer. (She is supposed to have been calved on the 1st of November).

TABLE I. — *Cost of Food for Stall Feeding.*

	£	s	d
1. Nov 1 to April 30, age ½ year			
132 gallons whole milk, at 8 ¼*d*	4	10	0
220 lbs. crushed oats and oatmeal, at 6*s* 9*d* per cwt.	—	13	4
880 lbs. tender meadow hay, at £2 2*s* 6*d* per ton	—	16	8
880 lbs. mangolds, at 12*s* 9*d* per ton	—	5	0
	£ 6	5	0
2. May 1 to Oct. 31, age 1 year			
814 lbs. oats, at 7*s* 8*d* per cwt.	2	15	6
1628 lbs. hay, at £2 2*s* 6*d* per ton	1	10	10
814 lbs. straw of spring grain, at 25*s* 6*d* per ton	—	9	3
3300 lbs. green fodder, at 8*s* 6*d* per ton	—	12	6
	£ 5	8	1
3. Nov. 1 to April 30, age 1 ½ year.			
405 lbs. rye bran, at 6*s* per cwt.	1	1	6
1210 lbs. dry fodder, at £2 2*s* 6*d* per ton.	1	3	0
1210 lbs. straw of spring grain, at 25*s* 6*d* per ton	—	14	0
4050 lbs. mangolds, at 12*s* 9*d* per ton	1	3	0
	£ 4	1	6
Carried forward	£ 15	14	7

	£	s	d
Bronght forward . . .	£ 15	14	7
4. May 1 to Oct. 31, age 2 years.			
202 lbs. rye bran, at 6*s* per cwt.	—	10	9
16 200 lbs. green fodder, at 8*s* 6*d* per ton	3	1	4
405 lbs. straw of spring grain, at 25*s* 6*d* per ton	—	4	7
	£ 3	16	8
5. Nov. 1 to April 30, age 2 ½ years			
405 lbs. rye bran, at 6*s* per cwt	1	1	6
814 lbs. dry fodder, at £2 2*s* 6*d* per ton	—	15	6
1628 lbs. straw of spring grain, at 25*s* 6*d* per ton	—	18	6
6070 lbs. mangolds, at 12*s* 9*d* per ton	1	14	6
	£ 4	10	0
Total cost of stall feeding	£24	1	3

TABLE II. — *Cost of Food at Grass.*

	£	*s*	*d*
1. Nov. 1 to April 30, age ½ year.			
As in Table I	6	5	0
2. May 1 to Oct. 31, age 1 year.			
Pasture, 184 days at 3*d*	2	6	0
3. Nov. 1 to April 30, age 1 ½ year			
As in Table I, but without bran	3	0	0
4. May 1 to Oct 31, age 2 years			
Pasture, 184 days at 4*d*	3	1	4
5. Nov. 1 to April 30, age 2 ½ years.			
As in Table I, but without bran	3	8	6
Total cost at grass	£18	0	10

Thus the difference in favour of pasturing is £ 6 0*s*. 5*d*.

1167 – **A Metayer's Family in Chianti (Tuscany).** — TASSINARI, G., in *Atti della Reale Accademia Economico-Agraria dei Georgofiii di Firenze*, Series 5, Vol. XI, No. 4, pp. 283-310. Florence, October 1914.

In order to enable comparisons to be made v ith other monographs on this subject, the data in this mcnograph have been arranged according to the plan elaborated by LE PLAY. The metayer's family which is the subject of this study represents with fair approximation the average type of farmer in the Chianti district from the point of view of eccnomic condition and moral and intellectual characteristics.

The holding is on hilly land and it comprises about 17 acres of arable land, with vineyard and fruit trees containing about 3 500 vines, 207 olives, 30 fruit and other trees, and 87 acres of woodland and rather steep pasture.

The area under herbaceous crops comprises about 7 to 10 acres of wheat (10 acres being the maximum), 2 ½ acres under forage and 4 ½ acres under the first crop after deep cultivation, which may include maize, beans, potatoes, tomatoes, etc; broad beans, chick peas and lentils are also grown.

Sainfoin and a little lucerne are grown as forage crops, and barley, oats, vetches, beans, etc., are sometimes grown for the same purpose.

The manure used is chiefly dung, particularly from sheep; chemical manures are rarely employed.

The farm products (those from the woodland being excepted) and the profits on the live stock are shared equally with the landlord, who provides half the cost of the seeds required and pays the estate taxes. The taxes on live stock are shared by the tenant and landlord. The house, garden and fire-wood are regarded as free allowances to the tenant, and the landlord is charged with the cost of fungicides. The annual charges of the tenant are about 400 ft of trenches for vines, etc., and 10 head of poultry.

The family includes 6 persons: 4 men and 2 women. The live stock belonging to the farm includes: 2 oxen, 1 sow, 4 pigs, 37 sheep and 6 lambs, valued at £ 100; the dead stock leased includes forage, litter and manure valued at £ 43, implements valud at £ 12, wine vats and materials for other industries valued at £ 6: the total, including poultry, reaching about £ 145.

The furniture, utensils, linen and clothing of the family are estimated at about £ 68.

The family balance sheet is summarised as follows:

	£	*s*	*d*
Farm products, farmer's half-share	78	7	8
Other profits allowed in the contract.	15	3	10
Total Receipts . . .	93	11	6
Expenses for permanent and temporary work, seeds, implements, machines, etc.	20	9	3
Net Profit . . .	£ 73	2	3

The total family expenses consume £67 4*s* 2*d* per annum, leaving £5 18*s* more or less, which goes to increase the credit of the metayer with his landlord.

This corresponds to a share of annual earning of £18 14*s* 11*d* per worker and of £13 8*s* 10*d* per consumer of the family (1).

AGRICULTURAL INDUSTRIES.

INDUSTRIES DEPENDING ON PLANT PRODUCTS

1168 – **The Origin, Quantity and Signification of Lactic Acid in certain Italian Wines.** — Mensio, C., and Garino Canina, E., in *Le Stazioni Sperimentali Agrarie Italiane*, Vol. XLVII, Part 6, pp. 385-409. Modena, 1914.

An attempt has been made to determine the quantity of lactic acid usually formed in some of the finest Piedmont wines as compared with the quantity in common wines; what are the conditions under which such formation takes place; what are the micro-organisms producing it; and what is its biological significance.

(1) This year's expenses have been increased owing to the military service of one of the sons, so that £15 figures in the account as outside labour.

The main results of the investigations are as follows:

1). Lactic acid is a constituent of all wines and may be present to the extent of 4 to 5 gms. per litre.

2). The amount increases gradually as the wine ages and though advantageous at first it may become distinctly injurious. In the case of many wines, *e. g.* Barolo, Barbaresco, Gattinara, malo-lactic fermentation is essential for the development of their organoleptic qualities. It is also of great importance for ordinary wines, especially those with a low percentage of alcohol.

3). This fermentation is due chiefly to micro-organisms analogous in shape and behaviour to *Bacterium gracile* of MÜLLER-THURGAU, which splits malic acid into lactic and carbonic acids but has no action on tartaric acid.

4) Malo-lactic fermentation causes a considerable decrease in the acidity of the wine.

5). "Turned" wines (containing decomposition products of tartaric acid and extractives which give rise to a disagreeable flavour and loss of the wine) are fortunately rare in Piedmont.

6) In testing wine for its origin, whether genuine or artificial, the determination of the lactic acid should never be neglected.

From a practical point of view it is important to remember that wine after a certain age should be considered as the product of two fermentations: the first and most important being the alcoholic fermentation and the second the malo-lactic fermentation. Wine makers should watch their wines with a view to increasing, preventing or retarding the decomposition of the acids according as it is desirable. The acidity may be diminished by retarding the racking, maintaining the cellar at a suitably high temperature, and avoiding the use of sulphurous compounds. The decomposition of the acids may be retarded by using sulphurous acid while making the wine, maintaining the cellar at a low temperature, and by the prudent repetition of the sulphurous acid treatment.

1169 – **Spanish Wines.** — DE LA ROSA, G. FERNANDEZ, in *Boletin de Agricultura técnica y economica*, Year VI, No. 67, pp. 622-626. Madrid, July 31, 1914.

According to the most recent statistics the area of vineyards in Spain is 3 396 460 acres, of which 1 891 160 are free from phylloxera, 1 047 420 have been reconstituted and 457 880 are infected and decadent, but still productive.

The methods of cultivation are, in many districts, antiquated and empirical. Propagation is by cuttings planted in holes and cultivation generally consists in ploughing, with hand-hoeing round each plant. Pruning is done annually and all the grapes are picked at once. In the best vine-growing districts, such as Jerez de la Frontera, Puerto de Santa Maria and Sanlúcar de Barranceda in the province of Cadiz, and several districts of the provinces of Malaga and Cordova, very different systems are practised. Before planting the vineyard the land is deeply trenched and thoroughly hoed over several times to aerate the soil; pruning, removing the surplus shoots and gathering the grapes are done at several times.

The best Spanish wines are the "finos" and "olorosos" of Jerez, "manzanilla" of Sanlúcar, muscatel of Malaga, "Pedro Ximenez" of Montilla, "pajarete" of Bornos, "tintilla" of Rota, "Cariñena" of Aragon (white wines); the wines of Alicante, Valdepeñas, Mudela and Calzada de Calatrava in the Mancha; those of "Priorato" in Catalonia; of Navarre and Rioja (red and rose-coloured wines).

The average annual production of grapes is 2 905 537 tons, of which 274 074 tons are used for direct consumption, and 2 631 464 tons are used for wine-making, producing 3 883 000 gals. of must. The average price has been 6*s* 2*d* per cwt. of grapes and 7.89 *d* per gallon of new wine. The average annual value of the wine products amounts to £14 454 138, not including £530 063 for lees and vinasse. It should be pointed out that this value would be considerably increased if it were based on the value of the mature wine instead of on the must and on new wine only a few months old.

Notwithstanding serious difficulties, the cultivation of the vine and wine-making in Spain are always improving, chiefly through the influence of educational centres, among which should be mentioned the Oenological Stations of Haro (Logroño), Villafranca del Panades (Barcelona) and Reus (Taragon).

1170 – **The Wines of Istria.** — BUFALINI, D., in *Giornale Vinicolo Italiano*, Year 40, No. 37, pp. 865-867. Casale Monferrato, September 13, 1914.

Agricultural conditions in Istria are little known to the outside world. During the last 10 years very rapid progress in the wine industry has been made, and this still continues. Istria may be divided into the following six wine-growing districts:

1. The Karst with the district of Castelnuovo.
2. The eastern coast with the districts of Albona and Volosca.
3. The southern coast with the districts of Pola, Dignano, Rovigno and Parenzo.
4. The northern and north-western coast with Tirano and Capodistria.
5. The mountain region and high plateau of the interior with Pisino and Pinguente.
6. The islands of the Quarnero: Cherso, Lussin and Veglia.

In a good year the total yeld of wine in Istria reaches 13 200 000 gallons, of which nearly half is exported.

The local wines are as follows:

1. "Vino terrano" or "refoteo" from white lands, characterised by a deep red colour and pronounced acidity.
2. White wine without special character, made from grapes which also yield a considerable product: Isolana, Durania, Malvasia, Dinella, Treolina, Tebbiano, Drasanella.
3. "Vino rosato", rich in alcohol and with limited acidity, rose coloured with an agreeable flavour, obtained from grapes which always yield well: Rossara, Planiva, Negra tenera, Bontempa, Moretta, Pignoletta, Crenatizza.

4. White muscat made from the grapes of the same name, especially in the districts of Buie, Momiano, Verteneglío.

5. The rose muscat wines of Dignano.

6. Sweet and sparkling " Refoschi " wines.

The foreign varieties grown successfully on American stocks are: Traminer, Pinot, Malvasia, Rhenish Riesling, Semillon, Burgundy (large bunched variety), Cabernet, Chasselas, Früher von der Lahn.

The control of phylloxera by replacing the vineyards with American stocks has enabled the introduction of foreign stocks which improved the local varieties. The production of large quantities of wine of uniform quality, which formerly presented such difficulties, is now an accomplished fact.

The provincial cellar of Parenzo produces about 110 000 gals., those of Brioni and Buie from 220 000 to 264 000 gals., the social cellars of Rovigno and Cittanova 11 000 gals. Vine-growing is the principal, though not the only, resource of the land in Istria.

1171 – **The Influence of Nitrogen Compounds on the Vulcanization of Rubber.** — — *The India Rubber World*, Vol. 4, No. 6, pp. 650-651. New York, September 1, 1914.

In the rubber industry it has not been until recently that the importance of small quantities of nitrogen compounds found in most rubbers has been recognized.

WEBER considered the protein contents of latex as " impurities " which may be eliminated by good coagulation.

Dr. DAVID SPENCE (*Journal of the Society of Chemical Industry*, 1907, p. 1287) investigated the distribution of protein in rubber and found that in the insoluble part there was sometimes as much as 5.4 per cent of nitrogen ; this would mean about 33 per cent protein.

SCHIDROWITZ in 1911 noted that plantation rubber is usually deficient in nitrogen.

At the Eighth International Congress of Applied Chemistry held in New York in 1912, CLAYTON BEADLE and H. P. STEVENS described an investigation of *Hevea* latex. They found that the latices contained from 1.31 to 1.56 per cent protein ; that the percentage of protein of the total solids varied from 5.1 to 5.5, and that about one half of this protein was retained in the washed and coagulated rubber in the form of dry crêpe. The same STEVENS in the *Colloid Zeitschrift* (Vol. XV, Nos. 1 and 2, pp. 36-49 and 86-96, Dresden and Leipzig, July, August, 1914), showed that the nitrogenous constituents had much influence, and the resinous constituents little influence on vulcanization.

CLAYTON BEADLE and H. P. STEVENS separated the protein matter which contained the nitrogen, from smoked sheet. (1) Then they vulcanized the nitrogenous part and the nitrogen-free part and the original sheet. It was found that the part of the rubber with high nitrogen contents vulcanized more rapidly and combined with more sulphur than the

(1) See No. 131, *B.* Feb. 1913. (*Ed.*)

original sheet and that the nitrogen-free part combined with the least. The strength and resiliency of the nitrogen-containing part was the greatest.

The question then arises whether nitrogenous compounds may be added to rubber to act as hasteners of vulcanization or to give improved products.

In the *Gummi Zeitung* (Year 28, No. 19, p. 731, Berlin, February 1914) it is shown that albumen added to rubber increases the speed of vulcanization.

In the French patent No. 466 243, scrap rubber is heated with caustic soda and a small quantity of an aromatic amino compound, which acts as a catalyst to unite the free and combined sulphur with the alkali. In a German and English patent piperidine or its homologues are added to the vulcanizing masses ; in another patent piperidine or its homologues are used for producing hard rubber by adding 25 per cent sulphur.

In other patents the following substances are used : the derivatives or salts of piperidine, aliphatic amines with open or closed chains, the addition product of carbon disulphide and dimethylamine, aniline, naphthyl amine, a paste of albumen and lime.

Almost all the above-mentioned agents are organic nitrogen compounds, usually in the form of amines, and this authorizes the conclusion that this form of nitrogen has some catalytic influence in hastening the combination of rubber and sulphur, and in polymerizing the rubber itself.

With the use of large quantities of plantation rubbers which are known to be deficient in both proteins and other nitrogen compounds, and which are recognized as being much slower in vulcanization than Para, it would seem to be desirable to determine on some substance, like the above, which will act as a hastener.

INDUSTRIES DEPENDING ON ANIMAL PRODUCTS

1072 – **The Cause of Acidity in Fresh Milk of Cows and a Method for the Determination of Acidity.** — VAN SLYKE, L. L., and BOSWORTH, A. W. (New York Agricultural Experiment Station) in *The Journal of Biological Chemistry*, Vol. XIX, No. 1, pp. 73-76. Baltimore, Md., September 1914.

The fact that milk is strongly alkaline to methyl orange would indicate that its acidity is due to the presence of acid phosphates of the type MH_2PO_4. Now when phosphates are titrated with alkali in the presence of calcium salts, some of the insoluble dicalcium phosphate ($CaHPO_4$) formed during the titration hydrolyses, changing into calcium hydroxide and phosphoric acid, and then the calcium hydroxide unites with more dicalcium phosphate to form tricalcium phosphate, which appears as a precipitate. These conditions occur when the acidity of milk is determined in the usual methods with $\frac{N}{10}$ caustic soda, and the free phosphoric acid formed increases the acidity as measured by titration.

Serum was separated from whole milk by filtration through a porous porcelain filter and the titration figure given by whole milk was about twice that obtained with the serum. This difference has been ordinarily interpreted as being due to the acidity of milk casein, but as the writers have some evidence that casein is present in milk in the form of a neutral com-

pound and the other constituents removed by the filter are fat and dicalcium phosphate, both of which are neutral to phenolphthalein, it would appear that the cause of the discrepancy is the removal of the dicalcium phosphate which permits the formation of phosphoric acid.

The writers therefore suggest that in estimating the acidity of milk samples, the calcium should be previously removed by treatment with a saturated solution of neutral potassium oxalate at the rate of 2 cc. per 100 cc. of milk.

1173 - **Ability of Streptococci to Survive Pasteurization.** — AYERS, S. HENRY, (Bacteriologist) and JOHNSON, WILLIAM T., Jr. (Scientific Assistant, Dairy Division, Bureau of Animal Industry) in *Journal of Agricultural Research*, Vol. II, No. 4, pp. 321-330 + 3 diagr. Department of Agriculture, Washington, July 1914.

It is generally assumed that cocci do not form spores and the vegetative cells would not be expected to withstand Pasteurization. It has been shown, however, by the writer and others, that certain strains of lactic-acid bacteria, which would be classified among the streptococci, and perhaps some streptococci found in cream, are able to survive Pasteurization.

The writers have resumed the experimental study of the question and they summarize the results obtained as follows:

1. When the heating was performed in milk for 30 minutes under conditions similar to Pasteurization the thermal death-points of 139 cultures of streptoccci isolated from cow feces, from the udder and the mouth of the cow, and from milk and cream, showed a wide variation. At 60° C. (140° F.) the lowest Pasteurizing temperature, 89 cultures, or 64.0 per cent, survived; at 62.8°C. (145° F.), the usual temperature for Pasteurizing, 46, or 33.1 per cent, survived; and at 71.1° C. (160° F.) 2.6 per cent of the cultures survived; all were destroyed at 73.9° C. (165° F.).

2. The streptococci from the udder were, on the whole, less resistant and those from milk and cream more resistant to heat than those from the mouth of the cow and from cow feces. When heated to 60° C. all of the 18 cultures from milk and cream survived; at 62.8° C. 17, or 94 per cent, survived; at 68.3°C. (135°F.) 9 cultures, or 50 per cent, withstood the heating process. All the streptococci from milk and cream were destroyed by heating to 73.9°C. for 30 minutes.

3. Among the 139 cultures of streptococci there were 22 that formed long chains and were considered (following the practice of some board of health laboratories) as typical streptococci The others were considered atypical. (The writers, however, do not believe the chain formation a proper basis for classification). Of the 22 typical streptococci, 12 survived heating for 30 minutes at 57.2°C. (135°F.), 9 at 60°C. and only 1 at 62.8° C. All of the typical streptococci were destroyed at 65.6° C. (150°F.).

The 117 atypical streptococci were more resistant; at 60° C. 68.4 per cent survived, at 62.8° C. 38.5 per cent survived, and at 71.1° C. 2.5 per cent survived; all were destroyed at 73.9° C.

4. Two classes of streptococci seem to survive Pasteurization:

a) Those which have a low majority thermal death point but among which a few cells are able to survive the Pasteurizing temperature. This

ability of a few bacteria to withstand the Pasteurization temperaturs may be due to certain resistant characteristics peculiar to a few cells, or may be due to some protective influence in the milk.

b) Streptococci which have a high majority thermal death point. When such is the case the bacteria survive because the majority thermal death point is above the temperature used in Pasteurization. This ability to resist destruction by heating is a permanent characteristic of certain strains of streptococci.

5. The thermal death point determinations in this work were made in milk in such a manner as to represent actual conditions of Pasteurization by the holder process ; consequently the results show what may be expected in commercial Pasteurization, and it is evident that some streptococci may survive the process. However, different results might have been obtained if a larger number of cultures had been studied and if other methods and media had been used for determining the thermal death points.

1174 – **Action of Bacteria on the Ripening and Flavour of Cheese of the Cheddar Type.** — I. – EVANS, ALICE C. (Bacteriologist, Dairy Division, Bureau of Animal Industry), HASTINGS, E. G. (Bacteriologist, Wisconsin Agricultural Experiment Station) and HART, E. B. (Chemist, Wisconsin Agricultural Experiment Station). Bacteria Concerned in the Production of the Characteristic Flavour in Cheese of the Cheddar Type.. — *Journal of Agricultural Research*, Vol. II, No. 3, pp. 167-192. Washington, June 15, 1914. — II. – HART, E. B., HASTINGS, E. G., FLINT, E. M. (Chemist, Dairy Division, Bureau of Animal Industry) and EVANS, ALICE C. Relation of the Action of Certain Bacteria to the Ripening of Cheese of the Cheddar Type. — *Ibid.*, pp. 193-216.

I. — This is a continuation of previous investigations (1) consisting 1) in many bacteriological analyses of cheeses in order to determine more fully the distribution of the groups of bacteria in ripening cheese; 2) in a detailed study of the pure cultures obtained, with the view of correlating the presence of certain types with desirable or undesirable flavour production.

In the previous work the pure cultures were obtained by isolation from lactose-agar plate cultures and from dilution cultures in sterile milk. In the present study the dilution cultures were made in milk to which was added 1 gram of peptone, 1 gram of dextrose and 200 cc. of water per litre. This was found to be more favourable for the development of some of the cheese organisms. An effort was made to obtain two pure cultures from each series of dilution cultures : *viz.* the predominating organism of the *Bacterium lactis acidi* and coccus groups, and the predominating organism of the *B. casei* group. The former was obtained by plating — in casein agar to which 1 per cent. of dextrose was added — the culture from the highest dilution of the cheese which shows a growth after two days incubation; the latter was obtained after three weeks' incubation. On every plate a portion containing 10 colonies was circumscribed, and the inclosed colonies were fished off into litmus milk.

(1) See No. 868, *B.* July 1913. (*Ed.*)

Those cultures from a single plate which caused the same changes in litmus milk and were of the same morphology, were considered of the same variety. Representatives of every variety were studied in detail. This method, which allows the examination of a large number of cheeses and gives a rough picture of their flora, was considered the best adapted to increase present knowledge on the subject.

The cultural characteristics, morphology, and the few biochemical reactions which are ordinarily considered in classification of bacteria, were found to be inadequate for distinguishing one variety of cheese organism from another of the same group. Therefore the system of classification based upon the fermentation of various test substances, used by Gordon and others, was adopted.

The results obtained by the writers are summarized as follows: The organisms constantly found in Cheddar cheese in such numbers as to indicate that they must function in the ripening process are included in four groups: *Bacterium lactis acidi*, *B. casei*, *Streptococcus* and *Micrococcus*. On the basis of the fermentation powers, each of the four groups may be divided into a number of varieties, the distribution of which in Cheddar cheese, prepared from both raw and pasteurized milk, has been studied. The flora of raw-milk cheese includes all the varieties into which the groups were divided. The flora of pasteurized milk cheese, with the exception of the *Bacterium casei* group, is dependent upon the flora of the starter. It seems that the pungent taste that develops late in the ripening period of both raw-milk and pasteurized milk cheeses is due to the *Bacterium casei* group. It is probable that growth of this group continues during the major part of the ripening period. The action of two or more organisms growing together is not the sum of their individual actions when growing alone. When growing together they may attack substances that neither can attack alone, or they may produce a larger quantity of acid than the sum of the quantities that either can produce alone. When added to pasteurized milk, the organisms of the *Bacterium casei* group produce a sour taste in the cheese during the early part of the ripening period. No Cheddar flavour is obtained in pasteurized-milk cheese when the organisms of the *Bacterium lactis acidi* group alone are used as starters. The varieties that are able to ferment the more complex substance are likely to produce a bitter taste.

Starters composed of both *Bacterium lactis acidi*, *b*, and *Streptococcus*, *b*, when added to pasteurized milk, improve the quality of the cheese. It does not seem unreasonable to hope that starters may be obtained that will give the characteristic Cheddar flevour to the cheese prepared from pasteurized milk.

II. — In a preliminary investigation of the non-nitrogenous constituents of Cheddar cheese, the very pronounced differences that were expected in the quantity and variety of volatile acids, esters and alcohols in good and poor types of cheese were not found. But since there were certain differences which could be only of biological origin, it was believed essential that the substances formed by the specific groups of organisms normally present in cheese should be more carefully studied. It was thus hoped to find

the groups of organisms to which the production of definite non-nitrogenous compounds that could be correlated with flavour production might be attributed. The compounds particularly sought were the alcohols and esters, and caproic and butyric acids. Formic, acetic, propionic, lactic and succinic acids were also included in the list of substances to be isolated. To some extent the sources of these bodies were also studied.

The writers summarize as follows the results of their very numerous and detailed experiments:

1. Representatives of the coccus groups of organisms isolated from Cheddar cheese, when grown in milk, produced large quantities of the volatile acids, particularly acetic acid. These acids were produced from citric acid or lactose or protein, as the medium was practically free from fat. These organisms did not produce formic acid. As they are present at times in very large numbers in cheese, they no doubt produce much of the volatile fatty acids which arise during the ripening process.

2. One of the strains of *Streptococcus b* was found to produce comparatively large quantities of alcohols and esters — bodies which contribute in a large degree to the flavour of cheese.

3. A dilute solution of acetic acid and alcohol formed esters by mere contact, without bacterial action.

In cheese, however, the dilution is probably too great for this manner of ester formation.

4. Lactic acid was generally not formed by the coccus groups.

5. The representatives of the *Bacterium casei* group examined, gave results differing from those obtained from the coccus forms. They produced no formic acid, but did form some propionic and much acetic acid.

6. These organisms produced a large quantity of lactic acid, both active and racemic, and decomposed the citric acid of the media.

7. Cheese made from chloroformed fresh milk did not yield any volatile fatty acids, showing that inherent milk enzymes are not capable of producing these bodies in any appreciable quantity.

8. Representatives of both the coccus and *Bacterium casei* groups were able to produce ammonia from milk.

9. Whey and fresh curds contained active lactic acid. Cheese one day old contained a mixture of active and racemic lactic acids.

10. The cause of the disappearance of active lactic acid and the appearance of racemic acid may be due to enzymic action, combined with the action of those bacteria which can produce both kinds of acid.

11. Some representatives of the *Bacterium casei* group produced levo-lactic acid and others dextro-lactic acid from milk. A mixture of these two varieties produced racemic lactic acid. A mixture of *B. lactis acidi* and a levo-producing member of the *B. casei* group gave racemic and active lactic acid. The active acid was probably the result of the longer continued activity of *B. casei*.

12. Racemic lactic acid found in curing cheese may therefore be produced in a small degree by enzyme action, but more probably by

the combined action of *Bacterium lactis acidi* and the organisms of the *B. casei* group.

1175 – **The Part Played by Micro-organisms in the Ripening and in the Production of the Pungent Flavour of Brindza, the Ewes' Milk Cheese made in Hungary.** — GRATZ, O., and VAS, K. (Experimental Dairy at Magyaróvár). — I. The part played by micro-organisms in the ripening and in the production of the pungent flavour of Brindza. — *Kiserletügyi Közlemények*, Vol. XVII, Part 3, pp. 347-394. Budapest, May-June, 1914. — II. On some new species of micro-organisms found in Bridza. — *Ibidem*, Vol. XVII, Part 4, pp. 635-644. Budapest, July-August 1914.

I. — The making of Brindza cheese differs essentially from that of other cheeses in that it is formed by kneading together several balls of curd prepared in different ways in different localities and under different conditions (1). The kneading, which is chiefly carried out in factories, undoubtedly causes a transformation of the bacterial flora and of the conditions of the enzymes in the paste of the balls. The objects of the present study are : 1) to determine the bacterial flora of Brindza and its qualitative and quantitative changes during the ripening of the stored cheese ; 2) to identify the organisms which produce the pungent flavour in Brindza and to explain its presence ; 3) to draw useful conclusions from the results obtained so as to improve the methods of making this cheese.

The experiments were made with five samples of fresh Brindza (some weeks old), which were subjected to control lasting six months. The bacteriological analyses were made at intervals of from 4 to 6 weeks.

The writers drew from their research the following conclusions :

1. The bacterial flora of Brindza is very varied. It includes *Micrococcus*, *Sarcina*, *Streptococcus*, *Bacterium*, *Bacillus*, *Actinomyces*, *Torula*, *Oidium*. Among the species isolated, there are several which have not hitherto been described in the literature on the subject. This great variety of microflora is to be attributed not only to the want of cleanness of the ewe's milk and to the bad rennet (made with water and easily liable to putrefaction), but also to contamination, during the making, due to the crust of the balls, the salt, the machines and implements.

2. Brindza is very rich in micro-organisms. There is no cheese with so high a germ content as Brindza, notwithstanding the fact that after it is made and during storage the multiplication of micro-organisms ceases. Most of these are lactic bacteria, especially *Bacterium casei*, *Streptococcus lactis*, *Micrococcus* ; nevertheless, though very numerous (61 per cent), they do not attain the proportion that they reach in other cheeses (79 to 95 per cent). The cause of this is in the difference of manipulation, as compared with other cheeses, which introduces a large number of accidental germs and thus reduces the number of lactic bacteria.

3. The accidental micro-organisms, the presence of which is very inconstant, disappear soonest. Quantitative analyses have shown that during storage the content of germs in Brindza diminishes. At first the decrease is very marked, while later it slackens. Streptococci and cocci die much

(1) See No. 1669, *B.* Dec. 1912. (*Ed.*)

sooner than lactic bacilli, which are found together with their spores even in very strong Brindza.

4. Research has shown that the accidental micro-organisms do not take part in the ripening of the cheese, because its conditions do not favour either their development or the activity of their enzymes. The agents which cause ripening are therefore the lactic bacteria ; nevertheless the enzymes of the rind of the curd balls also play an important part in the ripening of Brindza.

5. Results have demonstrated that the origin of the piquant flavour of some ewes' milk cheeses is due only in exceptional cases to butyric fermentation, and generally to a great decomposition of the fatty matter. This decomposition is not caused by the bacteria having the power of attacking fatty matter ; this is proved by the fact that they have often been found in greater numbers in sweet Brindza than in strong pungent Brindza.

6. The agents of the great decomposition of fatty matter are enzymes and in the first place the lipase of *Oïdium lactis*. The result is that if the outside of the curd balls (rich in butyric ferments and on which *Oïdium lactis* is always present) and the fat layer under this outside (in which the enzymes are found) are not carefully removed when the cheese is worked up again, as is often the case, the above parts come into contact with the whole of the kneaded paste and communicate a pungent flavour to the cheese.

7. Observations made during the process of ripening have shown that strongly flavoured Brindza has a pale orange colour ; it is dry, subject to crumbling, strongly smelling and never turns mouldy. On the other hand sweet Brindza has generally a normal consistence, but it becomes sticky and mouldy if it is not kept hermetically closed.

As for the practice of the manufacture of Brindza, the results of observations may be summarized as follows. It is not essentially necessary that Brindza should have a pungent flavour, because the origin of this flavour is not due to the action of micro-organisms the presence of which could not be avoided by the cheese-maker, but to the manipulation allowing the lipolytic enzymes existing on the rind of the balls to exert their influence, which fact had not hitherto been recognized. Knowing the factors which give Brindza this special taste, the cheese-makers will be able to modify it by adopting a suitable process of manufacture (careful removal of the rind of the balls).

The paper contains bibliographical notes, as well as diagrams and tables showing numerical results of the analyses made.

II. — Description of some new species of micro-organisms found during the research on the flora of Brindza and the part they play in the ripening and production of the special flavour of this cheese. Considering the various properties of these bacteria observed during their culture, and their biochemical action, they do not resemble any of the micro-organisms known so far to the literature of bacteriology. These new species are: *Bacterium saponificans, Bact. adipis, Bact. rufum, Bacillus gravidus, Bac. submergens, Bac. exilis, Bac. cerasinus, Bac. parabutyricus, Bac. indolicus.*

1176 – **The Phosphorus Content of Casein.** — BOSWORTH, A. W., and VAN SLYKE, L. L. (New York Agricultural Experiment Station) in *The Journal of Biological Chemistry*, Vol. XIX, No. 1, pp. 67-71. Baltimore, Md., September 1914.

The amount of phosphorus in casein has been commonly given as about 0.85 per cent. By treating a solution of casein in excess of dilute ammonia with ammonium oxalate and letting it stand twelve hours, the phosphorus content is reduced to 0.71 per cent. This lower percentage cannot be explained as being due to hydrolysis of casein and splitting of phosphorus, for though some of the casein is hydrolised, the hydrolised portion does not enter into the final preparation or affect its composition. The higher figure ordinarily given is due to the presence of inorganic phosphorus (dicalcium phosphate) carried from the milk into the precipitated casein and not entirely removed under the usual conditions of preparation. The lower figure corresponds very closely to two atoms of phosphorus in the casein molecule. Analyses of various preparations of casein containing varying amounts of ash show a general correspondence between the ash and phosphorus content.

1177 – **A Comparison between the Fat Stock and the Carcasses Exhibited at the Smithfield Show, 1913.** — LONG, JAMES, in *The Journal of the Board of Agriculture*, Vol. XXI, No. 1, pp. 1-12. London, April 1914.

The Smithfield Club holds each December a show of pure and cross-bred fat cattle, sheep and pigs. In 1896 a new section was added to the Smithfield show, for the best carcasses of beef and mutton, and this competition has continued ever since. In 1903 classes for pigs were added to the carcass section.

In the last competition the judges showed a decided preference not only for lean meet but also for small meat, and this applies to the carcasses of cattle and sheep as well as to pigs.

From the difference between the live-weight and the carcass-weight it appears that the younger the animal matures and can be finished for slaughter, the smaller will be the cost of producing a pound of meat, the better its quality and the smaller the waste.

In the 1896 carcass competition the two-year-old steers averaged 1323 lb. live-weight and 864 lb. in the carcass, or 65 per cent.

The average live-weight of steers under two years old is 1363 lb. Omitting the Highland cattle, the average weight in the class from 2 to 3 years is 1772 lb., which exceeds the former by 409 lb., or an estimated difference in the carcass-weight of 266 lb. This shows that it cannot pay the feeder to keep a steer for the additional year, since the actual weight of beef produced barely exceeds 5 lb. a week. The estimated carcass-weight of the steers under two years old is 886 lb., or 80 lb. more than that of the prize steers in the carcass class, while for steers between two and three years old, this estimated average is 1136 lb., or 282 lb. more than the actual average carcass-weight of the whole class. This difference represents much additional fat, that is, a factor which depreciates the unit of weight of the meat.

In the classes for heifers similar results are obtained. The average live-weight of the older animals is only 1576 lb., against an average of 1322 for the younger ones, showing an increase for one year of only 254 lb., which is reduced to 165 lb. of carcass. It is evident that this cannot pay. The accompanying tables show the weights observed:

1178 – **"Quality" in Wool.** — BAILEY, P. L., and ENGLEDOW, F. L., in *The Journal of Agricultural Science*, Vol. VI, Part 3 pp. 349-370. Cambridge, September 29, 1914.

NATHUSIUS, BOHM, KONIGSBOM, BOWMAN, MC MUTRIE and others have shown that "quality" in wool depends upon several factors, including

1) Fineness of fibre as measured by the average diameter.
2) Number of crimps or waves per unit length of the fibre.
3) Length.
4) Lustre.

The writers of this paper determined to repeat the work of the above writers and to subject the results to a statistical analysis. They studied the fleeces of crosses of Shropshire ewes with Australian Merino rams. They examined over 700 microscopic slides and made about 30 000 measurements. The present paper deals in particular with the relation between "fineness of fibre" and the commercial grading of the wool.

At shearing, samples were taken from both of the shoulders, the neck, the britch and the belly. A skilled Bradford sorter divided this wool into eight classes indicated by numbers 64's to 40's, which are based on the spinning capacity of a given weight of wool.

For the microscopic investigation, four sub-samples, A, B, C, D, were taken from each sample; from each sub-sample three portions were cut off, one at the tip end (T_1), another from the middle (T_2) and a third from the base (T_3). Each portion was placed on a glass slide and fixed with balsam. The measurements were made with a micrometer eye-piece, each division of the scale representing $\frac{1}{8000}$ of an inch. The figures in this paper are, unless otherwise stated, based upon a unit of measurement equal to one eye-piece-scale division.

The results and conclusions may be summarized as follows:

1. The method of taking four sub-samples and making in all 160 measurements of them gives a satisfactory value for the average diameter of the sample. The amplitude of the variation of the probable errors is given by the range 0.064—0.154 or, as percentages of the averages concerned, 1 to 1.6 per cent. Thus, if the largest magnitude of the probable error be taken, the odds are 20 to 1 that the average of 160 measurements is correct to within 5 per cent.

2. The average of the samples from each shoulder gives a good indication of the shoulder for each sheep. From a study of four cases showing exceptional fluctuation in the averages of the sub-samples it appeared that the probable error was 0.263 units, or a little over 3 per cent of the average. Consequently, even in cases of the greatest variability, one can rely upon the average obtained from the sub-samples representing the whole shoulder average to within 10 per cent. In the great majority of cases it will be correct to within 5 per cent.

3. In comparing two sheep, A and B, we may take as almost certainly significant a difference between their two average shoulder diameters such that the ratio

$$\frac{M_A - M_B}{\varepsilon_{AB}} > 3,$$

that is a difference of some 8 per cent of the average shoulder diameter of either of them for measurements taken as here indicated. In other words, if the averages of the shoulder samples of two sheep differ by more than three times the standard error (1) of their difference, one may be satisfied that this difference is real and not due to any small variations in the position on the individual sheep from which the shoulder sample was taken.

4. A relationship exists between the fineness of the wool (as measured by the average diameter) and the commercial quality into which the wool is graded. But this relationship is not absolute. Thus, sheep that had suffered from a *Strongylus* attack, produced finer wool during the illness, so that the fibre presented a line of weakness with decrease of diameter. In such cases the average diameter is smaller and yet the commercial quality is inferior.

There is a correlation between the fineness of wool and the number of crimps per inch, but this appears to cease after the number has reached about 23 per inch.

5. The average diameter at the tip is the best guide from a genetic point of view as to the fineness of the wool concerned, owing to the marked pathological influences which may affect the base average.

6. The distribution of the fibres of different sizes has a modifying effect upon the commercial quality which would be assigned from a consideration of the average size only. It is suggested that the standard deviation of the distribution of the fibres should be used as a measure of this modifying effect.

In the accompanying table are given the " qualities ", the average diameter sizes (M) of the fibres in those qualities and the standard deviations (σ) of the distributions. An examination of the figures there given shows that in the case of T_1 there is a distinct parallelism between the quality assigned by the sorter to the sample and the standard deviation of that

(1) See C. B. DAVENPORT: *Statistical Methods*, 1904; also R. LOCK: *Recent Progress in the Study of Variation, Heredity, and Evolution*, London, 1911 (chapter on *Biometry*, pp. 80-120). (*Ed.*)

sample, a fall in " quality " being accompanied not only by a rise in the average diameter size, but also by a rise in the standard deviation. This latter rise cannot be explained as being wholly due to the rise in the average diameter, as is shown by the fact that there is also a rise in the coefficient of variation $\frac{\sigma}{M}$.

In order to study more closely the question of influence of variability of sample on the commercial quality, the percentage occurrence of diameters of every size was calculated for all the qualities. From the Table of the numerical results the qualities are seen to group themselves into four classes :

Class I : the 60's and 58's. The fibre distributions for these two qualities are much alike and show a comparatively small dispersion.

Class II : the 56's. The distribution for this class is of the same general nature as that of the preceding class, but shows a distinctly greater dispersion.

Class III : the 54's and 50's. The distribution appears to be bimodal, and the range of variability is much increased.

Class IV : the 44's. Fibres distributed in two or three modes and tending to coarseness.

The writers make some reserves on the generalization of their results, owing to the hybrid nature of the sheep from which the samples came.

1179 - **Libyan Hides and Skins.** — ndustrial Experiments on Sudanese and Libyan Hides and Skins (From a Report of the Director of the Royal Experiment Station of the Leather Industry at Naples) in *Ministero delle Colonie, Ufficio economico, Bollettino di Informazioni*, Year II, No. 7-8, pp. 531-535. Rome, July-August 1914.

The production of cattle in Tripolitania amounts annually to about 50 000 head. The animals are somewhat small, and weigh, on an average, 660 lbs. The salted and dry hides of adult animals received from Tripoli by the Royal Leather Experiment Station at Naples, weigh on an average 21 lbs.; the calf skins weigh 6 lbs., while those from Cyrenaica weigh respectively 15½ lbs. and 6½ lbs.

The hides from Cyrenaica were better than those from Tripolitania and more carefully sorted. In general, the products of both places were fairly good, being soft and of equal body and substance. They, however, had some easily eliminated defects (imperfect flaying and preservation, brand marks, etc.) and some were perforated by warbles.

Goat breeding is extensively practised in Tripolitania. The goats are of medium size, with black or reddish hair; their tails are small and little covered with hair. The height of the withers is from 2 ft. to 2 ft. 2 in. Beneath the hair is a wool which the natives weave into materials for local use. A goat weighs about 66-88 lbs. and the kids, which are sold when very young, weigh from 11 lbs. to 15 ½ lbs. During the four months July-October 1913, 63 417 lbs. of untanned goatskins were exported from Tripoli and neighbourhood. The goatskins received from Cyrenaica and Tripolitania by the Royal Experiment Station at Naples are well suited to working *à chevreaux*, according to the English system of *semi-chromo* (tanning with gambier and a basic solution of chromium), for the preparation of a special leather "Dongola" (tanned with alum and gambier), and for cheap Morocco (tanned with sumach, gambier and quebracho and dyed with anilin colours). The goatskins of Tripolitania and Cyrenaica have proved to be of good quality and sufficient substance, without too much waste.

About 100 000 sheep are exported from Tripolitania. These animals belong to three species. The Orfella thin-tailed breed, the fat-tailed Gebel sheep with short legs, and the large Sudan animal which is without wool. In Tripoli medium-sized fat-tailed sheep are very plentiful. Their fleeces would be thick and uniform if they were well kept; but frequent skin diseases cause a partial loss of wool. The average weight of the Tripoli sheep is about 84 lbs., that of the rams is 88 lbs., while lambs 4-6 months old weigh 40 lbs., and those over a year old attain a weight of from 62 to 66 lbs. During the four months July-October 1913 about 117 115 lbs. of lamb and sheep skins were exported from Tripoli. The sheepskins received by the Royal Experiment Station at Naples were tanned as follows: 1) with the wool, for carpet leather; 2) for glove skins, from which excellent goods were obtained.

Libyan camel skins are not very important articles, as they are only sold when the animals are killed because they are past work, or when they die a natural death. From July-October 1913 about 11 365 lbs. of camel skins were exported from Tripoli. They are very irregular in shape and very defective. When tanned, they fetch barely £1 8*s* 3*d* per cwt. The inferior skins can be used for second quality sole-leather; those tanned with chromium serve for making lacings and straps.

AGRICULTURAL PRODUCTS: PRESERVING, PACKING, TRANSPORT, TRADE

1180 – **Experiments on Storing Swedes during the Winter, in Denmark.** — 58. *Meddelelse fra Statens Forsøgsvirksomhed i Plantecultur. Ved. Statens Plantcavlsudvalg.* Copenhagen, October 2, 1914 (Communicated by the Danish Correspondent of the International Institute of Agriculture).

The experiments were carried out during the four winters from 1909 to 1913 in the farms belonging to the Experiment Stations of Studsgaard, Varde and Holstebro.

Similar experiments made in 1906 showed that when mangolds were kept in large broad pits covered with seaweed and in field clamps, the loss in dry matter during the winter was not so great as when they were kept in cellars. The experiments which have now terminated show that the same holds true for swedes.

With a crop of swedes containing 59 ¾ cwt. of dry matter per acre, the losses were 7 cwt. of dry matter when they were kept in large pits till the middle of March, 8 cwt. in field clamps, and upwards of 13 ½ cwt. when they were kept in cellars.

The loss with swedes is somewhat greater than with mangolds, and this is especially noticeable after the month of January. The cause of this lies in the fact that towards spring the loss caused by rot in the swede pits is much greater than in the mangold pits, and besides this, the direct loss of dry matter due to the vegetative activity of the roots seems to be greater in swedes than in mangolds.

In the choice between pits and clamps it must be borne in mind that the pits, besides causing a somewhat smaller loss during the winter, have also the advantage of being cheaper to cover and uncover than the clamps. On the other hand frost gets into pits more easily than into clamps ; when no heather, seaweed or other suitable material is easily available, then clamps are to be preferred to pits. The experiments have shown that the winter losses in clamps are smaller when the ends are covered at once and the top only in December, unless continued frost should render this necessary sooner. The sides of the clamps were covered with earth and the top with heather.

The higher the temperature in the pit, the greater was the loss during the winter ; the importance of attending to ventilation at once in the autumn in order to keep the temperature as low as possible in the pit, was proved. By a suitable arrangement of air passages in the bottom of the pit, the temperature was lowered during the first months by 1 to 2° C. (1.8 to 3.6° F.). The lower temperature diminishes the vegetative activity of the roots ; consequently the loss of dry matter between autumn and the middle of March was 1 ½ cwt. per acre less in ventilated than in unventilated pits and 1 cwt. per acre less in ventilated clamps than in unventilated ones. As the value of the dry matter can be estimated at 5 *s* per cwt., the cost of ventilation is negligible in comparison to the loss that would be caused by neglecting to ventilate the pits. From New Year's day onwards the air passages in the pits were closed, as they had been previously during periods of frost.

When the clamps are made in the second half of October, the temperature in them is higher than when they are made at the beginning of November. The experiments have shown a loss of 16 cwt. of dry matter per acre when the clamps are made in October and not ventilated, as against 8 cwt. per acre when they are made in November. It is therefore advisable to make the clamps as late as possible, and if special weather conditions require the work to be done in October, ventilation becomes a necesssity.

The loss of dry matter increases progressively from autumn to the middle of March ; if the clamps remain untouched for another month, namely up to the middle of April, the loss during this month is equal to the total loss up to the middle of March. This is due to the fact that during the latter period a high percentage of the swedes rot in the clamp. On uncovering it in the middle of March, the loss during the succeeding month was one-third of what it is when the heap was uncovered in the middle of April. In districts in which mangolds are not grown and swedes must be available after the middle of April, it is useful to uncover the clamps in the middle of March. By measuring the temperature of the clamps, one can have an idea of the amount of the loss being caused. For this object special thermometers are made, by means of which the temperature is taken once every three days during the first month and once a week afterwards. If, in some points, an increase of temperature is noticed, it can be lowered by uncovering that part of the heap.

PLANT DISEASES

DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN.

1181. – **Further Notes on a Disease of Red Clover in Tuscany** (1). — I. BACCARINI, PASQUALE, and BARGAGLI-PETRUCCI, GINO. — II. DEL GUERCIO, GIACOMO. — *Atti della Reale Accademia economica-agraria dei Georgofili di Firenze*, Series 5, Vol. XI, Part 2. pp. 23-96, figs. 1-12, 1 plate; pp. 133-183, figs. 1-39. Florence, 1914.

I. — The researches of Profs. Baccarini and Bargagli-Petrucci on the disease of *Trifolium pratense* known as "incappucciamento", which first appeared in several parts of Tuscany in 1908, have brought to light several factors concerned in the damage, but without definitely deciding which is to be considered as the true cause of the destructive disease in question.

The theory of degeneration of the seed sown in laying down the crop cannot be accepted in this particular case.

The following fungi have been isolated on several occasions from the diseased clover: *Sclerotinia Trifolium*, *S. sclerotiorum*, sterile mycelia of *Dasyscypha* and *Helotium*, *Phoma* sp., *Botrytis cinerea*, *B. vulgaris*, *Torula* sp., *Fusarium metachroum*. Infection experiments have given results which, though not being definite, lead to the conclusion that the fungi, especially *Sclerotinia Trifoliorum*, *Botrytis cinerea* and *Fusarium metachroum*, cannot be considered as the ultimate causes of the disease.

Four types of bacteria have also been isolated, one of which (type *a*) is more constant and abundant than the others; it is capable of liquefying agar and gelatine and evidently belongs to the genus *Micrococcus*. Inoculations of red clover with this organism have resulted in the production of the chief symptoms of "incappucciamento" in both field and pot cultures. It therefore appears that the ultimate cause of the disease is bacterial infection, probably with the organism of type *a*. Inoculation experiments with this organism tend to show that some lesion, natural or artificial, is necessary for the organism to gain entry. Such lesion may be caused accidentally

(1) See No. 181, *B.* Feb 1914. (*Ed.*)

by moving, or by the action of certain insects or other animals boring in the stems and roots. Certain eelworms (*Heterodera*) have in fact been recorded on the diseased plants, and also insects belonging to *Apion*, *Hylastes*, *Anthonomus* (?), *Cecidomyia*, *Pteromalus*, etc. Of these, the species of *Cecidomyia* were found to be superficially infected by bacteria, among which type *a* was most abundant. The insects cannot be regarded as the primary cause of the disease, but rather as concomitant pathogenic causes (this may also be said of the fungi) and also disseminating agents of the bacteria, which they carry from plant to plant and inoculate direct into the tissues.

It is not very probable that a deficiency of lime in the soil can have given rise to the disease, nor can it be attributed to soil "sickness".

It is quite probable that the extensive floods of the Elsa in 1907 had established soil conditions favourable to an intense development and a rapid spread of pathogenic organisms previously localised or sporadic. Another hypothesis may also correspond to the facts; it is well known that the metabolism of micro-organisms is liable to variations and extraordinary adaptations, and that slight changes in the conditions of the medium are able to control the elaboration or suppression of definite substances (toxins or hormones). It is therefore by no means impossible that variations of the medium may exercise an influence on certain soil organisms so as to render them capable of a pathogenic action once they have gained an entry into the tissues of the plant. From this hypothesis it would appear that the intensity of the bacterial action would gradually diminish as the soil recovered its normal conditon, until it finally disappeared. The progress of this recovery would be facilitated by omitting clover from the rotation and substituting some other forage crop.

II. — Prof. Del Guercio observes that clover attacked by a disease known as "stremenzimento" or "incappucciamento" in the provinces of Florence, Siena, Pisa and Arezzo, showed symptoms which were evidently not due to insect or other animal pests and other symptoms of a different nature caused by worms, molluscs and various arthropods (Crustaceans, Arachnids, Myriapods and Insects).

The following insects are described in detail from the systematic and biological point of view, as pests of clover: *Rhizoberlesia trifolii* gen. et sp. nov., *Aphis scaliae* sp. nov., *Pemphigus trifolii* sp. nov., *Anthothrips* spp., Cecidomyids, *Apion* (especially *A. virens*), *Hylastinus* or *Hylastes trifolii*, etc.

The writer considers that this disease of clover is similar to that causing the dwarfing of other plants and draws the attention of agriculturists to the necessity of good manuring and rotation.

Though there is no doubt as to the damage caused by *Hylastes* and *Apion*, which is more than that due to Cecidomyids and *Tylenchus devastator*, no precise relation between these pests and micro-organisms can be determined in the present state of the researches. At present it can only be said that they are connected with damage to clover. It will be necessary to observe which action begins first and which is more effective in its results. The writer inclines to the opinion that insects and nematodes initiate the trouble and that subsequent developments of the disease are due to bacteria.

Future investigations should concern the relation between the microbes of the clover and of the soil, nematodes, insects and agricultural operations and the disease of clover, with a view to finding the best means of obtaining normal growth of this crop.

1182 – **Blossom-End Rot of Tomatoes.** – BROOKS, CHARLES, in *Phytopathology*, Vol. IV, No. 5, pp. 345-373, plates XXIV-XXVI, figs. 1-5. Baltimore, Md., October 1914.

Blossom-end rot or point-rot of tomatoes, first reported by Galloway in 1888, is of general occurrence in the United States and has been reported from Canada, Cuba, Australia, New Zealand and various parts of Europe.

The first symptom of the disease is a water-soaked appearance on the blossom portion of the fruit, followed by a spot at the base of the style or half a centimeter or more away from it, or, as is more commonly the case, the whole blossom surface of the fruit may be affected. In this stage the disease very much resembles a bruise. In a few days this dark green water-soaked area becomes black, later involving the whole blossom half of the fruit. The affected tissue collapses and becomes firm and leathery. This collapsing of the diseased tissue, together with the continued development of other parts of the fruit, may produce a definite depression on the blossom half of the fruit, but more often it results in only a flattening of the tomato.

The first effects of the disease are not always superficial. Fruit that appears entirely normal from an external view has often the tissue of several or sometimes all of its placentae collapsed and blackened in the parts nearest the blossom. In some cases this internal condition is accompanied by a very inconspicuous depression of the surface tissue above it or by a small water-soaked area on the surface.

The cause of the disease has been attributed to various organisms, *viz. Phytobacter lycopersicum*, *Macrosporium tomato*, *M. Solani*, *Fusarium erubescens*, etc., and many have regarded it as contagious. Recent results seem to show that it is not contagious and that its origin will be found along cultural and physiological lines.

Spraying experiments have generally given negative results, and the majority of authorities attach little importance to this means of control.

Culture experiments have led to the conclusion that neither bacteria, nor fungi, nor enzymes are the cause of this disease. Plants growing under the most favourable conditions are more liable to attack. Continued excessive watering, as well as a drought, may give rise to the disease. Manuring with potash salts in solution increases the disease in proportion to the amount of potash applied, whilst nitrate of soda causes a decrease in the intensity of the disease. These results were not confirmed in the field experiments. Nitrate of soda showed slightly less tendency to increase the disease than sulphate of ammonia or organic fertilisers having an equivalent amount of fertiliser. Heavy applications of horse manure have increased the disease out of all proportion to the increase in vigour of the plants. Plants well supplied with water on a sandy loam have developed less disease than those on a clay loam. Raising the soil temperature of greenhouse plants has increased the disease. The writer is of opinion that the increase in the disease from heavy watering is due to the development of harmful humic and

ammonium compounds and an accompanying decrease in nitrates. Susceptible tissue contains more starch and more oil than normal tissue, and its cell-sap has a higher osmotic value. The protoplasm of the cells from the fruit of the heavily-watered plants is more granular and contains more oil than that of the lightly-watered ones.

BACTERIAL AND FUNGOID DISEASES.

GENERALITIES

1183 - **Contributions to the Cryptogamic Flora of Thuringia.** — JAAP, OTTO, in *Annales Mycologici*, Vol. XII, No. 4, pp. 423-437. Berlin, 1914.

A systematic list of 300 species of Myxomycetes, Schizomycetes and Eumycetes, collected during the month of July in the years 1906 to 1911, in various parts of Thuringia. Some of them are new to Central Germany and also to Thuringia. One of two species of fungi new to Science is *Entomophthora Jaapiana* Bubák, found on the hemipterous pest *Euacanthus interruptus* L. (fam. Jassidae). The list includes numerous fungi living on the resin of spruce, which are very abundant and well developed, especially in the woods near Oberhof.

1184 - **Contribution to the Mycological Flora of Serbia.** — RANOJEVIC, N., in *Annales Mycologici*, Vol. XII, No. 4, pp. 393-421, figs. 1-5. Berlin, 1914.

This third contribution contains 271 species of fungi collected chiefly during 1910 and 1911 and partly during 1913, in various parts of Serbia, and on a large number of plants, many of which are cultivated or otherwise of economic value.

Of these, two genera and 19 species are new to Science; large numbers are new to the district and occur on host plants of economic importance.

The following, amongst others, are either new to Science or fresh records for Serbia: *Podosphaera tridactyla*, on leaves of *Prunus Armeniaca; Leptosphaeria Tritici* on the leaves of wheat; *Uromyces Tropaeoli* sp. nov. on the living leaves of *Tropaeolum majus*; *Phyllosticta Betae* on the leaves of *Beta vulgaris*; *Cicinnobolus Humuli*, parasitic on *Erysiphe Polygoni*, *E. Cichoriacearum* and *Sphaerothoeca Humuli* (1); *Septoria Nupharis* sp. nov. on the living leaves of *Nuphar luteum*; *Dilophospora graminis* on the ears and leaves of wheat; *Oidium Tuckeri* on grapes; *O. quercinum* on the leaves of *Quercus pubescens* and *Q. sessiliflora; Microbasidium Sorghi* (species representing the new genus *Microbasidium*, instituted by Bubák and Ranojevic, and synonymous with *Fusicladium Sorghi* Pass.), on the living leaves of *Sorghum saccharatum*.

1185 - ***Pellicularia Koleroga* injurious to Coffee in Porto-Rico** (2). — FAWCETT, G. L., in *Journal of Agricultural Research*, Vol. II, No. 3, pp. 231-233, figs. 1-3, Washington, D. C., 1914.

In 1912 J. Kuijper reported that comparisons of the fungus causing the disease known as "zilverdraadziekte" of coffee in Surinam with

(1) See in this connection, No. 75, *B.* Jan. 1914. (*Ed.*)
(2) See No. 2983, *B.* Aug.-Sept.-Oct. 1911. (*Ed.*)

the fungus causing the so-called leaf-blight of coffee in Porto Rico led to the conclusion that the latter disease is not identical with the descriptions of *Pellicularia Koleroga* Cooke in India, and observed also that it differed from the fungus causing the " candelillo " disease in Venezuela.

However, considering the mistakes in the original descriptions of fungi causing other coffee diseases, and on the other hand the fact that the descriptions correspond sufficiently with the characters of the fungus found in Porto Rico, it seems justifiable to identify this fungus with *P. Koleroga*. Further, the specimens of *P. Koleroga* collected in Mysore, where Cooke first studied the disease, agree perfectly with those found in Porto Rico. It is therefore erroneous to consider the Porto Rico disease as different from that of *P. Koleroga* Cooke.

The researches on the Venezuela disease (" candelillo ") support the conclusion of Kuijper that the fungus is distinct from *P. Koleroga*, though allied to it.

It is therefore concluded that *P. Koleroga* exists in the Antilles and the South American continent as well as in India, and that a fungus of similar appearance and causing a disease known as " candelillo " has also been found on the continent. This appears to be the only fungus of this nature found in Venezuela and was wrongly identified as *P. Koleroga* Cooke.

1186 – **A Contribution to the Morphology and Life History of *Pestalozzia funerea* Desm.** — WENNER, J. J., in *Phytopathology*, Vol. 4, No. 5, pp. 375-384, plate XXVII, figs. 1-7. Baltimore, Md., 1914. FUNGI

The question of the exact relation of *Pestalozzia funerea* Desm. to the various coniferous hosts on which it has often been recorded in both Europe and America, has for many years been more or less in doubt. Other species of *Pestalozzia* have often been reported as appearing in close relation with diseased plants, yet actual proof of their parasitism is lacking in many cases.

In plate culture, in addition to the typical 4-septate conidia, another kind of spore appeared, resembling a chlamydospore; on germination, this produced a mycelium, the hyphae of which under favourable conditions produced similar chlamydospores, or, on plate and tube cultures, the typical 5-celled conidia.

Inoculation experiments proved conclusively that this species is parasitic under certain conditions, the most important of which appears to be the presence of a great amount of moisture in the air. The fungus is capable of attacking both the leaves and stems of the hosts used in the experiment, *viz.* Weymouth Pine (*Pinus Strobus* L.), Norway spruce (*Picea Abies* [L.] Karst.), and hemlock (*Tsuga canadensis*). The symptoms of the disease are browning of the leaves, followed in some cases by the appearance of superficial mycelium, the drooping of the young shoots, and the development of the acervuli. The shoots finally die and eventually the whole tree is killed.

As means of control, diseased seedlings should be destroyed as soon as detected, and as a preventive, the ordinary methods of spraying with Bordeaux mixture will probably be effectual.

BACTERIAL AND FUNGOID DISEASES OF VARIOUS CROPS

1187. – ***Puccinia Menthae* on *Mentha canadensis* var. *piperascens* in Hungary** (1). — GRÓF, BÉL, in *Kisérletügyi Közlemények*, Vol. XVII, Part. 4, pp. 657-661, 2 figs. Budapest, 1914.

Puccinia Menthae Pers. attacks not only *Mentha arvensis*, *M. crispa* and *M. piperita*, but also *M. canadensis* var. *piperascens*, which has been grown in Hungary for some years.

On this host the aecidium stage develops towards the end of April on the stems of shoots 4 to 6 in. long. It causes a swelling between the first and second node, which results in a curvature of the stem; in some cases the swelling extends over the whole surface of the stem, resulting in twisting. The diseased plants retain green leaves only at the summit, the rest being shrivelled.

Uredospores appear in July and teleutospores at the end of September.

The disease causes a very poor yield owing to the damage to the leaves and the reduced quality of the essence.

Treatment consists in collecting and burning the fallen leaves in autumn and spraying the infected plots with a 2 per cent solution of copper sulphate. The spraying should be repeated in the spring and the crop cut during June before the appearance of the uredospores.

1188 – **American Gooseberry Mildew in Italy** (2). — GREPPI, CARLO, in *Rivista di Patologia vegetale*, Year VII, No. 4, pp. 97-99. Pavia, 1914.

The occurrence of American gooseberry mildew (*Sphaerotheca mors-uvae* [Shwein.] Berk. et Curt.) was recorded on the shoots, leaves and fruits of gooseberries in the middle of May 1914, in a garden at Tromello (prov. of Pavia).

Gooseberries are very little grown in Italy, so that this fungus cannot be of such importance as in other European countries.

1189 – ***Hypochnus Burnati*, a New Fungus on the Vine in Switzerland.** — LENDNER, A., in *Bulletin de la Société botanique de Genève*, 2nd Series, Vol. VI, No. 4, pp. 104-106, 1 fig. Geneva, 1914.

Towards the end of autumn in 1913, several vines growing near to each other in a vineyard at Bossey appeared to be diseased, and peculiar nodular excresences known to French growers as "broussins" were observed on the stems.

Surrounding these tumours was a white felted growth resembling in its characters the fungus *Aureobasidium Vitis* Viola and Boyer, but actually belonging to a new species of *Hypochnus*, described by the writer as *H. Burnati*.

Analysis of the soil showed a high percentage of lime, which the writer considers is the primary cause of the disease. This new *Hypochnus* is considered to be a secondary parasite, or perhaps a saprophyte.

(1) See also No. 1211, *B.* Oct. 1913. (*Ed.*).

(2) See also No. 183, *B.* Feb. 1914; No. 953, *B.* Oct. 1914; and No. 1068, *B.* Nov. 1914. (*Ed.*)

PARASITIC AND OTHER INJURIOUS FLOWERING PLANTS.

1190 – **Parasitic Flowering Plants on Para Rubber Trees in Negri Sembilan (F. M. S.).** — BROOKS, F. T., in *The Agricultural Bulletin of the Federated Malay States*, Vol. II, No. 7, pp. 165-166. Kuala Lumpur, February 1914.

A considerable number of trees in *Hevea* plantations were noticed to be attacked by two kinds of parasitic flowering plants, not yet determined (1), in a manner similar to that in which mistletoe attacks certain trees in Europe. The parasites possess green leaves, but weaken the host by obtaining supplies of water and mineral salts from the branches, to which they are attached by means of suckers. Several of the rubber trees carried many of these parasitic growths, which were evidently doing considerable damage, the portions of the branches beyond the place of attachment of the parasite being killed in a number of cases.

Their simple entire leaves and prominent position on the branches make the presence of these parasites easy to detect.

The area which was most affected by these parasitic plants consisted almost entirely of trees in poor condition. The foliage was thin and it was probably this circumstance which enabled these parasites to become established, for in a tree possessing a healthy and vigorous leaf canopy the light below the crown would probably be sufficiently reduced to prevent the development of these troublesome plants.

All branches bearing such growths should be cut out, and efforts should be made by manuring to stimulate a more vigorous development of the trees, which should be rested until a better leaf canopy has been developed.

1191 – **Experiments on the Food Requirements and Growth of Couch *(Agropyron repens).*** BURMESTER, HERMANN (Breslau), in *Fühlings Landwirtschaftliche Zeitung*, Year 63, Part 16, pp.547-556, 1 fig. Stuttgart, August 15, 1914.

The writer has made a number of experiments with couch-grass (*Agropyron repens*), in completion of those published by Kraus as No. 220 of the *Arbeiten der D. L. G.* (1).

In pot experiments with a light loam soil it was found that pieces of rhizome placed at a depth of 30 cm. (12 in.) did not succeed in reaching the surface, while at 15 cm. (6 in.) the growth made in more than three months was not much less than with pieces at a depth of only 4 cm. (1 ½ in.).

Manurial experiments showed that couch can grow well in very poor soils; when given abundant supplies of nutritive substances it makes a somewhat increased growth, but the increase is by no means proportional to the absorption of these substances, the result being that the plant becomes abnormally rich in the particular nutrients supplied.

In a series of pot experiments in which oats were sown with and without rhizomes of couch, it was found that the yield of grain of the oats was

(1) Probably *Loranthus* spp., which are common parasites on *Hevea*, *Citrus*, and other fruit trees in Malaya. (*Ed.*)

(1) See No. 1472, *B.* Oct. 1912. (*Ed.*).

always distinctly greater when couch was present, while the yield of straw was only slightly reduced ; comparison with similar series in which couch was grown alone showed that the oats had greatly hindered the growth of the couch, reducing it to from 5 to 15 per cent. of the normal.

INSECT PESTS.

GENERALITIES

1192 – **New Coccidae in Japan.** — KUWANA, S. I, in *Journal of Entomology and Zoology*, Vol. VI, No. 1, pp. 1-8, plates I-III. Claremont, Cal., 1914.

A systematic description of the following eight new species of *Coccidae* recently recorded :

1) *Xylococcus napiformis*, on *Quercus serrata*, at Nishigahara, Tokio, and other localities in Japan.

2) *Phenacoccus azaleae*, on the branches and underside of the leaves of *Azalea* ; closely allied to *P. pergandei* Ckll.

3) *Eriococcus festucae*, on *Festuca parvigluma*, at Nishigahara, Tokio (1910) ; closely allied to *E. insignis* Newst. and *E. greeni* Newst.

4) *Pulvinaria citricola*, on *Citrus*, at Okayama, Shizuoka, and on *Diospyros Kaki*, *Hibiscus syriacus*, *Citrus* and other plants at Tokio; closely allied to *P. cellulosa* Green; has one generation per year and is very injurious to *Citrus* at Shizuoka and Okayama.

5) *P. photiniae*, on *Photinia illosa* and *Celtis sinensis*, at Nishigahara, Tokio (1912).

6) *P. okitsuensis*, on oranges, at Okitsu, Shizuoka-ken (1912) ; allied to *P. thespesiae* Green.

7) *P. idesiae* on *Idesia polycarpa* and *Phellodendron amurense*, at Nishigahara, Tokio (1911) ; near *P. horii* Kuw.

8) *Lecanium* (*Eulecanium*) *pseudomagnoliarum*, on *Citrus*, at Tokio and Shizuoka (1911) ; allied to *Lecanium* (*Eulecanium*) *magnoliarum* Ckll. recorded as occurring on *Berberis nepalensis* at Tokio and on the vine at Shizuoka-ken (1912) ; this is the first record of this species in Japan.

MEANS OF PREVENTION AND CONTROL

1193. — **New Species of Hymenopterous Parasites on *Heliothis armigera* and *Caradrina exigua* in Russian Turkestan.** — KOKUJEV, NIKIA, in *Revue russe d'Entomologie*, 1913, Vol. XIII, No. 3-4, pp. 513-514. Petrograd, 1914.

A systematic description of the following new Hymenoptera: *Habrobracon simonovi*, reared from a larva of *Heliothis armigera* Hb. (= *H. obsolela* F.) (1); *Chelonus caradrinae* and *Microplites rufiventris*, obtained from a larva of *Caradrina exigua* Hb. (= *Laphygma flavimaculata* Harr.).

(1) See also No. 2584, *B.* Aug.-Sept.-Oct. 1911; Nos. 125 and 194, *B.* Feb. 1913; No. 203, *B.* March 1913; No. 627, *B.* June 1913; No. 1117, *B.* Sept. 1913. (*Ed.*).

1194 – ***Dichomeris ianthes, Catopsilia crocale* and *Catachrysops pandava*, injurious to Lucerne, Cassias and Cycas in Ceylon.** — RUTHERFORD, A., in *The Tropical Agriculturist*, Vol. XLIII, No. 3, pp. 222-224. Colombo, 1914.

In December 1913, the lucerne at the Experiment Station, Peradeniya, was badly attacked by the caterpillar of the Tineid moth, *Dichomeris ianthes* Meyr., which folds the leaflets from below upwards and eats them in patches. A few of the caterpillars had been parasitised by a small Braconid.

In April 1914, several of the Cassias in the Botanic Gardens were defoliated by the caterpillars of the butterfly *Catopsilia crocale* Cramer. The caterpillars have the habit during the heat of the day of climbing restlessly up and down the trunk and congregating between the limbs at the base of the tree. Advantage was taken of this to feed them with branches of Cassia sprayed with arsenate of lead. These cut branches, however, soon wilted in the strong sunlight. A few Chalcids were noticed about the pupae and several of the caterpillars contained Dipterous puparia. A small number were also attacked by a disease which prevented them from pupating. The surrounding bnshes and trees were covered with pupae. On the underside of one leaf of *Bryophyllum* sp. fifteen were suspended and on another fourteen. Hundreds were found on the neighbouring *Palmyras*, chiefly on the under-surface of the uncut leaf-bases.

Among the pupae crows and king-crows did good work, though the crows did some damage by breaking off leaves and twigs from the more tender plants. The king-crow was also observed feeding greedily on the caterpillars. A branch of parasitic *Loranthus* growing on one of the Cassias was untouched.

In March 1913, the larvae of *Catachrysops pandava* Horsf. attacked the fronds of *Cycas revoluta* in the Botanic Gardens and stripped them almost to the midrib. There were holes in the midrib at intervals, and the inside was eaten out and the cavity full of a blackish or brownish evil smelling frass.

Larvae and pupae were present, often several in the interior of each midrib. In January 1914, these same caterpillars were feeding on the underside of the fronds, eating through to the upper epidermis. They were attended by ants, *Camponotus* sp.

In May of the same year, the young fronds of *Cycas Rumphii* were attacked; they elongated but were reduced to the midrib, which was dead, withered and bent and hung limp at the apex, giving the tree a very unsightly appearance. In this case also holes had been eaten into the midrib, but there was no extensive mining in the interior, probably because there was sufficient food externally to enable them to complete their growth. The butterflies were actually observed ovipositing on the tender fronds. Many of the eggs were ruptured and a minute, brownish ant was observed actively nibbling at the eggs. An application of arsenate of lead when the larvae are young is recommended for this pest.

1195 – **Animal Pests of Camphor in Ceylon.** — RUTHERFORD, A., in *The Tropical Agriculturist*, Vol. XLII, No. 6, pp. 463-468. Colombo, 1914.

The writer describes the following insect pests of camphor (*Cinnamomum Camphora*) in Ceylon :

1) Thrips (probably *Cryptothrips floridensis* Watson, recently described as injurious to camphor in Florida), not previously recorded in Ceylon. It damages the buds, leaves and branches, causing them to blacken and die. Spraying with tobacco decoction is recommended.

2) Leaf-miner of camphor (*Acrocercops* sp.) ; the larva mines under the upper epidermis of the young leaves, causing a large blotch ; the gallery seems to start from any point, but in most cases the narrowest and presumably the earliest part of the gallery occurs towards the base of the leaf and often on the petiole. The larva is parasitised by a Chalcidid and a Braconid very effectively. Spraying the diseased leaves with tobacco decoction is recommended.

3) The large bagworm (*Clania variegata* Snell.) ; the case in which the grub lives is made of brownish-white silk surrounded by pieces of stout twigs lying in a horizontal direction. Probably the best way to deal with this pest is to collect and destroy the caterpillars.

4) Bagworm (probably *Amatissa consorta* Templ.); the case is composed of short pieces of twig arranged in a spiral.

5) Larvae of two species of Pyralid (?), one of which is injurious to the buds and the other to the young leaves.

The following insects are also mentioned :

1) *Xyleborus compactus* Eichh., occurring also on tea, coffee, and avocado pear ; 2) *X. arquatus* Wynne Sampson, which according to Green bores the living branches; 3) *Hylopertha* sp., recorded by Green on dead or diseased wood; 4) *Lepidiota pinguis*, recorded by Green as feeding on the roots ; 5) *Suana concolor*, *Papilio lankeswara*, *P. clytia*, *Attacus atlas*, whose caterpillars are recorded by Green as feeding on the leaves ; 6) twig girdler, a Lepidopterous larva which mines in the young twigs, often causing them to wilt and fall over ; it bears a marked resemblance to the one found feeding in the buds and referred to above, and it is possible they are one and the same species ; 7) *Coptosoma siamicum*, observed feeding on the young shoots; 8) *Aspidiotus* (probably *A. camelliae*) observed on the buds and twigs ; 9) *Tetranychus bioculatus*, recorded by Green as occurring in injurious numbers on the upper surface of the leaves ; 10) *Brevipalpus obovatus*, recorded by Green ; 11) mice, recorded by Green as digging up and devouring seed in the nursery.

1196 **Outbreak of *Malacosoma fragilis* in California.** — VAN DYKE, EDWIN C. (Dept. of Entomology, University of California, Berkeley, Cal.), in *The Monthly Bulletin of State Commission of Horticulture*, Vol. III, No. 9, pp. 351-354, figs. 90-92. Sacramento, Cal., September 1914.

The genus *Malacosoma* (*Lasiocampidae*) contains several species liable to be injurious to various trees, including apples, in California : they are *M. californica* Pack. (on live oaks and apple), *M. constricta* Stretch (on

black and white oaks), *M. pluvialis* Dyer (on alder and apple) and *M. fragilis* Stretch.

The larvae of the last-named, known as the Great Basin tent caterpillar, were found to be present in enormous numbers during the past summer on species of *Ceanothus* forming brush in the country about Mt. Shasta. They appeared early in June ; by the beginning of July, having defoliated the *Ceanothus* bushes, they migrated in vast hosts, attacking the leaves of any trees (except Conifers) they came across : a few reached some apple trees, where they showed themselves as destructive as the other species mentioned above. They also became a great nuisance on the railways, owing to their crushed bodies causing slipping ; eventually the engines were fitted with steam jets to blow them off the rails.

Many of the caterpillars were parasitized by various species of Tachinid flies, which, however, made little impression on the numbers ; others were parasitized by ichneumon flies, while two species of *Calosoma* and two wasps were preying on them.

1197 — ***Phloeotribus scarabaeoides* and *Hylesinus oleiperda*, Beetles injurious to Olives in the Arezzo District, Italy** (1). — DE ROSA, ANTONIO, in *Il Coltivatore*, Year 60, No. 28, pp. 301-305, figs. 47-49. Casale Monferrato, 1914.

Phloeotribus scarabaeoides Bern. (*P. oleae* F.) and *Hylesinus oleiperda* F. (fam. *Ipidae*,) bore galleries in olive branches, and are the cause of considerable damage in the country round Arezzo, especially on the hills facing east near Staggiano.

For the control of these insects the writer recommends: *a*) destruction of the insects during the winter by cutting and burning the diseased branches ; *b*) rational pruning of the trees; *c*) careful cultivation of the soil ; *d*) complete manuring for the trees.

1198. — ***Tetropium gabrieli* var. *crawshayi* on Larch in England.** — OSMASTON, B. B., in *Quarterly Journal of Forestry*, Vol. VIII, No. 4, pp. 277-279, figs. London, 1914.

Tetropium gabrieli var. *crawshayi* has recently been reported on larches in several widely separated localities in England, *viz.* Maer (North Staffordshire), Gerard's Cross (Berkshire) and Hayward's Heath (Sussex).

The insect deposits its eggs in the crevices of the bark of unhealthy trees. The larvae devour the phloem and cambium and even penetrate into the wood before pupating. The tree succumbs quickly and the external layers of the wood,especially the sapwood, show slight damage. Healthy trees do not appear to be attacked. This beetle finds conditions in England favourable to its development, since most larch plantations contain trees attacked by canker (*Dasyscypha calycina* Fuckl.) and by "chermes" (*Chermes laricis* Hartig), and it will not be surprising if it assumes considerable importance in the future.

(1) See also No. 3064, *B.* Aug.-Sept.-Oct. 1911 ; *B.* Oct. 1913, p. 1561 ; No. 1312, *B.* Nov. 1913. (*Ed.*).

Plantations should as far as possible be cleared of all unhealthy or diseased trees. As soon as a tree is attacked by the insect, as indicated by the wilting of the leaves in summer and confirmed by the presence of larvae under the bark, it should be cut down and made into timber or stripped of its bark and the chippings burnt. If the green woodpecker (*Gecinus viridis* L.) is present, the diseased trees may be recognised by the holes in the bark. Dead larches are sometimes found with holes from which the woodpeckers have extracted the grubs, so that only a small number survive to propagate the species.

The following rules are recommended for new plantations: *a*) they should be limited to districts where the larch is known to thrive; *b*) mixed plantations should be made, so as to maintain more natural conditions; *c*) the trees should not be too dense at the time of thinning out as poles.

INTERNATIONAL INSTITUTE OF AGRICULTURE
BUREAU OF AGRICULTURAL INTELLIGENCE AND PLANT DISEASES

MONTHLY BULLETIN
OF AGRICULTURAL INTELLIGENCE
AND PLANT DISEASES

INDEX 1914

* * * ROME: PRINTING OFFICE OF THE INSTITUTE, 1915 * * *

PREFACE

This index, though arranged alphabetically, retains the grouping of the subjects used in the *Monthly Bulletin*. The arrangement of the subjects in each group is in chronological order of publication, except in the case of those relating to Agricultural Development, where the alphabetical arrangement was considered more useful.

Except in the case of the original articles, which are numbered according to their pages, the numbers of each subject refer to the paragraphs in the *Monthly Bulletin*.

The index consists of three parts : one, of the original articles, one concerned only with Agricultural Intelligence and the last with Plant Diseases.

This volume of contents has been prepared by the redacteur Dr. Giulio Provenzal.

THE INTERNATIONAL INSTITUTE OF AGRICULTURE

The International Institute of Agriculture was established under the International Treaty of June 7th, 1905, which was ratified by 40 Governments. Thirteen other Governments have since adhered to the Institute.

It is a Government Institution in which each Country is represented by delegates. The Institute is composed of a General Assembly and a Permanent Committee.

The Institute, confining its operations within an international sphere, shall :

a) Collect, study, and publish as promptly as possible, statistical, technical, or economic information concerning farming, vegetable and animal products, the commerce in agricultural products, and the prices prevailing in the various markets.

b) Communicate to parties interested, also as promptly as possible, the above information.

c) Indicate the wages paid for farm work.

d) Make known new diseases of plants which may appear in any part of the world, showing the territories infected, the progress of the diseases, and, if possible, the remedies which are effective.

e) Study questions concerning agricultural co-operation, insurance, and credit in all their aspects; collect and publish information which might be useful in the various countries for the organisation of works connected with agricultural co-operation, insurance and credit.

f) Submit to the approval of the Governments, if there is occasion for it, measures for the protection of the common interests of farmers and for the improvement of their condition, after having utilized all the necessary sources of information, such as the wishes expressed by international or other agricultural congresses, or by congresses of sciences applied to agriculture or agricultural societies, academies, learned bodies, etc.

PERMANENT COMMITTEE
OF THE INTERNATIONAL INSTITUTE OF AGRICULTURE

President: Marquis RAFFAELE CAPPELLI, *Delegate of Italy.*
Vice-President: M. LOUIS-DOP, *Delegate of France.*
List of the Delegates of the Permanent Committee:

1	GERMANY	I	Dr. T. MUELLER, Privy Councillor.
2	ARGENTINE REPUBLIC.	I	Dr. OCTAVIO PIÑEIRO SORONDO.
3	AUSTRIA	I	Chev. V. DE POZZI, Government Councillor.
4	HUNGARY	I	E. DE MIKLÓS, Secr. of State, Member of House of Magnates.
5	BELGIUM	IV	O. BOLLE.
6	BRAZIL	I	ANTONINO FIALHO, Ex-Deputy.
7	BULGARIA	III	D. RIZOFF, Minister Plenipotentiary.
8	CHILE	I	S. ALDUNATE, Minister Plenipotentiary.
9	CHINA	I	M. OUETZEKING, Secretary to the Legation of China.
10	COLUMBIA	..	. . . . .
11	COSTA-RICA	V	. . . . .
12	CUBA	V	M. A. MARTIN RIVERO, Minister Plenipotentiary.
13	DENMARK	IV	A. DE OLDENBURG, Chargé d'affaires.
14	OTTOMAN EMPIRE	I	Dr. MEHMED DJEMIL BEY.
15	EGYPT	II	B. CHIMIRRI, Senator, Delegate of Eritrea.
16	ECUADOR	V	. . . . .
17	SPAIN	I	ENRIQUE RODRIGUEZ DE CELIS, Agricultural Engineer.
18	UNITED STATES	I	DAVID LUBIN.
19	ABYSSINIA	V	Prof. G. CUBONI, Director, Station of Plant Pathology, Rome.
20	FRANCE	I	LOUIS-DOP, Vice-president of the Institute.
21	ALGERIA	V	LOUIS-DOP.
22	MOROCCO	V	LOUIS-DOP.
23	TUNIS	V	LOUIS-DOP.
24	GT. BRITAIN & IRELAND	I	Sir JAMES WILSON, K. C. S. I.
25	AUSTRALIA	IV	Sir JAMES WILSON, K. C. S. I.
26	CANADA	II	Sir JAMES WILSON, K. C. S. I.
27	BRITISH INDIA	II	Sir EDWARD BUCK, K. C. S. I.
28	NEW ZEALAND	IV	Sir JAMES WILSON, K. C. S. I.
29	MAURITIUS	V	Sir JAMES WILSON, K. C. S. I.
30	UNION OF SOUTH AFRICA	IV	Sir JAMES WILSON, K. C. S. I.
31	GREECE	IV	M. COROMILAS, Minister Plenipotentiary.
32	GUATEMALA	V	G. MONTEFIORE, Consul General for Guatemala.
33	ITALY	I	Marquis R. CAPPELLI, Deputy, President of the Institute.
34	ERITREA & IT. SOMAL.	IV	B. CHIMIRRI, Senator.
35	TRIPOLI AND CIRENAICA	IV	B. CHIMIRRI.
36	JAPAN	I	Baron OTORI, Attaché to the Embassy.
37	LUXEMBURG	V	O. BOLLE, Delegate of Belgium.
38	MEXICO	III	G. A. ESTEVA, Minister Plenipotentiary.
39	MONTENEGRO	V	G. VOLPI, Minister Plenipotentiary.
40	NICARAGUA	V	V. E. BIANCHI, Consul General.
41	NORWAY	IV	Dr. A. FJELSTAD, Counsellor to the Agricultural Department.
42	PARAGUAY	V	Prof. ORAZIO COMES, Director Portici Agr. College.
43	NETHERLANDS	IV	Baron W. B. R. de WELDEREN RENGERS, Minister Plenip.
44	DUTCH EAST INDIES	IV	Baron W. B. R. de WELDEREN RENGERS.
45	PERU	V	LOUIS-DOP, Delegate of France.
46	PERSIA	IV	A. DEL GALLO, Marquis of ROCCAGIOVINE.
47	PORTUGAL	IV	EUSEBIO LEAO, Minister Plenipotentiary.
48	ROUMANIA	I	DEMETRIUS C. PENNESCO, Counsellor to the Legation.
49	RUSSIA	I	His Excell. G. ZABIELLO, Consul General for Russia.
50	SALVADOR	V	A. BIANCHI CAGLIESI, Vice-Consul.
51	SAN MARINO	V	His Excell. L. LUZZATTI, Minister of State.
52	SERVIA	III	C. SCOTTI, Consul General for Servia.
53	SWEDEN	IV	Baron C. N. D. DE BILDT, Minister Plenipotentiary.
54	SWITZERLAND	IV	M. DE PLANTA, Minister Plenipotentiary.
55	URUGUAY	V	Dr. E. ROVIRA, Vice-Consul.

Prof. GIOVANNI LORENZONI, *General Secretary.*

EDITORIAL STAFF OF THE BUREAU OF AGRICULTURAL INTELLIGENCE AND PLANT DISEASES

Chief of Bureau: Dr. A. HERMES.
Chief of Section - Dr. JULES M. SAULNIER.
Rédacteurs: Prof. A. BRUTTINI, Chief Rédacteur. - C. J. ALEXANDER, B. Sc. (Agric.) - N. W. BARRITT, B. A Dipl. Agr. Camb. - J. BENNINGER, Ingénieur-Agronome. - Dr. THÉODORE BIÉLER. - Dr. GUIDO BORGHESANI. - Dr. VITALE DE TIVOLI. - Dr. LEO GABRICI. - JOSEPH GLAUDEN, Ingénieur-Agronome. - J. GUERBER Ingénieur-Agronome. - P. III. — PLANT DISEASES

A) INDEX OF SUBJECTS.

ABIES GRANDIS : Wood-destroying Fungi, 962

Abies pectinata : Injurious Insects observed in Ireland, 86.

Abu el mum, 963.

Acacia : Uganda Coccidae, 293. *A. arabica* host of *Pseudococcus filamentosus*, 697.

Acœna ovina and *A. Sanguisorbae* or " sheep burrs ", 88.

Acanthosoma haemorroidale, 86.

Acer: Wood-destroying Fungi which Grow on Both Coniferous and Deciduous Trees in the United States of America and in Europe, 962. *A. saccharinum*, 398.

Acheta morio, an Orthopterous Insect injurious to Sisal in German East Africa, 194.

Acontia graellsii on Cotton, 690.

Acrida turrita on Tobacco, 690.

Acridium lineatum on Tobacco, 690.

Acrocercops sp., 1195.

Acrotylus patruelis on Tobacco, 690.

Adoretus hirtellus, 391 ; *A. vestitus*, 869.

Aecidium : A. Grossulariae, 76. *A. Epimedii*, 481. *A. Mori*, 578. *A. parile* on *Loranthus*, 787.

Africa : Parasites of the Fruit Fly, 190. *Acheta morio* injurious to Sisal in German East Africa, 194. On the Occurrence of *Aphis maidis* in West Africa, 487. *Pseudococcus filamentosus* on Tropical Trees, 697. Leaf Spot Disease of Sisal in German East Africa, 785.

Agave rigida var. *sisalana*, *see* Sisal.

Agrilus biguttatus, 76.

Agriotes sp., in Sweden, *p. 1546*.

Agromyza : A. pusilla on Alfalfa, etc., in U. S. A., 87. *A. pruinosa* on *Betula nigra*, in U. S. A., parasitised by *Sympha agromyzae*, 591.

Agropyron : The Occurrence of Rust Spores, 73. Notes on the Biology of Leather Jackets, *Tipula oleracea*, 964. Experiments on the Food Requirements and Growth of Couch, *Agropyron repens*, 1191.

Agrotis : A. corticea on *Trifolium pratense*, 292. *A. segetum*, 86.

Aira caespitosa, *p. 303*.

Alang-Alang, 250.

Albizzia Lebbek, host of *Pseudococcus filamentosus*, 697.

Aleyrodes vaporiarum on *Azalea indica*, 297.

The figures in italics refer to the number of the page, the others to the number of the abstract.

Alfalfa: The Serpentine Leaf-miner, *Agromyza pusilla*, 87.

Algeria: The Rotting of Bunches of Grapes produced by *Phoma* sp., 80. The Importation of Cotton Seed, 179. Decree of the President of the French Republic, April 18, 1914, relating to the Importation into Algeria of Plants other than Vines and Resin-yielding Trees, 681.

Allorhina nitida, 864.

Allotria, parasitic on *Aphis evonymi*, 800.

Alloxysta, parasitic on *Aphis evonymi*, 800.

Almus: Wood-destroying Fungi in the United States, 962.

Althaea rosea: The Hereditary Transmission of Rust in Hollyhock, 290.

Amaranthus retroflexus: Impurities in Seeds in Victoria, Australia, 724.

Amaryllis, 974.

Amatina consorta, 1195.

Anagrus ovijentatus, a Hymenopterous Parasite of the Eggs of *Lygus pratensis*, 692.

Andropogon: Uganda Coccidae, 293. *A. scoparius*, host of *Blissus leucopterus*, 588. *A. Sorghum* in India, 481.

Anoda triangularis in the Argentine Republic, 623.

Anomopterus fasciipennis, New Genus of Hymenoptera Parasitic on *Ectoedemia*, 802.

Anona muricata in Uganda, 293.

Anthemis Cotula in Tasmania, 286.

Anthomyidae, 397.

Anthonomus grandis var. *thurberiae* (a Cotton-Boll Weevil) on *Thurberia thespesioides*, in Arizona, 193.

Anthurium magnificum, 797.

Antiperonospora, 793.

Apamea gemina, 292.

Aphelinus: New Species of *Aphelinus* Parasitic on Injurious Aphids in Russia, 801.

Aphidius parasitic on *Aphis evonymi*, 800.

Aphids in Belgium, 76.

Aphis: *A. bituberculata* on Sugar Cane, 866. *A. evonymi*, 296, 800 and 965. *A. maidis*, 487. *A. pomi*, 86. *A. scaliae*, 1181. *A. sorbi*, 86. *A. sorghi*, 487.

Apogonia comosa, 1084.

Apple: *Cicinnobolus* sp. Parasitic on Apple Mildew, *Oidium farinosum*, 75. Injurious Insects and Other Animals observed in Ireland during the Year 1912, 86. The Control of the Codling Moth in the Sacramento Valley, California, 399. Small Ermine Moths (*Hyponomeuta malinella* and *H. padella*) in the United States, 400. The destruction of Woolly Aphis by Fumigation with Hydrocyanic Acid, 587. Parasitic Fungi from Northern Japan, 789. *Recurvaria nanella* in the United States, 804. The Status of Investigational Work on Apple Blight, 952. A contribution to our Knowledge of Apple Scab, 959. *Malacosoma* sp. injurious in California, 1196.

Apricots: Fungi injurious in Servia, 1184.

Apterite, *p. 1412*.

Arctium Lappa and *A. minus* in Tasmania, 286.

Argentine Republic: the Cultivation of Sugar Cane, *p. 424*. *Euxesta chavannei* and its Relation to the Sugar Cane Disease caused by *Bacillus Sacchari* in the Province of Tucuman, 1079.

Armillaria mellea, Wood-destroying Fungi in the United States, 962.

Arsenic, chemical means for the control of Parasites of Farm Crops, 88, 180, 392.

Artocarpus incisa, 787.

Artona waleri parasitic on Rice in Conchinchina, 971.

Asbecesta cyanipennis, 690.
Ascochyta Gerberae n. sp., parasitic on *Gerbera Jamesoni*, 186.
Ascomycetes, 789.
Asphodelus fistulosus in Tasmania, 286.
Aspidiotus: *A.* spp. in British Guiana, 797. *A. bromeliae* and *A. ficus* in the Seychelles, 798. *A. bromeliae*, 967. *A. aonidum* and *A. aurantii* in Egypt, 970. *A.* sp. in Ceylon, 1195.
Aspidistra, 76.
Asterolecanium sp., 797.
Atelocera serrata in Belgian Congo, 1080.
Attacus atlas, 1195.
Aulacaspis rosae on *Mangifera indica* and on *Laurus Cinnamomum*, 797.
Australia: *Haltica pagana* in Victoria, 88. *Godara comalis*, a Cabbage Moth Attacking Turnips in Queensland, 868. Potato Diseases in Victoria, Australia, 1070. The "Leaf Case Moth" (*Hyalarcta hübneri*) injurious to Fruit Trees in Victoria, 1083.
Austria: Contribution to the Mycological Flora of the Tyrol and Istria, 788. Experiments in Growing Medicinal Plants at Korneuburg, 827. Results of Investigations made in Austria in 1913 into the Leaf-curl of Potatoes, 858.
Avocado: The Scale Insects of British Guiana, 797. *Xyleborus* sp. on Avocado, 1195.
Azalea indica, 297.
Azia trinitatis, 797.

BACILLUS AMYLOVORUS: Status of Investigational Work on Pear and Apple Blight, 952.
Bacillus Cortynae, *B. Pyrameis I* and *B. Pyrameis II*, parasitic on the larvae of *Gortyna ochracea* and *Pyrameis cardui*, 84.
Bacterium aptatum n. sp. Injurious to the Leaves of Sugar Beets and Nasturtium (*Tropaeolum*) in the United States, 483. *B. castaniculum* n. sp., 484.
Baden: Phytopathological Observations in the Grand Duchy, 1913, 577.
Bagworm, 1195.
Bamboos: *Bambusa* sp. 697. *Coniosporium Shiraianum* in Tyrol, 788. *Asterolecanium bambusae*, common on bamboos, in British Guiana, 797.
Bananas: *Aspidiotus destructor*, 797. Parasitic Fungi collected in the Straits Settlements and Fiji Islands, 1066.
Baris sp., 86.
Barley: Occurrence of Rust Spores in the Interior of Barley Grains, 73. Contribution to the Biology of Naked Smut of Barley, *Ustilago nuda*, 74. *Ustilago Hordei*, 76. In Egypt, 387. *Pleospora trichostoma*, 388. *Bibio hortulanus*, 691.
Bathurst Burr, *Xanthium spinosum*, 286.
Bean: Insects injurious in the Nyasaland Protectorate, 690.
Beets: The Life-History of *Aphis evonymi*, Injurious to Sugar Beets, 296. The Cultivation of Sugar Beets in the Island of S. Miguel in the Azores, 434. *Bacterium aptatum* n. sp., injurious to the leaves of Sugar Beets in the United States, 483. Phytopathological Observations in the Grand Duchy of Baden, 577. Hymenoptera Parasitic on *Aphis evonymi*, the Beet Aphis, 800. Observations on the Life-History of the Beet Aphis (*Aphis evonymi*), 965.
Belgian Congo: Fungus Diseases of Hevea, 1071. Diseases of Cacao, 1072. *Sahlbergella singularis* on the Cacao, 1080.
Belgium: Diseases and Pests of Plants in Belgium in 1911 and 1912, 76. *Aleyrodes vaporiarum*, a Para-

site of *Azalea indica* in Belgium, 297.
Berberis nepalensis, 1192.
Betula : Wood-destroying Fungi in the United States, 962. *B. nigra*, injuried by *Agromyza pruinosa*, 591.
Bibio hortulanus : Contribution to the Biology of *Bibio hortulanus*, and its Control, 691.
Bidens leucanthus and *B. scabiosoides* in the Argentine Republic, 623.
Big Bluestem, *Andropogon furcatus*, host of *Blissus leucopterus*, 588.
Black Rot, *Guignardia Bidwellii*, in Spain, 958.
Blastodacna vinolentella, 86.
Blattrollkrankheit of Potato, 577, 580, 683, 858.
Blighia sapida, 797.
Blissus leucopterus, 588.
Blister Blight of Tea in India, 244.
Blossom-End Rot, 1182.
Borassus flabellifer, 962.
Bordeaux Mixture, 577, 1069.
Botrytis : *B. anthophila* n. sp. on *Trifolium pratense* in Russia, 955. *B. necans* on *Brachastona catoxantha*, 1066.
Brachastona catoxantha, 1066.
Brachycolus noxius, 294.
Brachysporium Phragmitis, 481.
Brachytrypes membranaceus on Cotton, 690.
Bramble-leaf : The Presence of Endocellular Fibre in the Tissues of the Vine and of other Dicotyledons, 576. Observations on Bramble-leaf of Vines in Hungary, 684.
Brazil : *Stilbum flavidum*, 78. *Remigia repanda* (Lepidoptera), injurious to Crops in São Paulo, 803.
Brevipalpus obovatus, 1195.
Bromus mollis, 73.
Broussonetia Kazinoki injured by *Aecidium*, 978. *B. papyrifera*, 790.
Bryobia praetiosa in Sweden, *p. 1546*.
Bud rot, *Pythium palmivorum*, 961.
Buckwheat : *Fagopyrum tartaricum* as a Weed among Buckwheat in Volhynia (Russia), 82.
Bud-rot of Coconut Palms (*Pythium palmivorum*) in Malabar, 961.
Bunch grass, *Andropogon scoparius*, 588.
Burdock, 286, 398.
Burgundy Mixture, 954.
Busseola fusca on Maize, 690.

Cabbage : Diptera injurious to Cabbages, 397. Phytopathological Observations in the Grand Duchy of Baden, 1913, 577. *Godara comalis*, a Cabbage Moth, Attacking Turnips in Queensland, 868.
Cabbage Webworm, *Hellula undalis*, 868.
Cacao : Diseases and Pests, Legislation in Ceylon, 285. A List of Uganda Coccidae, 293. Entomological Pests of Southern Nigeria, 391. The Scale Insects of British Guiana, 797. Fungus Diseases of Cacao in the Mayumbe, Belgian Congo, 1071, 1072. *Sahlbergella singularis* and other Pests on Cacao in the Mayumbe, Belgian Congo, 1080.
Californian thistle, *Cnicus arvensis*, 286.
Camphor : *Cinnamomum Camphora* in Ceylan, 1195.
Canavalia ensiformis, 787.
Candelillo, 1185.
Canker of Potato, 956, *p. 1548*.
Cape Weed, *Cryptostemma calendulaceum*, 286.
Capsicum, 796.
Caradrina, 1193. *C. reclusa*, parasitic on Tobacco in Hawaii, 1081.
Carbolineum, Chemical Means of Control, 180.
Carduus pycnocephalus, a Proclaimed Weed in Tasmania, 286, 287.
Carpinus, *p. 304*.
Carpocapsa pomonella 86, 399 and *p. 1545*.
Carragaheen : The Destruction of In-

sects Injurious to Fruit Trees and Vines by means of "Carragaheen" or "Pearl Moss" Jelly (*Chondrus crispus*), 488.

Carrot: *Erica rosae*, 86. The Effect on Carrots of being Grown in Soil infected by Finger-and-Toe, 184. Phytopathological Observations in the Grand Duchy of Baden, 1913, 577.

Catachrysops pandava, parasitic on Cycas in Ceylon, 1194.

Catantops opulentus, parasitic on Tobacco, 690.

Catopsilia crocale, on Cycas in Ceylon, 1194.

Cattleya superba, 797.

Cecidomyia of Trefoil, 1181.

Celery Leaf-spot Disease (*Septoria Petroselini* var. *Apii*) in England, 957.

Centistidea ectoedemiae n. sp., parasitic on *Ectoedemia castaneae*, 802.

Cephaleuros virescens on Cacao, 1072.

Ceratitis: *C. capitata*, 190. *C. punctata* on Cacao, 391.

Cercospora: *C. Artocarpi* on *Artocarpus incisa*, *C. Canavaliae* on *Canavalia ensiformis*, *C. pachyderma* on *Dioscorea alata*, *C. Puerariae* on *Pueraria phaseoloides*, 787. *C. Myrti* on *Myrtus*, 788. *C. Musae* on bananas, 1066.

Cerdidymsulfat, 577, 793.

Cereals: Inquiry and Observations on Straw Blight of Wheat in the Department of Aisne, France, 77. *Tapinostola musculosa*, a Noctuid Moth injurious to Cereals in Hungary, 192. Recent Work of the Royal Entomological Station of Hungary, *p. 316*. The Fungi causing Straw Blight of Wheat in France, 291. *Diaretus* (*Aphidius*) *obsoletus* n. sp., a Braconid Parasitic upon the Aphides *Brachycolus noxius* and *Toxoptera graminum*, injurious to Cereals in Russia, 294. Insects in Flour Mills and Granaries, 394. Phytopathological Observations in the Grand Duchy of Baden, 577. Wintering of Cereal Rusts in the Uredo Stage, 579. The Chinch Bug (*Blissus leucopterus*) injurious to Cereals in Kansas, 588. On the Presence of Sori and Mycelium of Rusts in the Caryopses of Cereals, 685. The 1914 Outbreak of Rust on Winter Grain in Bavaria, 795. Research on the Rust of Cereals in Sweden, *p. 1548*. *See also* Wheat, Oats, etc.

Ceroplastes: Uganda Coccidae, 293. Coccidae in British Guiana, 797.

Ceroputo barberi on *Schinus terebenthifolius*, 797.

Ceuthospora phacidioides var. *Oleae*, 788.

Ceylon: Diseases and Pests, Legislation, 285. *Dichomeris ianthes*, *Catopsilia crocale*, and *Catachrysops pandava*, injurious to Lucerne, Cassias and Cycads, 1194. Animal Pests of Camphor, 1195.

Chaetogedia monticola, 1081.

Chamaerops excelsa, 388.

Chacarita, *p. 287*.

Charlock: in Tasmania 286. Experiments on the Destruction of Charlock by Mechanical and Chemical Means, 577, 583.

Cheimatobia: *C. brumata*, 86 and *p. 1546*.

Chelonus: *C. blackburnii* on *Phtormaea operculella*, 1081. *C. caradrinae* parasitic on *Caradrina exigua*, 1193.

Chenopodium opulifolium, in the Argentine Republic, 623.

Cherry: *Myzus cerasi*, 86. Gummosis of *Prunus avium*, 786.

Chermes piceae, 86.

Chestnut: *Castanea americana*, susceptible to the Destructive Bark Disease *Endothia parasitica*, 348. A New Chestnut Disease, 484. The Anatomical and Physiological Conditions of Chestnut Branches attacked by the Ink Disease, 689. *Anomopterus*

fasciipennis, 802. *Polyporus frondosus*, 962. *Endothia parasitica* in the United States, 1074.
Chilomenes on Cotton, 391.
Chimney: The Importance to Vegetation of the Dissipator (Lattice-work) Chimney, 386.
China, Fungi, 578.
Chinch Bug, 588.
Chionaspis: parasitic on *Citrus* in British Guiana, 797.
Chloridea: *C. obsoleta* on Cotton, 391. on Maize and on Tobacco, 690.
Chlorita flavescens, 244.
Chondrus crispus, 488.
Chrotogonus on Tobacco, 690.
Chrysomphalus in British Guiana, 797.
Chrysopa vulgaris, 292.
Chrysophlyctis endobiotica in Belgium, 76. In Sweden, 182. On Potato, 956.
Cicas revoluta, 581.
Cichorium Intybus, 724.
Cicindela sexpunctata on *Leptocorisa varicornis*, 971.
Cicinnobulus sp., 75. *C. Humuli* parasite on *Erysiphe Polygoni* and *Sphaerotheca Humuli*, 1184.
Citrus Trees: Diseases and Pests, Legislation in Ceylon, 285. Fungus Diseases of Wheat, Barley and Citrus Fruits in Egypt, 387. *Pseudococcus filamentosus*, a Scale Injurious to Tropical Trees, 697. The Scale Insects of British Guiana, 797. *Coccus citricola*, a New Scale infesting Citrus Trees in California, 805. Relation of Bacterial Transformations of Soil Nitrogen to Nutrition of *Citrus* suffering from Chlorosis, 811. Fumigation of Citrus Trees in Egypt, 970. Insect Pests of Citrus in Ceylon, 1084. New Coccidae in Japan, 1192. *See also* Lemon, Orange, etc.
Cladochytrium Mauryi n. sp., in France, 862.
Cladosporium: *C. episclerotiale* n. sp. on *Sclerotinia cinerea*, 788. *C. herbarum*, 688.
Clasterosporium degenerans on *Prunus Mume* in Japan, 789.
Clover: The Serpentine Leaf-miner, *Agromyza pusilla*, 87. A Disease of Red Clover, 181. A New *Botrytis* on Flowers of Red Clover in Russia, 955. Further Notes on a Disease of Red Clover in Tuscany, 1181.
Cnaphalocrocis medicinalis on Rice in Cochinchina, 971.
Cnicus arvensis in Tasmania, 286.
Coccidae: in the Uganda, 293. In British Guiana, 797.
Coccinella septempunctata, 586.
Coccus: *C.* spp. in British Guiana, 797. *C. citricola* n. sp. on Citrus Fruits, 805.
Coconut: In Ceylon, 285. Coccidae in British Guiana, 798. In Cochinchina, 855. *Pythium palmivorum*, 961.
Coffee: *Stilbum flavidum*, Parasitic on Coffee, and its Systematic Position, 78. *Hemileia* in Ceylon, 285. Uganda Coccidae, 293. Entomological Pests and Problems of Southern Nigeria, 391. Insects injurious to Crops in the Nyasaland Protectorate, 690. *Lachnodius greeni*, a New Scale injurious to Coffee in Madagascar, 695. Thielaviopsis ethaceticus, 285.

Thripoctenus brui n. sp. parasitic on *Frankliniella robusta* in France, 585.

Thrips, *Cryptothrips floridensis* Watson, on Camphor, *Cinnamomum Camphora*, 1195. On Olive, 693.

Thuya: Wood-destroying Fungi in the United States, 693.

Tilletia: *T. Caries*, 577. *T. horrida* on Rice in Cochinchina, 971.

Tipula oleracea: Notes on the Biology of Leather Jackets (*Tipula oleracea*) in the Pastures of the Avesnois (Nord, France), 964.

Tmetocera ocellana, 804.

Tobacco: On "Kroepoek" of Tobacco in Kamerun, 288. *Orobanche ramosa*, 577. Insects injurious in Nyasaland Protectorate, 690. Experiments in Harvesting Tobacco Leaves, 742. Two New Species of Fungi in Tobacco Seedbeds: *Gloeopeziza turricula* and *Hyalopus geophilus*, 861. Insects injurious to, Tobacco in Hawaii, 1081.

Tomaspis: *T. flavilatera* n. sp. in

British Guiana, 589. Froghopper, 188.

Tomatoes: Black Spots on Tomatoes caused by *Cladosporium herbarum*, 688. The Presence of the Hibernating Mycelium of *Macrosporium Solani* in Tomato Seed, 1067. Blossom-End Rot of Tomatoes, 1182.

Tortrix: Peach Tip Moth, injurious to Peaches and other Fruit Trees in New South Wales, 1082. *T. pilleriana*, 577, *T. ribeana*, 86.

Toxoptera: on the Citrus in Ceylon, 1084. *T. graminum*, 294.

Trametes: in the United States, 962. *T. setosus* n. sp. and *Fomes putearius*, 1075.

Tremella Koreaensis, 481.

Trichogramma pretiosa, 1081.

Trifolium pratense, *see* Clover.

Trioxys, 800.

Triplasis purpurea, 588.

Tropaeolum: *Bacterium aptatum* n. sp. 483. *T. majus*: *Uromyces Tropaeoli*, 1184.

Tsuga heterophylla: Wood-destroying Fungi, 962.

Tulipa: *Merodon equestris*, 924.

Turkestan: Destruction of Locusts, 393. New Species of Hymenopterous Parasites on *Heliothis armigera* and *Caradrina exigua* in Russian Turkestan, 1193.

Turnips: *Ceuthorrhynchus pleurostigma*, 86. In the Grand Duchy of Baden, 577. *Godara comalis*, 868.

Twig-girdler on Camphor, 1195.

Tylenchus devastratrix, 86, 867.

Typhlocyba comes, 398. *T. rosae*, 76.

Typhula Betae, 434.

Uganda: Coccidae, 293. *Dirphya* (*Nitocris*), *princeps* on Coffee, 696. Coffee, 824.

United States: The Control of the Codling Moth in the Sacramento Valley, California, 399. *Bacterium aptatum* n. sp. Injurious to the Leaves of Sugar Beets and Nasturtium, *Tropaeolum*, 483. *Polyporus dryadeus*, Root Parasite of the Oak, 485. *Cylindrosporium Juglandis* injurious to the Leaves of Walnut in Alabama, 582. The Chinch Bug, *Blissus leucopterus*, injurious to Cereals in Kansas, 588. Wilt Disease of Sweet Potato, 687. The Control of Damping-off Disease in Plant Beds, 794. Two New Genera of Hymenoptera Parasitic on *Ectoedemia*, 802. Lesser Bud-Moth *Recurvaria nanella* on Apples in Michigan, 804. *Coccus citricola*, a New Scale infesting Citrus Trees in California, 805. *Micrococcus nigrofaciens* as Cause of an Infectious Disease of the Larvae of *Lachnosterna* sp., 864. A New Sugar Cane Aphid, *Aphis bituberculata* in Louisiana, 866. The Status of Investigational Work on Pear and Apple Blight, 952. A Contribution to our Knowledge of Apple Scab, 959. Rotting of Pomegranates in India: *Sterigmatocystis castanea*, 960. Wood-destroying Fungi which Grow on Both Coniferous and Deciduous Trees, 962. Field Studies on the *Endothia* Canker of Chestnut in New York State, 1074. Two New Wood-destroying Fungi: *Fomes putearius* and *Trametes setosus*, 1075. Outbreak of *Malacosoma fragilis* in California, 1196.

Urania-Grün, 577.

Uredo: Wintering of Cereal Rusts in the Uredo Stage, 579.

Urocystis occulta, 76, 389.

Uromyces Tropaeoli sp. nov. on the Living Leaves of *Tropaeolum majus*, 1184.

Uropyxis Fraxini on *Fraxinus longicuspis* in Japan, 789.

Uruguay: Decree Placing *Mytilaspis citricola* (= *Lepidosaphes beckii*) amongst Notifiable Insects, 574.

Ustilaginoidea virens on Rice in Cochinchina, 971.
Ustilago: U. Maydis and *U. nuda*, 74. *U. Rottboeliae*, 481.

VALLOTA: *Merodon equestris*, 974.
Vanessa cardui, 84.
Vanilla in Madagascar, 635.
Vaporite, *p. 1412*.
Venturia inaequalis, 959.
Vigna Catjang: Agromyza pusilla, 87.
Vine: Modification of the Laws on Phylloxera Control in Italy, 71. The Rotting of Bunches of Grapes produced by *Phoma* sp. in Algeria, 80. *Monolexis lavagnei* n. sp., Braconid, parasitic on *Sinoxylon sexdentatum* on Vine Shoots, 189. Vine Caterpillars in Hungary, *p. 318*. On the Pathological Significance of Endocellular Fibres in the Tissues of the Vine, 289. The Grape Leaf-Hopper (*Typhlocyba comes*) in New York State, 398. On the Pathological Significance of Endocellular Threads in the Tissues of the Vine, 480. The Destruction of Insects Injurious to Vines by Means of Carragaheen or Pearl Moss Jelly, 488. Recent Work of the Royal Hungarian Central Ampelological Institute of Budapest, 529. The Presence of Endocellular Fibre in the Tissues of the Vine and of other Dicotyledons, 576. Phytopathological Observations in the Grand Duchy of Baden, 577. Relation between the Larvae of Vine Moths and the Weeds of Vineyards, 584. *Conchylis ambiguella* and *Polychrosis botrana* in Italy, 590. In Hungary, 684. Control of the Second Generation of Vine Moths by means of Protecting Envelopes, 694. Comparative Spraying Experiments with Several Fungicides against Vine Mildew, 793. Experimental Demonstration of a Difference in Biological Race between the Phylloxera of the South of France and that of Lorraine, 799. The Conditions Determining the Outbreak of Vine Mildew in Hungary, 857. Black Rot of Grapes (*Guignardia Bidwellii*) in Spain, 958. The Emergence from the Soil of the First Larvae of *Phylloxera vastatrix* in Italy, 966. The Practical Efficiency of Food Traps in the Control of Vine Moths and the Presence of the Vine Pyralid in Piedmont, 1078. *Otiorrhyncus sulcatus* attacking Vines in the Ile d'Oléron, France, 1085. Fungi in Servia, 1185. *Hypochnus Burnati*, a New Fungus on the Vine in Switzerland, 1189. *Lecanium magnoliarum* in Japan, 1192.
Viper's bugloss, 286.
Voles: The Control of Voles in the Val di Chiana, Italy, 89. Recent Work of the Royal Entomological Station of Hungary, *p. 316*. A Law Placing at the Disposal of the Minister of Agriculture of France from the Budget of 1913 the Sum of 750 000 frs. for the Control of Voles, 385. Act allotting 500 000 Francs to the Minister of Agriculture of France for the Control of Voles, 682.

WALKERIANA sp. on the Citrus, 1084.
Water hyacinth, *Eichhornia crassipes*, 798.
Walnut: *Cylindrosporium Juglandis* in Alabama, 582. *Sterigmatocystis castanea* in the United States, 960.
Wart Disease of Potatoes: *Chrysophlyctis endobiotica* (*Synchytrium endobioticum*), 182.
Weeds: A Poisonous Buttercup (*Ranunculus sceleratus* L.) in New South Wales, 187. List of Proclaimed Noxious Weeds in Tasmania, 286. *Ranunculus sceleratus* and *R. Guilelmi-Jordani* in Egypt, 390. Phytopathological Observations in the

Grand Duchy of Baden, 1913, 577. Experiments on the Destruction of Charlock (*Sinapis arvensis*) by Mechanical and Chemical Means, 583. Relation between the Larvae of Vine Moths and the Weeds of Vineyards and other Plants, 584. Impurities in Seeds in Victoria, Australia, 724. *Papaver Rhoeas* and *P. hybridum* in Egypt, 963.

Wheat : The Occurrence of Rust Spores in the Interior of Wheat and Barley Grains, 73. *Puccinia glumarum*, 76. *Oscinis frit*, 86. In Egypt, 387. Phytopathological Observations in the Grand Duchy of Baden, 577. *Bibio hortulanus*, 691. *Puccinia Triticina*, 789. The 1914 Outbreak of Rust on Winter Grain in Bavaria, 795. The Contortion and Breaking of Wheat Straw, 1065. Contribution to the Mycological Flora of Servia, 1184.

White grubs, 864.

White Weed, *Lepidium Draba*, 286.

Wild onion, 286.

Winsonia in British Guiana, 798.

Wood-destroying Fungi in the United States and in Europe, 963.

Wurzelbrand, 577.

XANTHIUM SPINOSUM, 286.

Ximenia americana : *Pseudococcus filamentosus*, 697.

Xyleborus on Tea and on Coffee, 1195. *X. fornicatus*, 285.

Xylococcus napiformis on *Quercus serrata*, 1192.

Xylonites praeustus : *Monolexis lavagnei*, 189.

Xylopertha sp., 1195.

YELLOW-HEADED Coffee Borer, 696.

Yponomeuta, *see Hyponomeuta*.

Yucca americana : *Heterosporium Yuccae* n. sp., 788.

ZABRUS TENEBRIOIDES, *p. 316*.

Zaghlil, 963.

Zaghlul, *Ranunculus*, 390.

Zamia : *Aspidiotus ficus*, 798.

Zea Mais, *see* Maize.

Zebronia phenice on Cotton, 391.

Zilverdraadziekte, 1185.

Zinc, Arsenite of Zinc as an Insecticide, 392.

Zonocerus elegans on Tobacco, 690.

Zophosis sp. on Cotton and on Tobacco, 690.

B) INDEX OF AUTHORS.

BACCARINI, P., 181.
Baccarini Pasquale and Bargagli-Petrucci Gino, 1181.
Ballard, E., 690.
Bancroft, C. K., 796, 859, 860.
